PREFACE

TO FIRST EDITION

Physiology is a science in its own right and the laboratory worker who pursues his researches quite detached from medical problems need offer no apology for his academic outlook Indeed some of the most valuable contributions to medical science have been the outcome of laboratory studies whose applications could not have been foreseen Nevertheless, we feel that the teacher of physiology in a medical school owes it to his students, whose ultimate interest it must be conceded is in the diagnosis and treatment of disease, to emphasize those aspects of the subject which will throw light upon disorders of function The physiologist can in this way play a part in giving the student and practitioner a vantage point from which he may gain a rational view of pathological processes

We have endeavored to write a book which will serve to link the laboratory and the clinic , and which will therefore promote continuity of physiological teaching throughout the pre-clinical and clinical years of the under-graduate course It is hoped that when the principles underlying diseased states are pointed out to the medical student, and he is shown how a knowledge of such principles aids in the interpretation of symptoms or in directing treatment, he will take a keener interest in physiological studies When such studies are restricted to the classical aspects of the subject, apparently remote from clinical application, the student is likely to regard them only as a task which his teachers in their inscrutable wisdom have condemned him to perform Too often he gains the idea, from such a course, that physiology is of very limited utility and comes to believe that, having once passed into the clinical years, most of what he has "crammed" for examination purposes may be forgotten without detriment to his more purely medical studies Unfortunately, he does not always realize at this stage in his education how great has been the part which physiological discoveries have played in the progress of medicine, and that the practice of today has evolved from the "theories" of yesterday

Many physiological problems can be approached only through animal experimentation Advances in many fields, most notably in those of carbohydrate metabolism, nutrition, and endocrinology, bear witness to the fertility of this method of research On the other hand, many problems can be elucidated only by observations upon man, and physiology has gained much from clinical research The normal human subject as an experimental animal possesses unique advantages for many types of investigation, and in disease, nature produces abnormalities of structure and function which the physiological laboratory can imitate only in the crudest way Within recent years the clinical physiologist, fully realizing these advantages and the opportunities afforded by the hospital wards, has contributed very largely to physiological knowledge In many instances, clinical research has not only revealed the true nature of the underlying process in disease, but has cast a light into some dark corner of physiology as well, several examples of clinical investigation which have pointed the way

to the physiologist could be cited In the last century knowledge of the processes of disease was sought mainly in studies of morbid *anatomy*, biochemistry was in its infancy and many of the procedures now commonly employed for the investigation of the human subject had not been devised Today the student of scientific medicine is directing his attention more and more to the study of morbid *physiology* in his efforts to solve clinical problems This newer outlook has borne fruit in many fields It has had the beneficent result of drawing the clinic and the physiological and biochemical laboratories onto common ground from which it has often been possible to launch a joint attack upon disease We feel that this modern trend in the field of research should be reflected in the teaching of medical students, and have therefore given greater prominence to clinical aspects of the subject than is usual in physiological texts

In order to understand the function of an organ it is usually essential to have a knowledge of its structure For this reason we have followed the plan of preceding the account of the physiology of a part by a short description of its morphology and, in many instances, of its nerve and blood supply The architecture and functions of the central nervous system are so intimately related that some space has been devoted to a description of the more important fiber tracts and grey masses of the cerebrum, cerebellum and spinal cord

We wish to thank our colleagues in physiology, biochemistry and anatomy whom we have drawn upon on so many occasions for information and advice without their generous help the undertaking would have been an almost impossible one We are also deeply grateful for the unstinted assistance which we have received from our friends on the clinical staff, several of whom have read parts of the text in manuscript or in proof

TO NINTH EDITION

We agree In preparing this Ninth Edition we have tried to preserve all of the virtues of earlier editions, and to follow the principles set down by the original authors We have attempted particularly to meet the needs of students in physiology courses in professional schools—medicine, dentistry and veterinary medicine—by offering a volume that is comprehensive but not encyclopedic, and that surveys physiological mechanisms related to problems encountered in clinical practice

Nevertheless, the book has an appearance somewhat different from before The figures are all new and, we trust, more informative Furthermore, the nine sections have been manufactured independently so that they can be revised more easily, and so that they can be published separately as reprints from the complete volume The edge markers serve as guides to section location, and take the place of a continuous pagination

We wish to thank the editors and the staff of The Williams and Wilkins Company for their counsel and cooperation in this effort to present a textbook that is both attractive and easy for readers to use

General Physiological Processes

1 / BY WAY OF INTRODUCTION—THE CELL

A multicellular organism is a society of cells which like the units of any society, manifest division of labor, specialization, and mutual interaction according to a set of rules and centralized controls Consider the levels of organization of the human organism *Atoms* are combined in different ways to yield *monomers* (amino acids, nucleotides, sugars) which are the building blocks of biological *polymers* (proteins, nucleic acids, polysaccharides) These macromolecules are combined with smaller molecules to form *organelles* (subcellular units with distinctive function and morphology), which in turn are combined to form cells The study of mammalian physiology involves the dynamic interrelationships among cells, tissues, and organs and reaches ultimately to the level of the organism as a whole In this chapter we will consider the structure and function of the organelles which comprise the cell One group of organelles is bounded by a limiting membrane, a second group is not so delimited The former group encompasses the nucleus, endoplasmic reticulum, Golgi apparatus, lysosome, peroxisome, and mitochondrion—and in this category we also include the plasma (outer) membrane of the cell as a whole The group of organelles that are not bounded by a membrane includes the chromosomes, nucleoli, microtubules, microfilaments, and centrioles

Although there was some knowledge of the cell boundary and subcellular organelles prior to the advent of the electron microscope, the complicated ultrastructure of intracellular membrane systems was unforeseen (Fig 1 1)

The following two membrane properties are particularly significant in accounting for differences of function among the various membrane-delimited subcellular organelles *1*) the property of selective permeability which establishes and maintains compartments of specific character within the cell, and 2) the ability to provide a matrix which lends its surface as well as its interior for the arrangement of an ordered sequence of molecules (enzymes, cofactors, carriers) in a functionally meaningful pattern

Cell Membrane

The cell membrane is a permeability barrier If a cell is placed in hypotonic solution and if it contains molecules which cannot penetrate its outer membrane, it will swell, conversely it will shrink if placed in a hypertonic medium In both instances water moves down its concentration gradient (chap 2) Thus, the cell behaves as an osmometer Nonpolar molecules (gases, lipids) move freely across the membrane, polar molecules penetrate the membrane much less readily and indeed it is the selective permeability of the plasma membrane to certain ions which determine the excitability characteristics of nerve and muscle cells

COMPOSITION OF THE CELL MEMBRANE

Although the general chemical nature of the membrane found at the cell boundary was predicted on the basis of physiological data, the detailed molecular structure of the membrane is not yet known Models of cell membranes prepared by combining their lipid and protein constituents (partly known from chemical analysis of purified cell membrane preparations) exhibit some physiological characteristics similar to those of natural membranes The role of lipid-lipid interactions in membrane structure has been at the center of attention because such interactions can explain much of the presently known phenomena of membrane transport Quantitative studies of isolated cell membranes revealed that enough lipid is present to be arranged as a bilayer coating the cell Artificial mixtures of extracted cellular polar lipids (lecithin, phospholipid, and steroids) under appropriate conditions will form a biomolecular layer

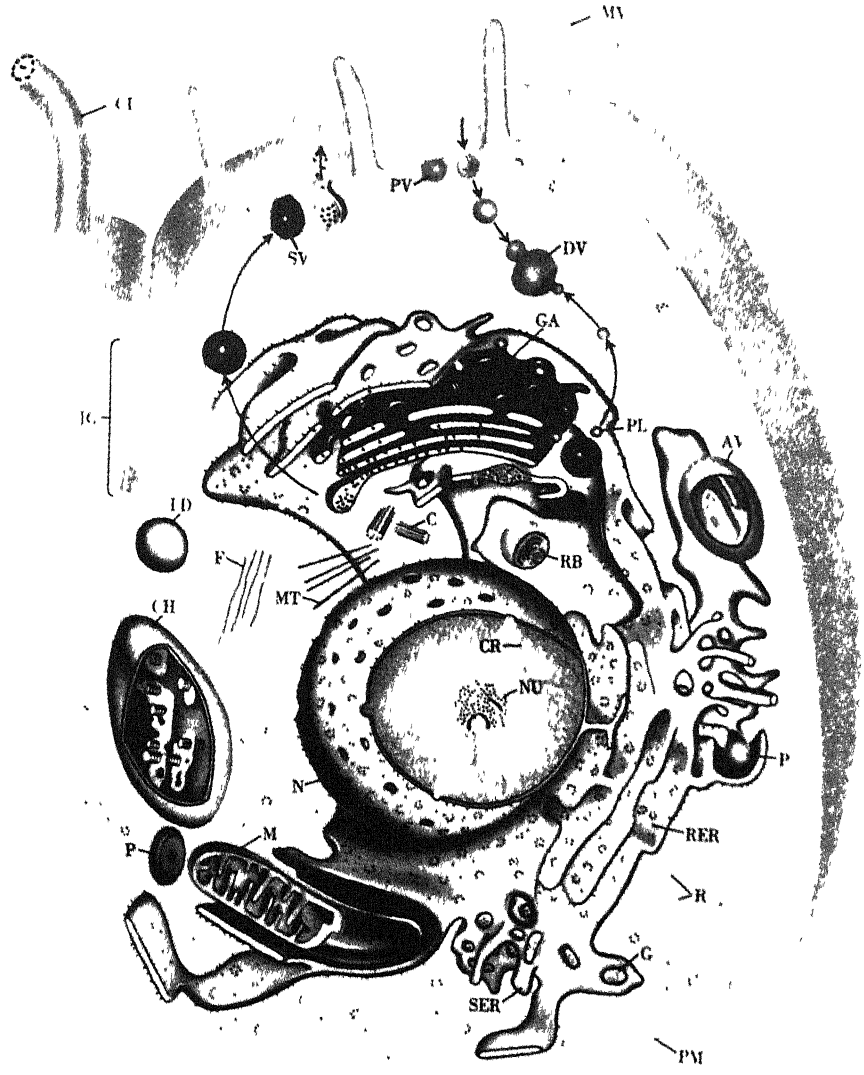

Fig 1 1 Schematic diagram of a cell and its organelles drawn to reveal their three dimensional structure *AV*, autophagic vacuole *C* centriole *CH* chloroplast *CI*, cilium *CR* chromatin *DV* digestion vacuole *F* microfilaments *G* glycogen *GA* Golgi apparatus, *JC* junctional complex *LD* lipid droplet *M* mitochondrion *MT* microtubules *MV* microvillus *N* nucleus *NU* nucleolus *P* peroxisome *PL* primary lysosome, *PM*, plasma membrane *PV* pinocytosis vesicle *R* ribosomes and polysomes *RB* residual body, *RER* rough endoplasmic reticulum *SER* smooth endoplasmic reticulum *SV* secretion vacuole The organelles have been drawn only roughly to scale Also the sizes and relative amounts of different organelles can vary considerably from one cell type to another For example only plant cells show chloroplasts and among animal cells only a few types show peroxisomes (× 58 000) (From Novikoff and Holtzman 1970)

spontaneously Presumably the polar (hydrophilic) ends of the lipids form the two outer borders making them available for interaction with other polar molecules such as proteins (Fig 1 2) On a weight basis membranes contain a significantly larger amount of protein than lipid (ratio up to 4 1), however, due to the high molecular weight of proteins, this relationship is reversed on a molar basis (protein· lipid ranging from 1 to 10·100) At least some of the protein must be present in a globular rather than extended form, unfolding of enzymic protein results in loss of activity In fact, some of the proteins are probably not restricted to the surfaces of the plasma membranes but rather extend into the bimolecular lipid layer

In addition to lipid and protein, carbohydrate appears to be associated with the cell membrane as lipopolysaccharide and as protein-polysaccharide The carbohydrate moieties of the membrane serve to modify the electrical charge at its surface and provide specific surface-binding sites Cytochemically demonstrable polysaccharide and protein is associated with many cell surfaces as an extracellular layer In some places, particularly at luminal surfaces this layer forms a fuzzy coat—often referred to as a glycocalyx (Fig 1 3)—which may act as a crude filter and/or facilitate the attachment of molecules for endocytic (see below) transport across the cell membrane

STRUCTURE OF UNIT MEMBRANE

A pattern generally found in almost all cellular membranes prepared for microscopy by conventional techniques consists of three layers, two electron-dense layers on either side of a single electron-lucent layer (Fig 1 3 and 1 4) This is termed a *unit membrane* Electron microscopic examination of osmium tetroxide-fixed, sectioned tissue shows the cell membrane to be 70 to 100 Å wide The electron-lucent line in the unit membrane is thought to represent the lipid layer Hydrophobic bonding in the lipid bilayer region may make it inaccessible to osmium deposition Thus, the two electron-dense lines would result from deposition of osmium at the surfaces of this bilayer There is much physiological evidence to suggest that the lipid bilayer is interrupted by hydrophilic molecules (Fig 1 2*A*) which connect the two outer surfaces of the membrane and provide transmembrane channels (a few Å in width) for transfers of water molecules and ions (chap 2)

Evidence for the unit membrane structure has been provided by x-ray diffraction patterns

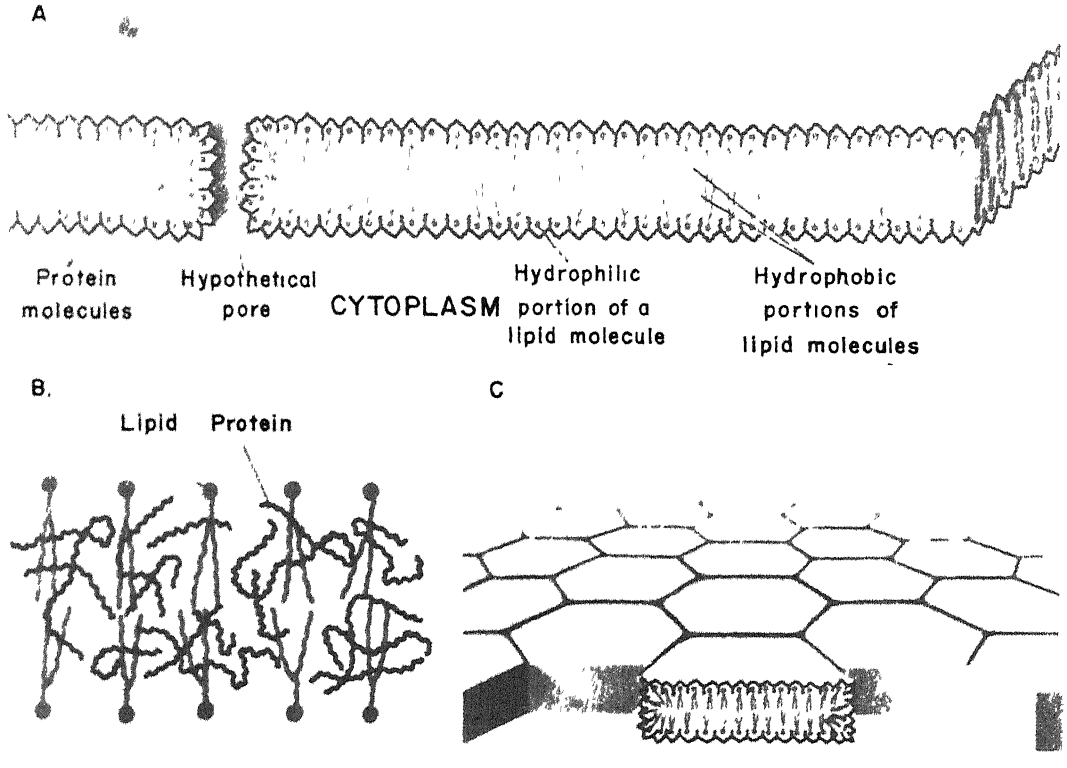

Fig 1.2 Diagram of various models of the cell membrane *A* represents the classic biomolecular lipid leaflet coated by protein note inclusion of a hypothetical hydrophilic pore *B* represents a less ordered protein component found within the lipid bilayer *C* represents a mosaic of subunits each made up of lipid bilayers with protein or other hydrophilic molecules forming the borders All of these forms of the membrane (and others) could be present simultaneously and in different proportions under different conditions (From Novikoff and Holtzman, 1970)

of the myelin sheath This membrane-derived structure lends itself well to x-ray studies because of its jelly roll nature (Fig 1 4) which gives rise to a highly ordered and repetitive form Indeed, the myelin diffraction pattern can be explained on the basis of repeating bilayers of lipids in the cell membrane

Additional structural information comes from unfixed membranes studied by the freeze-etch technique This technique involves the quick freezing and sublimation of unfixed membranes Membranes so treated tend to fracture along the middle layer of the unit membrane as would be expected from a bimolecular lipid leaflet Moreover, repeating structures are visible at various intervals within the layer, these structures may represent proteins that extend through much of the thickness of the membrane

STRUCTURAL ASPECTS OF TRANSPORT ACROSS THE MEMBRANE

Although the physiology of the movement of molecules across membranes is dealt with in Chapter 2, we will here indicate a few selected examples of transport phenomena correlated with structural features of the cell membrane The lipid bilayer serves as a transport medium for lipid-soluble molecules to gain entry into the cell, whereas, protein-lined hydrophilic "pores" probably provide channels for diffusion of polar entities such as water and ions Specialized membrane-bound proteins seem to be involved in enzymatically controlled transport

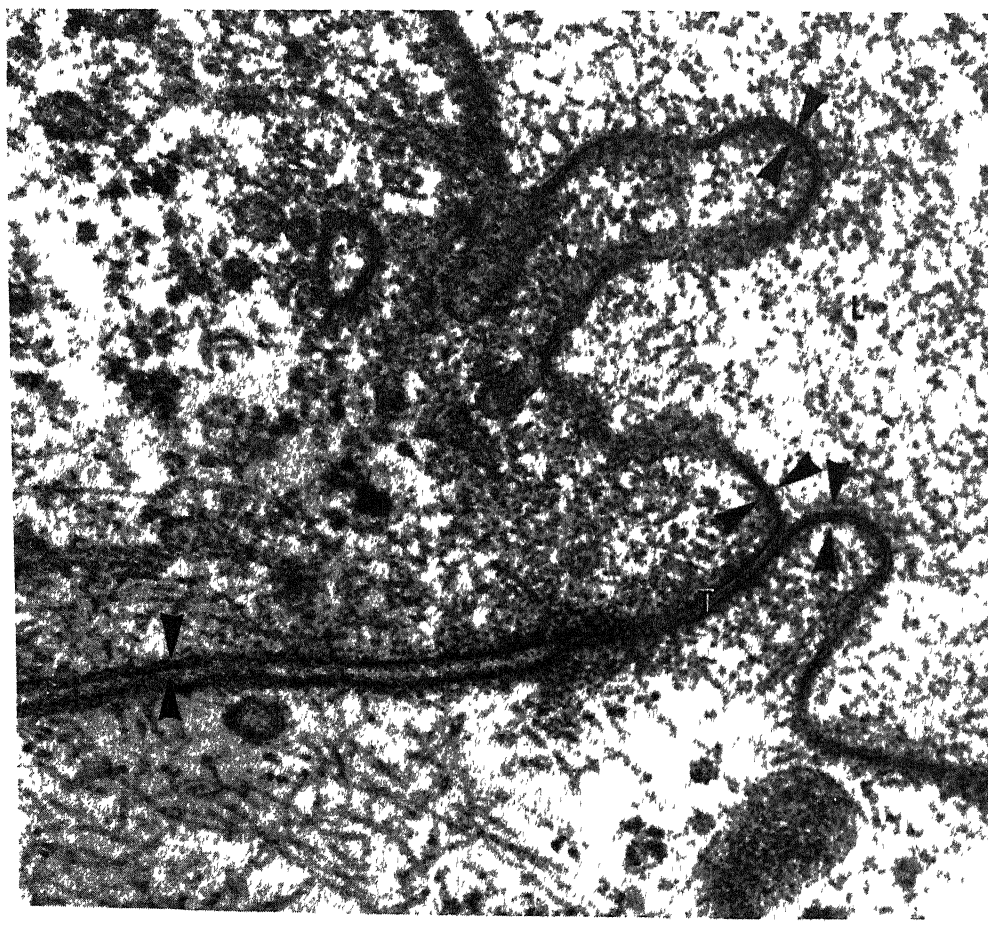

Fig 1 3 Electron micrograph of portions of epithelial cells (E) bordering the lumen (L) of the toad urinary bladder The unit membrane structure of two cell membranes is seen between the arrows In the tight junction (T) between the cells the external surfaces of the two cell membranes appear to have fused so that three rather than four dense lines are seen The fuzz in the lumen is associated with the cell surface (see text) (× 58,000)

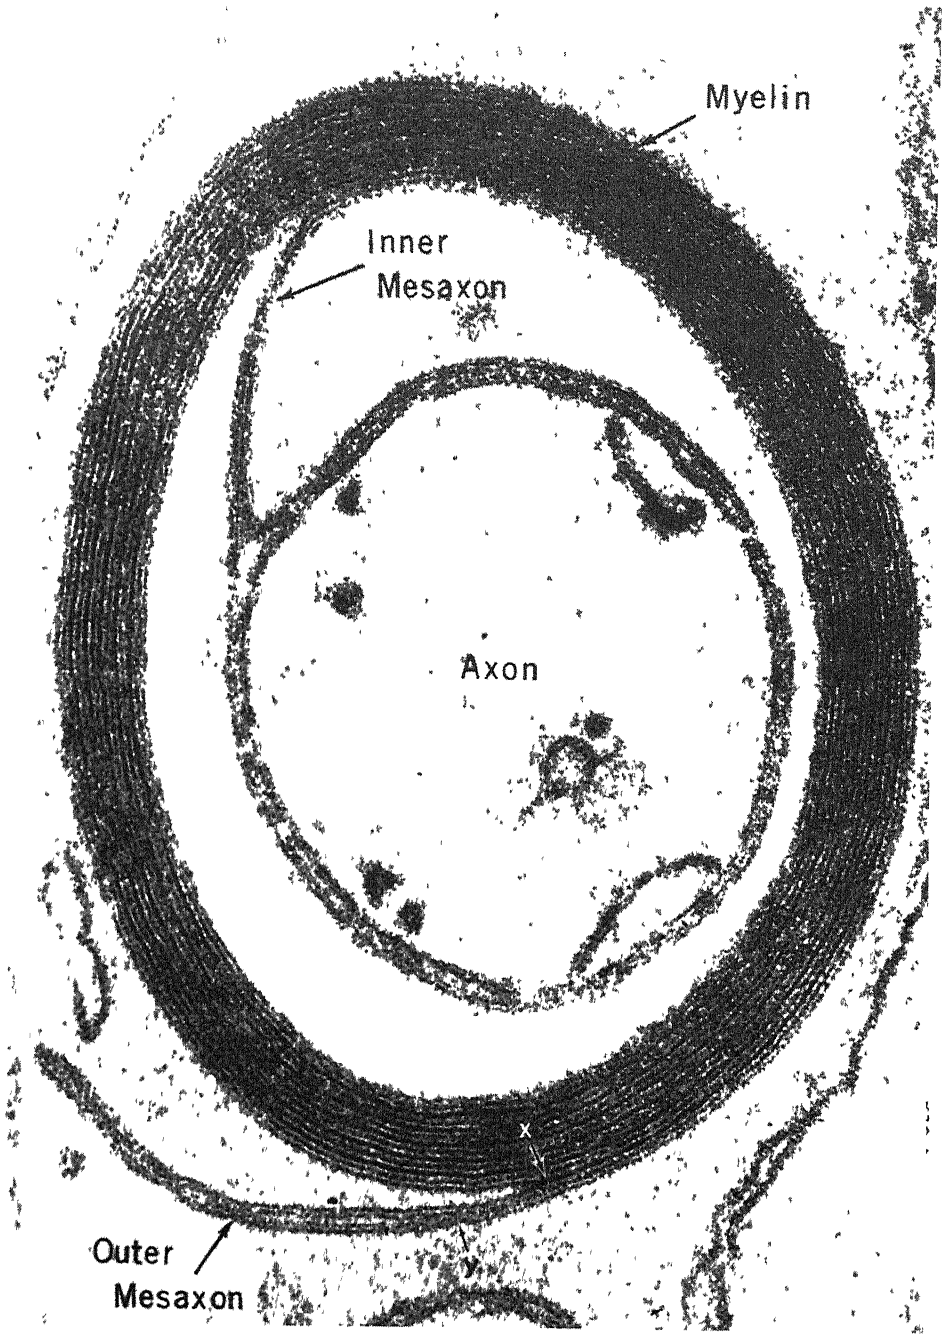

Fig 1 4 Electron micrograph of cross section of axon surrounded by the Schwann cell including the myelin sheath The unit membrane of the axon and the inner and outer mesaxon can be seen surrounding the axon At the arrow marked *x*, the cytoplasmic surfaces of the two Schwann cell membranes come together to form the denser line and at the arrow marked *y*, the outer surfaces of the two membranes of the outer mesaxon come together to form the thinner line (Potassium permanganate fixation, × 193 000) (Robertson from Fawcett 1966)

processes. For example a particular type of adenosine triphosphatase (ATPase) is involved in the active transport of Na^+ and K^+ ions, a variety of "permeases" are involved in the initiation of transmembrane sugar transport, and adenylcyclase, a membrane-bound enzyme that

converts adenosine triphosphate (ATP) to 3′-5′-cyclic adenosine monophosphate (AMP), serves to mediate the actions of several hormones which attach to "receptor sites" on the surface of their target cells

STRUCTURAL ASPECTS OF TRANSPORT OF THE MEMBRANE

Membrane components are subject to continual turnover In certain cell types, portions of the membrane invaginate into the cell and pinch off to form the boundary of an intracellular vesicle, vacuole, or tubule External material is carried into the cell by this process, referred to as *endocytosis* (Fig 1 1, see also chap 2) This material and its enclosing membrane generally fuses with lysosomes (see below) *Exocytosis*, on the other hand, involves the fusion of membranes of intracellular origin, such as those delimiting secretory granules, with the cell membrane These granules release their internal material to the outside of the cell As a result there is a flow of membrane and of material enclosed in membrane-delimited spaces between the surface and intracellular compartments Similar exchanges seem to occur between certain intracellular organelles, notably the endoplasmic reticulum and the Golgi apparatus

STRUCTURAL ASPECTS OF INCREASING THE CELL SURFACE

Stable evaginations and invaginations of the cell membrane are important elements in providing a dramatic increase in surface area contact between cell and environment Microvilli, finger-like evaginations, are generally associated with cell surfaces involved in absorption processes such as in the intestine and kidney Conversely, in striated muscle, one finds an invagination of the cell membrane, the transverse tubule, associated with each sarcomere Since the transverse tubules are continuous with the surface membrane they provide a direct route for the communication of alterations at the cell surface to the contractile system deep within the muscle fiber (chap 4)

The Nucleus

FUNCTION OF NUCLEUS

The nucleus has two principal functions replication of deoxyribonucleic acid (DNA) and synthesis of ribosomal messenger and transfer ribonucleic acid (RNAs) Because it is best understood, we shall discuss in some detail ribosomal RNA synthesis which occurs in the nucleolus

Each nucleus possesses one or more *nucleoli* not delimited by membranes Each nucleolus consists of a roughly spherical, dense array of fibrils and granules rich in RNA Often the nucleolus is found in intimate association with special regions of DNA (known as nucleolar organizer regions) which are presumed to carry the information for *ribosomal RNA* (rRNA) Nucleolar RNA (45S predominantly) is almost certainly a precursor form of ribosomal RNA found in the cytoplasm if one "labels" RNA synthesized in the nucleolus with radioactive nucleotides, labeled RNA molecules are subsequently detected in the cytoplasm These RNA molecules (18S and 28S) complex with protein and form, respectively, a 40S and a 60S subunit One small and one large subunit combine to form a *ribosome* (80S) 150 to 250Å in diameter There may be several million ribosomes in a given cell

The specific function of ribosomal RNA is not well-understood, generally speaking however, all three types of RNA are involved in the translation of genetic information contained in the DNA molecule into specific proteins, synthesized in the cytoplasm (chap 7) The ribosomes interact in the process of protein synthesis with two other types of RNA large *messenger RNA* molecules (mRNAs) determine the sequence of amino acids in proteins by specifying the order of attachment of the small *transfer-RNAs* carrying the appropriate amino acids Our belief that DNA is the template for these RNAs is derived largely from experiments with procaryotic (bacterial) cells

As the information in a messenger RNA molecule (mRNA) is being "read," several ribosomes attach via their smaller subunits to the mRNA The combination of an mRNA and its attached ribosomes is referred to as a *polysome*. The nascent peptide seems to be attached to the larger ribosomal subunit (60S), completed protein is released to the cytoplasm (chap 7)

MORPHOLOGY OF THE NUCLEUS

The interphase nucleus is readily seen in the light microscope as a spheroidal body with a "suggestion" of internal organization (Fig. 1 1)

The DNA containing material can be specifically stained The nuclear chromatin can be resolved into two types euchromatin (loosely coiled) and heterochromatin (compact) It seems likely that the euchromatic regions are more active in the transcription process than the heterochromatic regions, i e , there is little demonstrable RNA synthesis in chromosomes that are largely or entirely composed of heterochromatin as in the case of sperm cells, polymorphonuclear leukocytes and the Barr body (one of the X chromosomes of female cells) The association of euchromatin with active transcription may account for some of the selective genetic expression associated with characteristic chromosomal uncoiling patterns found in different tissues within the same organism or at different developmental stages in the same tissue

Chemical analysis has shown that the chromosome consists of DNA associated with basic proteins (histones) and with other (nonhistone) protein It has been speculated that the complexing of histone with DNA may have a protective or structural function (preventing alteration or denaturation of the DNA, controlling coiling, etc) or the histone may have a repressor function (interfering with the template activity of DNA)

Isolated chromosomes studied by electron microscopy appear as masses of fibers around 250 Å in diameter, but the architecture of these fibers is not known An individual DNA double helix coated with protein measures less than 50 Å and while it is known that the fibers of chromosomes are coiled, the nature of the packaging of nucleic acid and proteins is yet to be described. Nevertheless, there are theories consistent with current evidence, suggesting that a single chromosome contains one, or at most a very few, extremely elongated DNA molecules complexed with protein and coiled into a fiber structure which is seen in the electron microscope.

Intracellular Membrane Systems

THE NUCLEAR ENVELOPE

The boundary of the nucleus, the nuclear envelope, is a double membrane complex (Fig 1 5) Each membrane is approximately 70 to 80 Å thick The envelope, a flattened sac with an enclosed perinuclear space, resembles the rough endoplasmic reticulum (ER) (see below) *1*) the cytoplasmic surface of the outer (cytoplasmic) nuclear membrane has granules which appear to be ribosomes, *2*) direct continuities are seen between the cytoplasmic portion of the nuclear membrane and the ER (Fig 1 5), and *3*) the presence of certain enzymes can be demonstrated cytochemically in both the perinuclear space and the cisternae of the ER

The inner surface of the nuclear membrane is often associated with chromatin and an "internal dense lamella," the latter may provide some rigidity to the structure The inner and outer membranes of the envelope join at intervals to form "pores" several hundred Å in diameter (Fig 1 5)

How does a "directive" of the nucleus reach the cytoplasm or, conversely, how do cytoplasmic and other external feedback messages reach the nucleus? Non-nuclear substances can act as inducers or repressors (chap 8) of the synthesis of specific proteins in the cytoplasm This almost certainly requires interaction with genes Furthermore, most gene products (e g , mRNA) must leave the nucleus and enter the cytoplasm to express their effects Permeability properties of the nucleus are too complex to be explained by simple holes The morphology of the nuclear boundary provides for two alternative routes for the transfer of information—either across membranes of the perinuclear sac or through "pores " The pores are often referred to as "annuli" to emphasize that they are not simple holes but rather organized regions often pores are seen which contain a diaphragm or plug In addition, the membrane adjacent to the pore may show morphological traces of special organization

To date, the morphological evidence in support of the physiological and biochemical data on transnuclear transport through pores rests mainly on a few observations, such as the movement of electron-dense material (thought to be RNA-containing granules) through the nuclear pores in the insect salivary gland and some other tissues, and the movement of a marker (colloidal gold) into the nucleus when it is injected into the cytoplasm of ameba Clear morphological evidence on passage of material across the nuclear membranes, as distinct from the pores, is not available

THE ENDOPLASMIC RETICULUM

Often an integrated biochemical and ultrastructural investigation (involving cell disrup-

tion, isolation, and analysis of a homogeneous organelle population) leads to the clearest understanding of organelle function in situ From such studies, in a variety of cell types, a fraction of membrane-delimited vesicles, referred to as *microsomes*, is recovered The microsomes perform several functions including the provision of a base for the attachment of ribosomes, the biosynthesis of lipids and, in the case of striated muscle, the accumulation and release of calcium In the intact cell, microsomal vesicles are not found as such, rather one observes a tubular network known as the endoplasmic reticulum (ER) (Figs 1 1 and 1 5) It is assumed that the majority of microsomal vesicles represent a reproducible, preparative artifact arising during cell disruption by the shearing into fragments and closing up of the tubules and sacs of the endoplasmic reticulum

Rough ER. As noted above, the endoplasmic reticulum (and/or the microsomes derived from the ER) can provide a base for the attachment of ribosomes (Fig 1 6) Such ribosome-carrying endoplasmic reticulum is referred to as *rough ER* Microsomal vesicles derived from this rough ER were found to be capable of protein synthesis, the newly synthesized protein appearing in the vesicle lumen In the rough ER in situ the nascent protein likewise can be demonstrated within the reticulum lumen

The rough ER seems to grow by synthesizing more of itself The newly made rough ER may lose its ribosomes, and thus become converted to *smooth ER* The relative proportions of rough and smooth ER vary within different cells for example, the rough ER is extensive in cells which specialize in synthesizing protein for export, while the smooth ER is extensive in steroid secreting cells

Smooth ER. As noted above, the ER which lacks ribosomes is referred to as the smooth ER The membrane of the endoplasmic reticulum carries enzymes which are important in several biosynthetic pathways For example, the enzymes required for the synthesis of steroid are found in microsomal fractions of steroid-secreting cells Enzymes involved in triglyceride synthesis as well as phospholipid synthesis are also found in this fraction, the phospholipid sometimes appearing in the ER as small fat droplets In liver cells, important drug-degrading enzymes are associated with the smooth ER Also, in the hepatocytes the close spatial relationship of the smooth ER with glycogen, the major form of glucose, suggests that the smooth ER may function in glycogen me-

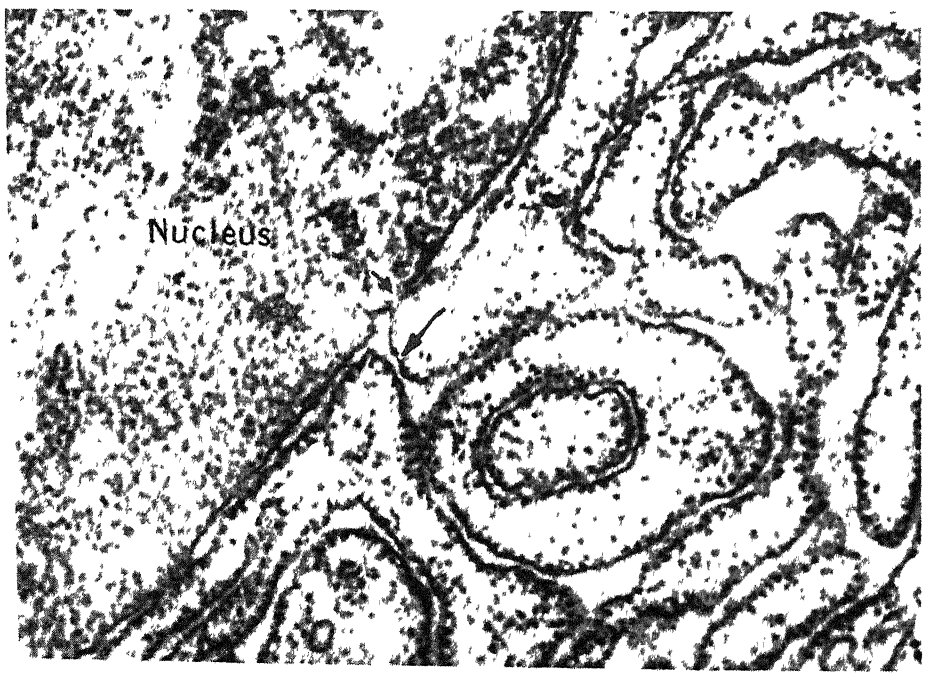

Fig 1 5 Electromicrograph of a portion of a serous cell of mouse salivary gland The rough ER (large arrow) of the cell is continuous with the outer membrane of the nuclear envelope A nuclear pore is indicated by the small arrow (Osmium fixation × 84 000) (Parks from Fawcett, 1966)

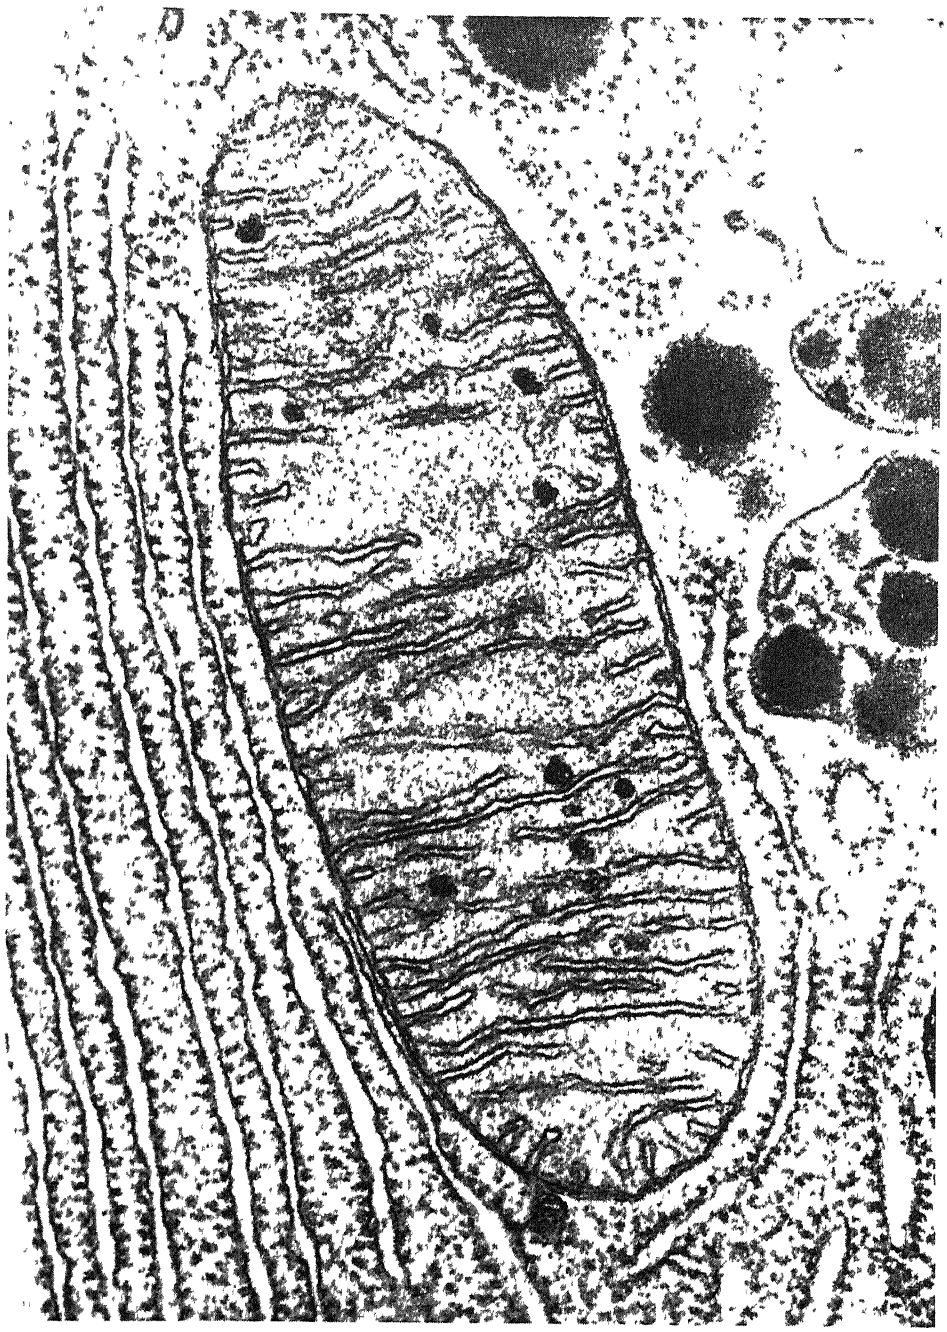

Fig 1 6. Electron micrograph of a portion of a pancreatic cell showing the mitochondrial structures labeled in the diagramatic representation in Figure 1 8 A parallel array of cisternae of rough ER is also evident, 95 000 × (Porter, from Fawcett 1966)

tabolism. In muscle, the smooth ER (sarcoplasmic reticulum) controls the local concentration of calcium ions near the contractile machinery and thereby influences the contraction and relaxation process (chap 4)

THE GOLGI APPARATUS

The Golgi apparatus is believed to be a site for the concentration of protein and polysaccharide. It is also a site for completion of the

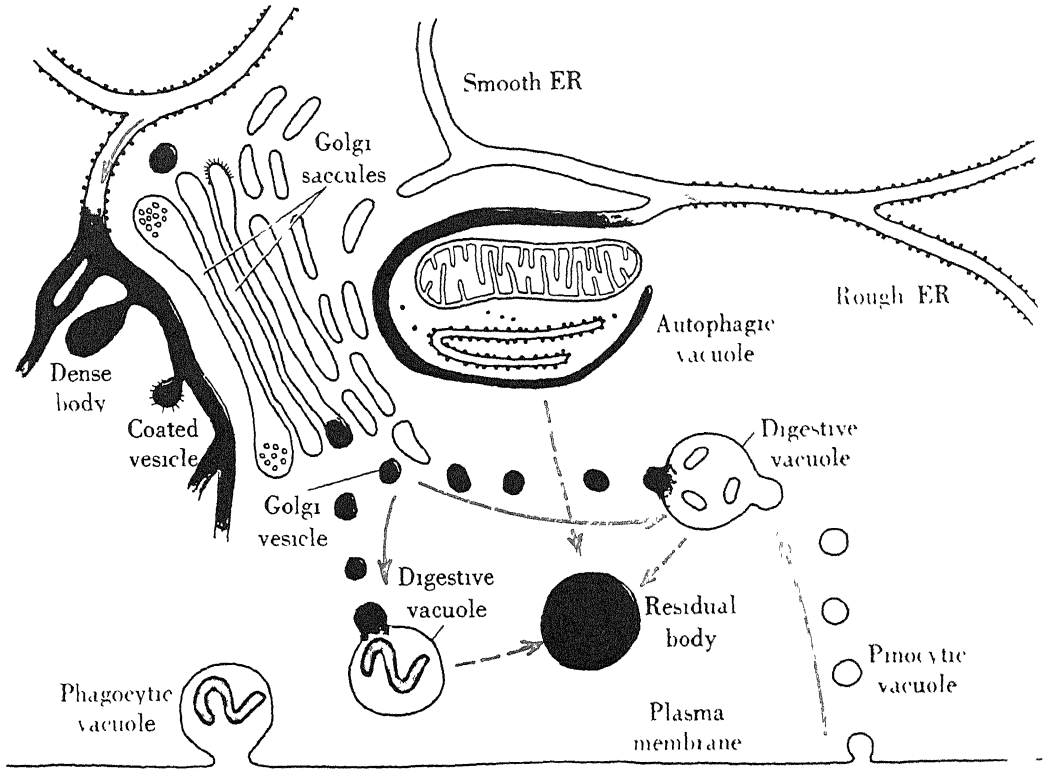

Fig 1 7 Diagram suggesting probable interrelations of some organelles in the transport of lysosomal hydrolases (gray) and the formation of lysosomes Illustrated are *1)* Fusion of primary lysosomes (Golgi vesicles) with phagocytic and pinocytic vesicles resulting in the formation of digestive vacuoles Some of the vesicles are coated (see text) *2)* Movement of hydrolases within the RER and SER to the vicinity of the Golgi apparatus and to lysosomes Dense bodies (bodies containing electron dense grains and other material) and autophagic vacuoles are among the structures that may form from the ER or from closely interrelated components of the ER and Golgi apparatus *3)* Formation of residual bodies by the accumulation of indigestible residues within lysosomes (From Novikoff and Holtzmann 1970)

synthesis of the carbohydrate moiety of glycoprotein, e g , the synthesis of the carbohydrate moieties of thyroglobulin and immunoglobulin begins in the ER, but the terminal sugars are added in the Golgi apparatus These products are usually packaged as "granules" within Golgi-derived vacuoles or vesicles which then migrate away from the Golgi apparatus

The Golgi apparatus consists of a stack of several membranous saccules with associated vacuoles and vesicles (Fig 1 7) The ER in some cell types is assumed to contribute to the "forming face" or "top" of the Golgi apparatus Within the stacked membranes of the Golgi apparatus materials are concentrated as they pass from the saccules on the "top" surface to those forming the "bottom" surface of the apparatus (Fig 1 1) In exocrine and endocrine cells the mature secretory granules are generally found in association with the "bottom" saccules

LYSOSOMES

Lysosomes have been found in virtually all animal cells which have been studied As organelles they are best defined by biochemical and cytochemical criteria a lysosome is a membrane-delimited body containing demonstrable acid-hydrolase activity Over 30 acid hydrolases are known to occur in the lysosomes, these enzymes can digest essentially all macromolecules Material to be digested becomes enclosed within lysosomal membranes permitting isolated, controlled degradation There are numerous findings suggesting that release of hydrolases from the lysosome into the cell may be important in various pathological states,

many of these findings are yet to be fully evaluated

Morphologically, the lysosomes are a motley group of subcellular bodies (Fig 1 7) Their appearance depends largely on the origin of the enclosed material which is destined for intracellular digestion by the lysosomal hydrolases In polymorphonuclear white blood cells Golgi-derived lysosomal granules fuse with phagocytic vacuoles formed as a result of endocytosis of foreign material Other lysosomes are *autophagic*, these lysosomes contain bits of the cell's own substance which have been separated along with the hydrolases from the rest of the cytoplasm within a membrane-delimited space Autophagia, which may be enhanced by stress, is hypothesized to be important for the turnover of some cell constituents

The degraded soluble products of lysosomal hydrolysis can either enter the anabolic pool to be reused in biosynthesis or to be secreted An example of the latter is the secretion of thyroid hormone thyroid colloid travels from the follicle lumen within endocytic vacuoles which then fuse with the lysosomes, the colloid is hydrolysed and thyroxine is released It is also noteworthy that indigestible residues accumulate within lysosomes, a phenomenon which accompanies the aging process in neural and other cells

PEROXISOMES

The peroxisomes constitute another group of membrane-delimited bodies They are often associated with the ER from which they are thought to derive (see Fig 1 1) They are concerned with the metabolism of peroxide peroxisomes contain enzymes which produce hydrogen peroxide (such as amino acid oxidase and in some species, urate oxidase) and other enzymes which destroy hydrogen peroxide (such as catalase) Peroxisomes have, thus far, been found in only a few cell types, of which liver and kidney are among the best established examples The function of peroxisomes is currently under active investigation and there are hints that, in some species, they are involved in carbohydrate synthesis from fat and in the degradation of purines (chap 6) as well as in the detoxification of hydrogen peroxide

MITOCHONDRIA

The early cytologists noted that mitochondria were closely associated with motile processes and were situated in regions of intense metabolic activity such as sites of active transport Biochemists have since shown that two major metabolic pathways, the tricarboxylic acid cycle and the electron transport chain, are situated within the mitochondrion, thus, this organelle is involved in the metabolism of lipids, amino acids, and carbohydrates

The "typical" mitochondrion (Fig 1 6) has a length of 5 to 10 μm and a diameter of 0 5 to 1 0 μm It is bounded externally by two lipoprotein membranes (each about 70 Å thick) the inner one of which is thrown into folds termed cristae or tubules (Figs 1 6 and 1 8) Within the inner membrane is a matrix containing granules, RNA and DNA, the latter is a small circular molecule and is thought to provide some, but not all, of the necessary information for replication of the mitochondria From physiological and biochemical evidence, it is generally believed that the respiratory enzymes and the components of oxidative phosphorylation are associated in an ordered array on the inner membrane The order is thought to promote the sequential interaction of substrates and enzymes in these multienzyme systems with concomitant conservation of energy Therefore, much effort has been directed toward isolation of modular physiological units from inner membrane fractions The fact that multienzyme assemblies can be obtained from mitochondria has been encouraging Moreover, morphological studies support the multienzyme assembly hypothesis First, the respiratory activity of mitochondria is roughly proportional to the amount of inner membrane—a finding which could be explained by presuming an increased number of repeating units or respiratory assemblies associated with the increased membrane area Second, a repetitive array of particles found in certain preparations suggests a similarly repetitive assemblage of inner membrane enzyme systems These regularly spaced particles are found to be attached by small stalks to the inner membrane of isolated mitochondria, unfixed and negatively stained (in negative staining the surface details of the material under study appear as light objects against a dark background) Surprisingly after isolation the stalked particles contained an ATPase predominantly, however, it is suspected that the equilibrium of the reaction catalyzed by the ATPase in the stalked particles is reversed in the intact mitochondrial oxidative

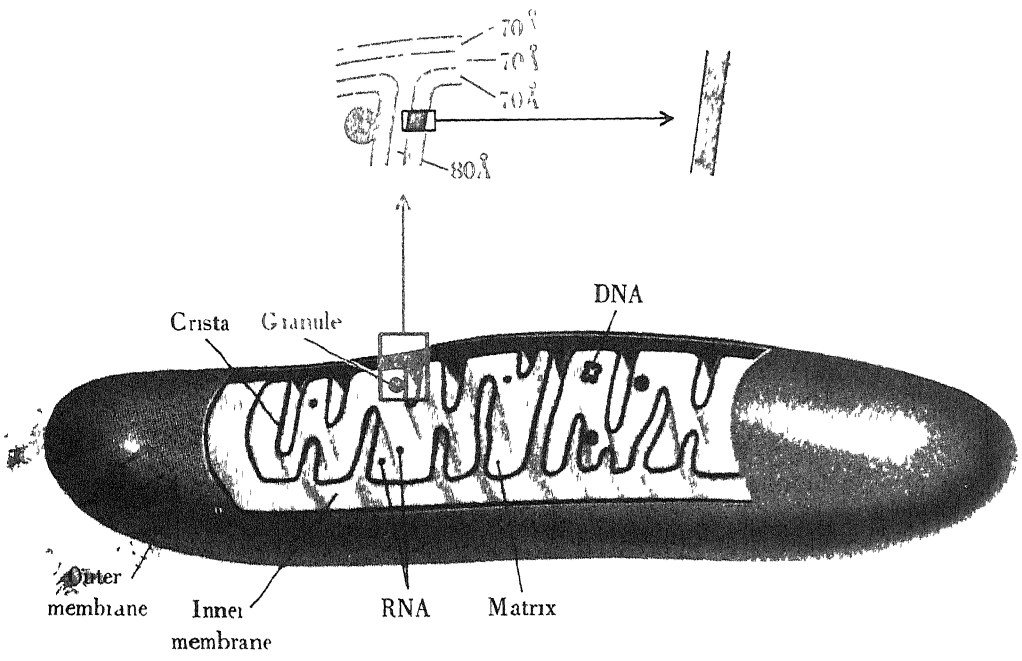

Fig 1 8 Diagrammatic representation of a mitochondrion After work of Ornstein Palade Sjostrand Fernandez Moran and others (From Novikoff and Holtzman 1970)

phosphorylation system, and that it couples phosphorylation of adenosine diphosphate (ADP) with electron transport This suggestion is supported by the fact that dissociation of the particle from submitochondrial preparations abolishes the ability of the preparation to carry out oxidative phosphorylation, when the particles are added back, oxidative phosphorylation returns too These particles are closely associated with the assemblage of enzymes and cytochromes—distributed in the inner membrane—which form the electron transport system of the cell The morphology of the inner membrane enzyme system remains a matter of current dispute

The outer membrane of the mitochondrion has a different enzyme content, a larger percentage of lipids and is more permeable to simple sugars than the inner membrane In addition to the demonstrably membrane-anchored enzymes of both inner and outer membranes, certain enzymes (such as those of the tricarboxylic acid cycle) are solubilized after disruption of the mitochondria These enzymes are presumed to be situated in the matrix or possibly loosely attached to a mitochondrial membrane

Physiologists can clearly define the metabolic state of the mitochondria in terms of electron transport and oxidative phosphorylation Careful electron microscopic study of isolated mitochondria, and in a few cases of mitochondria in situ, has resulted in the identification of two functionally related states 1) the condensed state in which the matrix appears dense and the space between the inner and outer membrane is enlarged, this state is seen when oxidative phosphorylation is proceeding at a rapid rate under conditions of excess ADP and P_i, and 2) the orthodox state (see Fig 1 6) when ADP and P_i are rate limiting in oxidative phosphorylation It is hoped that this kind of structural alteration can be explained eventually in terms of the interaction of mitochondrial macromolecules.

Microtubules and Microfilaments

The asymmetry observed in certain cell types is sharply at variance with the picture of an idealized cell in which all the organelles surround a central nucleus symmetrically A nerve cell in which the axon runs several feet as an extension of the perikaryon, an elongated muscle cell and a squamous (or columnar) epithelial cell all exemplify such asymmetry Likewise the nonrandom (asymmetric) movement of

subcellular elements is exemplified by transport of neurosecretory products (axonal flow), sliding myofilaments in muscle contraction, and chromosomal movement in cell division Electron microscopy of aldehyde-fixed tissue has revealed a morphological basis for asymmetric structure and movement in the form of entities referred to as *microtubules* and *microfilaments*, these structures are not membrane-delimited

MICROTUBULES AND CENTRIOLES

In cross-section microtubules are 200 to 300 A in diameter and may be followed for several microns in longitudinal sections They are found in many regions in which phase-contrast and polarizing microscopy had previously demonstrated the presence of formed oriented, elongated elements Microtubules are often associated with oriented movement The best established example is chromosomal movement in the mitotic spindle the mitotic poles—towards which the microtubules of the spindle orient and towards which the chromosomes move—have centrioles, usually two per cell

In the interphase cell the pair of centrioles are generally found with long axes at right angles to one another Each centriole is a cylinder 0 15 μm in diameter and 0 5 μm in length, composed of nine sets of microtubule-like elements (Fig 1 9)

The organization of microtubules can be disrupted by physical means (freezing or high pressure) or by chemical treatment, especially with colchicine When this is done, motion is inhibited and some of the structure collapses Therefore, the affinity of microtubules for colchicine serves as a means of identifying microtubular protein in a cell fraction Isolated and disrupted microtubules yield protein subunits of approximately 6×10^4 MW These appear to be globular subunits which may be arranged in a helical fashion to form the microtubules In normal cells the microtubular protein appears to be present in a form which is assembled into tubules (e g , for the formation of the mitotic spindle) under appropriate, but as yet not understood, stimulation

CILIA AND FLAGELLA

Microtubule-like structures may also be organized into organelles as diagrammed in Figure 1 9 Cilia and flagella are rapidly beating

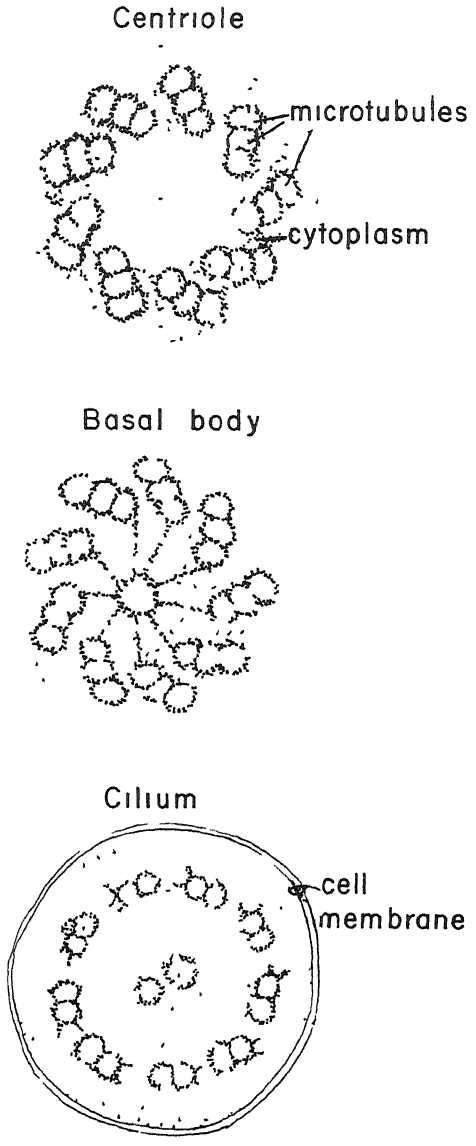

Fig 1 9 Diagrammatic representations of organelles composed of microtubules (After work of Fawcett and Gibbons)

cell processes which extend 10 to 100 μm from the cell The intracellular basal bodies of cilia and flagella are also composed of microtubular structures arranged in the pattern of nine basic units (often referred to as "9 + 0"), they are widely assumed to be an alternate form of the centriole

Cilia and flagella generally have, in addition to the basic nine outer sets, a central pair of microtubules ("9 + 1") It is not known how these elements interact in the matrix to pro-

duce beats, however the process requires cellular energy as indicated by the findings that exogenous ATP can cause beating in isolated cilia and flagella and that the "arms" of the nine sets of microtubules contain an ATPase

MICROFILAMENTS

Microfilaments are a heterogeneous class of long, thin nontubular structures of various diameters Among the most commonly seen microfilaments are those which appear to serve as the structural core of microvilli Also frequently encountered are tonofilaments on the intracellular side of desmosomes (see below) The best example of association of microfilaments with motion is the extensively developed myofilament system which forms the basis of muscle contraction (chap 4)

The Junctional Complex

We have thus far limited our view of the cell to those entities circumscribed by and including its boundary, the plasma membrane Cells rarely are continuous with one another, usually a space of 100 to 200 Å separates them The cells are associated in tissues by various means, the best described is the *junctional complex* in epithelial cells (Fig 1 1) In this complex the plasma membranes of two adjacent cells contribute to specialized attachment sites a tight junction (*zonula occludens*) a desmosome (*macula adherens*) and between these two usually a less well-defined *zonula adherens* where the two membranes are separated by a constant 200 Å space The desmosome may contain organized extracellular material between the two cell membranes which may be seen as an additional dense line in parallel with the membranes

In the region of the tight junction the outermost layers of the two cellular unit membranes appear to be very closely associated or fused with one another (Fig 1 1), externally applied tracer molecules (such as ferritin, an iron-containing electron dense protein) cannot penetrate between the cells at the tight junction Movement across epithelial cell layers with tight junctions requires a pathway through cells rather than around them Between some cells the usual insulation effect on passage of an applied electric current is greatly reduced at the tight junction, such cells are referred to as *electronically coupled* Communication between and coordination of the individual cells of cardiac and smooth muscle may be effected via tight junctions

2 / PHYSICOCHEMICAL PROPERTIES, PERMEABILITY, AND TRANSPORT FUNCTIONS OF CELL MEMBRANES

Several aspects of structure and function of the cell membrane—often referred to as the plasma membrane—were reviewed in Chapter 1 In this chapter we shall further consider the physicochemical properties of this important boundary structure and examine the processes by which it regulates the molecular traffic between the extracellular and intracellular fluids

The two sides of the cell membrane appear to have different properties One may therefore provisionally label the two sides of the membrane as the *outside* (extracellular) and *inside* (cytoplasmic) surfaces In the case of the cell membrane the "outside" surface is in contact with the cell environment, the "inside" surface is in contact with the cytoplasm

Physicochemical Properties

ELECTRICAL PROPERTIES

Even before the nature of the cell membrane had been demonstrated by electron microscopy, electrical measurements gave rise to the interesting generalization that the boundaries of all kinds of cells shared a common property the capacitance per unit area of the cell boundary material was about 1 μf /cm ^{2} This figure can be combined with the 75 Å thickness of the unit membrane in an interesting manner The cell membrane can be pictured, to the first approximation, to be the dielectric material of a charged condenser In general the charge is negative on the inside surface and positive on the outside surface There is a difference of potential across the membrane, for example in resting nerve, on the order of 0 06 v The intensity of an electric field is usually expressed in dimensions of volts per meter Thus, the electric field within the cell membrane of resting nerve is on the order of

$$(0\ 06\ \text{v})/(75 \times 10^{-10}\ \text{m}) = 8{,}000{,}000\ \text{v/m}$$

The dielectric strength of a commercial insulator is the maximum electric field (volts/meter) which the material can stand without breaking down The highest dielectric strength for a good commercial insulator such as rubber is about 1,000,000 v /m Thus, the cell membrane material, viewed as an electrical insulator, must have a very high dielectric strength, i e , 8,000,000 v /m

A second number of interest which we are able to estimate is the dielectric constant, k, of the cell membrane material The capacitance of a condenser is a measure of the amount of charge which can be stored in the plates of the condenser when a given voltage is impressed across these plates The capacitance, C, is directly proportional to the cross-sectional area, A, of the condenser, and to the dielectric constant, k, of the insulator between the condenser plates, the capacitance is inversely proportional to the thickness of the dielectric, x, that is, the distance between the condenser plates In mks units $C = \epsilon_0 kA/x$, where ϵ_0 is the constant 9×10^{-12} farads/m Solving for k and substituting we find that

$$k = \frac{Cx}{\epsilon_0 A} = \frac{(10^{-6}\ \text{farad})(75 \times 10^{-10}\ \text{m})}{(9 \times 10^{12}\ \text{farads/m})(10^{-4}\ \text{m}^2)} \cong 8$$

Again compared to commercial electrical insulators a dielectric constant of 8 is relatively high We conclude that the nerve (cell) membrane has a relatively high dielectric constant and dielectric strength

MOLECULAR PROPERTIES

The postulated molecular structure of the cell membrane is best understood in terms of the hydrophilic and hydrophobic nature of certain chemical groups Hydrophilic groups are polar

groups which may or may not bear a formal electrical charge Substances containing these groups tend to dissolve in water by interacting with the dipolar water molecules, such interactions are enhanced as a consequence of the high dielectric constant of water Accordingly, there is a reduction in the strength of the interactions of polar solutes (dipolar molecules, ions) with each other Amino acids and sugar molecules, for example, are hydrophilic The long-chain hydrocarbons (e g , long-chain fatty acids) on the other hand, are hydrophobic, such molecules are relatively insoluble in water The aggregation of hydrophobic molecules in the presence of water has been explained as follows The structure of water is in an ordered, icelike state in the vicinity of nonpolar molecules When nonpolar molecules leave the water phase and form an aggregate, the degree of order of the water phase is decreased, the entropy (degree of disorder) of the whole system is thereby increased Since systems tend to change spontaneously towards a state in which the entropy is maximized, nonpolar (hydrophobic) molecules tend to separate from the water phase and to aggregate, i e , they do not "dissolve" in water This complex set of ideas for explaining the association of nonpolar molecules is represented in the current literature by the term "hydrophobic bond" (see chap 5)

A long-chain fatty acid is an hydrophobic molecule for the most part but it bears a hydrophilic (carboxyl) group at one end When hydrophobicity exceeds hydrophilicity, such a substance does not appreciably dissolve molecule-by-molecule in water If enough molecules of this kind are present however they can enter the water phase and simultaneously satisfy their hydrophobic and hydrophilic tendencies by forming spherical or lamellar *micelles* A micelle is a multimolecular structure in which the hydrophilic parts of its constituent molecules are at the surface in contact with water, while the hydrophobic parts are in the interior in a milieu of other hydrophobic groups

A considerably simplified model of the cell membrane pictures it to be a lamellar micelle consisting of two rows of phospholipid molecules (Fig 1 10, see also Fig 1 2) The hydrophobic hydrocarbon chains are on the interior The two surfaces of the micelle are covered by a macromolecular material The asymmetry of this membrane is attributed to differences in the macromolecular materials which line the two surfaces of the micelle

The biological role played by the cell membrane can best be interpreted from the point of view of evolution It is unlikely that at the time of the origin of life the first organism was already equipped with a membrane boundary It is more likely that this early organism was a relatively simple, self-replicating molecule With the development of biological complexity, however, an "organelle" arose which isolated the organism from its environment This organelle, the cell membrane, had selective value since it tended to reduce the influx of injurious molecules from the environment while tending to preserve useful molecules for the exclusive use of the organism

From this point of view the cell membrane should be thought of as a barrier to diffusion

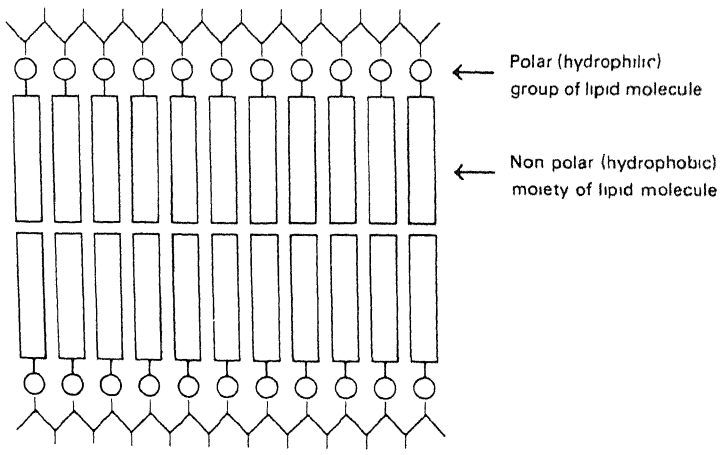

Fig 1 10 Model of cell membrane as laminar micelle

Basically, the cell membrane should be regarded as a relatively impermeable rather than a permeable structure

We have considered the cell membrane to be basically a lipid micelle To the *first* approximation, it is convenient to treat the cell membrane as if it were a thin oil film (Fig 1 11*a*) This crude approximation suffices to explain a number of important permeability and electrical properties of the cell membrane For example, the movement of a substance across the cell membrane may be viewed as follows Each individual molecule of the substance leaves the aqueous phase on one side of the membrane and dissolves in the oil film The molecule then diffuses across the oil film and enters the aqueous phase on the other side

A slightly more sophisticated model of the cell membrane is required to explain a number of experimental findings, which can best be interpreted by assuming that some molecules can pass through the membrane without leaving the aqueous phase In other words, to the *second approximation*, the cell membrane behaves as if it were an oil film pierced by pores (Fig 1 11*b*) The aqueous phase is continuous across the membrane through the pores These pores may be statistical rather than permanent in nature, that is, they may be temporary holes in the oil film created by the thermal agitation From osmotic studies on the human erythrocyte, it has been inferred that the effective diameter of individual pores is about 7 Å and that the total pore area is only about 0 0001 of the total surface area of the cell From the cell size of the pores it is evident that only small particles (e g , water, urea) can cross the cell membrane via the pores Larger molecules will have to cross the membrane in the region which we have referred to as the "oil film" Thus, for the purposes of our survey, it will be useful to view the cell membrane as a perforated oil film To this simple model more complex features (carrier molecules, enzymes, virus attachment sites) can be added as needed

We may now consider the manner and the relative rates at which substances of biological significance cross the cell membrane The following modes of transport will be discussed

1) Bulk Flow In this mode water molecules do not pass through the membrane by dissolving in it and diffusing across it, one by one, rather, the motion of each molecule is correlated with that of neighboring water molecules,

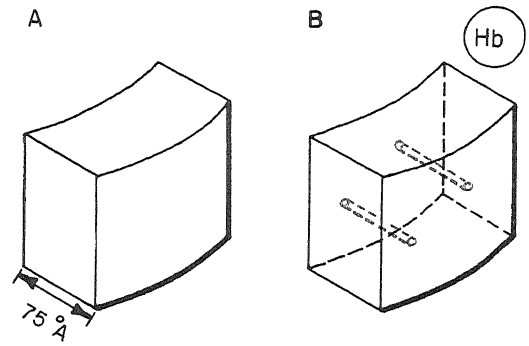

Fig 1 11 Simple models of cell membrane
a) First approximation Oil film 75 Å thick
b) Second approximation 75 Å thick oil film perforated by pores Assuming 7 Å for the average diameter of a pore each pore is about ten pore diameters long The diameter of a hemoglobin molecule (Hb) is shown to the same scale

that is, water flows through the pores in the membrane in bulk as it does through a pipe

2) Diffusion Solute and water molecules cross the membrane individually as a consequence of their thermal motion

3) Carrier-Mediated Diffusion Solute molecules combine with membrane-bound carrier molecules The carrier-solute complex diffuses or otherwise moves across the membrane

4) Active Transport Molecules move across the membrane by a carrier-mediated process which requires a coupled input of metabolic energy

Transport

PHYSICAL BASIS OF DIFFUSION

Consider a tube which is divided into two parts by a thin, removable partition The tube contains an aqueous solution of some substance The concentration of this substance is higher to the right of the partition than to the left After the partition is carefully withdrawn it is found that with time the concentration on the left increases and that on the right decreases Ultimately the concentration becomes the same throughout the tube The physical explanation of this phenomenon is quite simple Every solute molecule has motion of its own and in addition is under constant bombardment from adjacent solute and solvent molecules As a result a given solute molecule follows an erratic path through the liquid However, because there is initially a greater concentration of solute at the right of our tube

than at the left, more solute molecules move from right to left than from left to right until the solute concentration throughout the whole tube is equalized Thus, although each individual solute molecule moves at random, the average motion of a large collection of such molecules results in a net flow of solute from a region of high concentration into a region of low concentration

Diffusion Through a Membrane In view of our interest in the diffusion of molecules through the cell membrane we shall define a number, the *permeability coefficient*, which is descriptive of the ease with which a *given solute* can diffuse through a *given membrane* Clearly this number will be a function both of the nature of the membrane and of the nature of the solute molecule

Consider a tube which is divided into two parts by a fixed membrane of thickness, x (Fig 1 12) The tube is filled with a solution containing a solute, S, which is at concentration $[S]_1$ to the left of the membrane and at concentration $[S]_2$ to the right Assuming that $[S]_1$ is greater than $[S]_2$ there will be a net transfer of solute across the membrane from left to right To simplify the mathematics we assume that over the period of observation the concentrations $[S]_1$ and $[S]_2$ (in moles/cm ^{3}) remain constant with time These restrictions can be approximated in a real system by taking measurements over a sufficiently short period so that the concentrations do not change appreciably, and by stirring the solutions on each side of the membrane Under these conditions there will be a net *rate of flow*, Q (moles/sec) of solute across the membrane This flow rate Q, is proportional to the *concentration gradient*, $([S]_1 - [S]_2)/x$ (When the concentration is equal on both sides, that is when $[S]_1 = [S]_2$ then Q is zero) Q is also proportional to the area A (cm ^{2}), of the membrane, i e , the greater the area the greater the flow rate Introducing the proportionality constant p we obtain the equation

$$Q = pA([S]_1 - [S]_2) \qquad (1)$$

It can be seen that p includes the membranes thickness, x and has the dimensions of centimeters per second

$$p = \frac{Q}{A([S]_1 - [S]_2)}$$

$$\text{(cm)}\left(\frac{\text{moles/sec}}{\text{cm}^2}\right)\left(\frac{1}{\text{moles/cm}^3}\right) = \text{cm/sec} \qquad (2)$$

p is the *permeability coefficient* for the given solute and membrane the greater p the greater the rate with which the solute diffuses across the membrane From equation (2) it can be observed that p defines the flow rate of solute per unit membrane area per unit concentration gradient maintained across the membrane

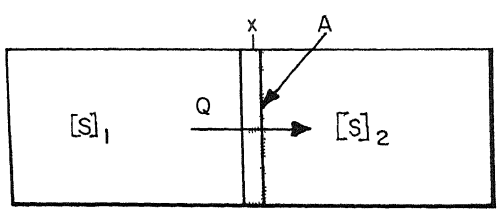

Fig 1 12 Permeability Chamber divided by a thin membrane of area A and thickness x The concentration of a given substance is $[S]_1$ on the left and $[S]_2$ on the right The rate Q in moles/sec at which the substance diffuses from left to right is

$$Q = pA([S]_1 - [S]_2)$$

where p is the permeability coefficient of the membrane for the given substance Note that p may include such factors as the solute diffusion coefficient the membrane thickness the geometry of aqueous channels in the case of polar solutes etc

Any rate of transfer of mass (particles) or energy across a boundary may be referred to as a *flux* Thus, the term Q in equation (1) above may be spoken of as the net flux of solute across the membrane area, A In recent years the letter, J, has been used as a general designation for flux whether the moving particles are molecules, ions, electrons, packets of energy such as calories or quanta, etc In this chapter we are using J to represent the flux, Q, per unit membrane area, A In other words,

$$J \equiv Q/A$$

Therefore, equation (1) for simple diffusion can be rewritten

$$J \equiv Q/A = p([S]_1 - [S]_2) \qquad (3)$$

If the solute particles are ions, the movement or flux can be measured in terms of specific ionic electrical current, I, instead of flux, J Current and flux are related as follows

$$I = zFJ$$

where z is the valence of the ion and F is Faraday's constant (96,500 coul /eq) Typical units

of current are μamp or μamp /cm ^{2} if normalized A handy equation for converting electrical current to ionic flux is

$$I\ (\mu\text{amp /cm}^2) = 26\ 8\ z\ J\ (\mu\text{mole/hr -cm}^2)$$

Physicochemical Criteria for Rates of Diffusion across All Membranes *Lipid Solubility* Let us consider a vessel in which two aqueous phases are separated by an oil phase (analogous to a lipoidal cell membrane) A solute, S, is introduced into aqueous phases 1 and 2 to establish concentrations $[S]_1$ and $[S]_2$, respectively If equilibrium is established across each interface, the concentrations in the oil phase (membrane) and the adjoining aqueous phases can be related to B, the oil-water partition coefficient, which is defined as follows

$$B = [S]_{1\ (oil)}/[S]_{1\ (water)} = [S]_{2\ (oil)}/[S]_{2\ (water)}$$

where $[S]_{1\ (oil)}$ and $[S]_{2\ (oil)}$ are the concentrations of the substance in the oil phases at oil-water interfaces 1 and 2, respectively, and $[S]_{1\ (water)}$ and $[S]_{2\ (water)}$ are the concentrations of the substance in the water phases 1 and 2, respectively There will be a gradient of concentration in the oil phase (membrane) when the concentrations established in the aqueous phases are unequal A gradient across the oil phase gives rise to diffusion of the substance through this phase The net flux per unit area, $J \equiv Q/A$, from aqueous phase 1 to aqueous phase 2 is given by

$$J \equiv Q/A = p'([S]_{1\ (oil)} - [S]_{2\ (oil)})$$

where p' is a proportionality coefficient Knowledge of the oil-water partition coefficient, B, makes it possible to substitute the concentration in the aqueous phases for the concentration in the oil phase at the interfaces (where an equilibrium distribution is assumed to prevail), thus

$$J \equiv Q/A = p'B([S]_{1\ (water)} - [S]_{2\ (water)}) \qquad (4)$$

The apparent permeability coefficient, $p'B$, corresponds to p in equation 3 It is seen that flux through the oil phase (membrane) is proportional to the oil-water partition coefficient, B, all other factors being equal For many substances of biological interest B is very much less than one, for substances which can enter the cell membrane only to a limited extent, Q is small In general, although there are exceptions, the greater the oil-water partition coefficient, B, for a substance, the greater its rate of transfer through the cell membrane (Overton's rule)

Hydrophilicity Chemical groups are said to be polar when the positive nuclei and negative electrons are so unevenly arrayed that the local net electrical charge does not average to zero Let us consider some examples Ionized groups, that is, groups which have lost or gained electrons, are polar Groups in which there has been no net gain or loss of charge, but where a displacement of charge within the group has led to a concentration of negative charge in one region, and positive charge in another, are also polar The alcoholic hydroxyl group is polar because the two valence electrons shared by the hydrogen and oxygen atoms are attracted toward the more electronegative oxygen atom ($-\bar{O}\overset{+}{H}$) This is also why water is a highly polar substance

The greater the number of hydroxyl groups on an organic molecule, for example, the greater the hydrophilicity As one would expect from the lipid (hydrophobic) constitution of biological membranes, the permeability of the cell membrane to a substance is inversely related to the hydrophilic nature of that substance Thus, hydrophilic substances, such as sodium ions, potassium ions, sugars, and amino acids, will penetrate the cell membrane only very slowly by simple diffusion In Table 1 3 it is seen that the permeability constant of sodium ion, Na^+, is only about one hundred millionth that of water It is equally evident, that from the point of view of the economy of the cell certain hydrophilic substances must be brought into the cell in appreciable quantities As we shall see such substances are transported into the cell by a process which involves membrane-bound carrier molecules While it is generally true that electrically charged particles penetrate the cell membrane only very slowly by simple diffusion, it is to be noted that in the case of the mammalian red blood cell, the anions OH^-, Cl^- and HCO_3^- as well as the cation H^+ have permeabilities which are very high compared to that of the cations Na^+ and K^+ In general the electrical charge distribution in the walls of the pores favors the diffusion of anions over cations

Molecular Size In general it may be said for a series of homologous substances that the greater the molecular weight, the smaller the permeability coefficient This follows from the fact that the larger a particle the slower its

thermal motion and, consequently, the smaller its rate of diffusion For polar molecules, such as proteins, nucleic acids, and viruses, the permeability coefficient is exceedingly small not only because of low diffusibility but also because of molecular sieving, i e , large polar molecules tend to be sieved by the cell membrane owing to the geometry (size and shape) and the electrical characteristics (charge distribution) of its aqueous channels Hence, since such particles do indeed cross the cell membrane, we must seek an explanation for their transport in terms of special mechanisms other than simple diffusion

CARRIER-MEDIATED TRANSPORT

The Carrier Model. We have noted that many substances, such as amino acids and sugars, which are vital to the economy of the cell can be expected to cross the cell membrane by simple diffusion only at low rates A considerable body of experimental evidence has accumulated to suggest the following mode of transport The substrate to be transported combines with specific, membrane-bound *carrier* molecules and crosses the cell membrane as part of a substrate-carrier molecular complex The carrier molecules are assumed to be confined to the membrane and to shuttle back and forth from one side of the membrane to the other The carrier is like a ferryboat—it accelerates the rate of transport across a barrier Presumably the carrier reduces the thermal energy needed by the substrate molecule to leave the aqueous phase and to enter the membrane phase Consider a sugar molecule which is strongly bound to the surrounding water by hydrogen bonds For this molecule to enter the nonaqueous phase, the membrane, it is necessary to await a thermal collision of sufficient magnitude to break its hydrogen bonding to the water If, however, there is a carrier molecule in the membrane to which the sugar molecules can readily attach, then the thermal energy needed by the sugar molecules to enter the membrane is decreased because the hydrogen bonds between the sugar and the water molecules can be replaced by bonds between the sugar and the carrier molecules Thus, the entry of the sugar molecules into the membrane is greatly facilitated At the present time many laboratories are engaged in the isolation and characterization of membrane components possessing the required specificity to serve as carriers for the substrate molecules that are believed to undergo carrier-mediated transport in biological systems

Carrier-mediated transport can be distinguished from simple diffusion by the following criteria

Saturation When there is no carrier equation 1 tells us that for simple diffusion the rate of transport is proportional to the concentration difference $[S]_1 - [S]_2$. If this difference doubles, the rate of transport doubles This is not the case for carrier mediated transport Here concentrations can be reached at which virtually all the carrier molecules are in constant use, then further increases in concentration will not appreciably increase the rate of transport since unoccupied carriers are not available The carrier system is saturated and the carrier mediated transport operates at the maximum possible rate

Competition Inhibition Two substances A and B which attach to the same carrier *compete* for the carrier system If B is added to the extracellular fluid, the cellular uptake of A is decreased because molecules of B now occupy carrier molecules which were previously available for the transport of A The competition, of course, is mutual so that addition of A reduces the rate of uptake of B

Specificity One carrier molecule may transport one amino acid or group of amino acids, while another transports one sugar or group of sugars If the addition of a substance X does not decrease the carrier-mediated uptake of a substance A, then A and X do not share the same carrier system and the chemical specificity of the substance-carrier interaction is thereby demonstrated. This specificity is never perfect and a given carrier may carry, with varying efficiencies, a number of substances of related chemical structure

Noncompetitive Inhibition A substance I may interact with a carrier in such a manner as to prevent the carrier from combining with its usual substrate, A In this case, even though I is not being transported, the transport of A is inhibited

Finally, it should be noted that carrier-mediated transport generally shows the high temperature coefficients characteristic of chemical reactions

The carrier-mediated transport of a substance along a concentration gradient (i e , in the direction of simple diffusion) is called *facil-*

ıtated dıffusıon On the level of the organism an analogy to facılıtated dıffusıon may be found ın the transport of oxygen from the lungs to the tıssues The *carrıer* ıs the hemoglobın molecule, the substrate beıng transported ıs oxygen The carrıer manıfests *specıfıcıty*—ıt combınes wıth oxygen but not wıth nıtrogen, *saturatıon*—an ıncrease ın alveolar oxygen tensıon beyond certaın levels does not yıeld a proportıonal ıncrease ın oxygen transport, *competıtıon*—carbon monoxıde competes wıth oxygen for the same carrıer and prevents oxygen uptake

Electrochemıcal Potentıal ($\tilde{\mu}$) The transport processes whıch we have dıscussed so far have dealt wıth the movement of molecules from regıons of hıgh concentratıon to regıons of low concentratıon For generalıty and scıentıfic precısıon we should be referrıng to the movement of molecules from regıons of hıgh *electrochemıcal potentıal* to regıons of low electrochemıcal potentıal However, ın the ınterest of sımplıcıty and clarıty for students who have not been exposed to physıcal chemıstry, we wıll contınue to use the term, concentratıon, ınterchangeably wıth the more rıgorous term, electrochemıcal potentıal Nonetheless, ıt ıs approprıate at thıs tıme to consıder brıefly the meanıng of the electrochemıcal potentıal of a substance, S, ın solutıon ($\tilde{\mu}_S$)

$\tilde{\mu}_s$ ıs a measure of the "useful" energy content of S Typıcal unıts are joule/mole or kcal /mole Electrochemıcal potentıal ıs composed of a chemıcal part and an electrıcal part

$$\tilde{\mu}_s = \underset{\substack{\uparrow \\ \text{chemical} \\ \text{part}}}{\mu_s} + \underset{\substack{\uparrow \\ \text{electrical} \\ \text{part}}}{z_s F \Psi} \tag{5}$$

where z_s ıs the valence of S, F ıs Faraday's constant and Ψ ıs the electrıcal potentıal (voltage) measured wıth respect to any reference poınt The chemıcal part may be separated ınto component parts

$$\mu_s = \mu_s^0(T,P) + RT \ln a \tag{6}$$

where a ıs the actıvıty, R ıs the gas constant, T ıs the absolute temperature, and P ıs the pressure μ_s^0, as ındıcated, ıs a functıon only of T and P, ı e , ıt ıs constant when T and P are constant The actıvıty a may be broken down as follows

$$a = \gamma\ [S] \tag{7}$$

where γ ıs the actıvıty coefficıent (usually ın the neıghborhood of unıty) and $[S]$ ıs the concentratıon of S Therefore, the electrochemıcal potentıal on sıde $ı$ ($ı$ beıng 1 or 2) ıs

$$\tilde{\mu}_{s(ı)} = \mu_s^0(T_ı, P_ı) + RT_ı \ln (\gamma_ı\ [S]_ı) + z_s F \Psi_ı \tag{8}$$

One of the "forces" drıvıng S across the membrane ıs the dıfference ın electrochemıcal potentıal across the membrane In bıologıcal systems, there ıs usually neıther a sıgnıfıcant temperature dıfference ($T_1 = T_2$) nor a sıgnıfıcant pressure dıfference ($P_1 = P_2$) across the membrane and the actıvıty coefficıents are treated as equal ($\gamma_1 = \gamma_2$) In thıs case,

$$\Delta\tilde{\mu}_s = \tilde{\mu}_{s(1)} - \tilde{\mu}_{s(2)} \tag{9}$$

$$= \underset{\substack{\uparrow \\ \text{chemical part}}}{RT \ln ([S]_1/[S]_2)} + \underset{\substack{\uparrow \\ \text{electrical part}}}{z_s F \Delta\psi} \tag{10}$$

where $\Delta\psi = \psi_1 = \psi_2$

ACTIVE TRANSPORT

When a solute moves downhıll from a regıon of hıgh electrochemıcal potentıal to a regıon of low electrochemıcal potentıal, the transport process ıs generally thermodynamıcally spontaneous or dıssıpatıve ın character ın that the free energy of the matter under observatıon decreases durıng transport (Fıg 1 13A), thus, no expenditure of energy ıs requıred on the part of the cell However, a transport process ın whıch the net flow of substance ıs from a regıon of hıgh to a regıon of low electrochemıcal potentıal need not be exclusıvely spontaneous, for example a metabolıc energy source ($\Delta\mu_M$) mıght be coupled to such a downhıll process so as to ıncrease the net rate of flow of substance above that whıch would prevaıl ın a purely dıssıpatıve process A sıtuatıon of thıs type ıs sketched ın Fıgure 1 14 to show the net flux of a substance, J_S^{NET}, beıng drıven by a metabolıc energy source, $\Delta\mu_M$, as well as by the electrochemıcal potentıal gradıent, $\Delta\tilde{\mu}_S$ Thıs ıs an ıllustratıon of *actıve downhıll* transport Another case of actıve downhıll transport ıs observed when the metabolıc component of transport (ı e , that component whıch ıs lınked to $\Delta\mu_M$) ıs orıented ın the reverse dırectıon from but overwhelmed by the electrochemıcal potentıal gradıent, $\Delta\tilde{\mu}_S$ (Fıg 1 15) It ıs also possıble for actıve transport to be manıfest when the electrochemıcal potentıal gradıent has been elımınated ($\Delta\tilde{\mu}_s = 0$) In thıs sıtuatıon, referred to as *actıve level* flow, $\Delta\mu_M$ alone drıves the transport process (Fıg 1 16)

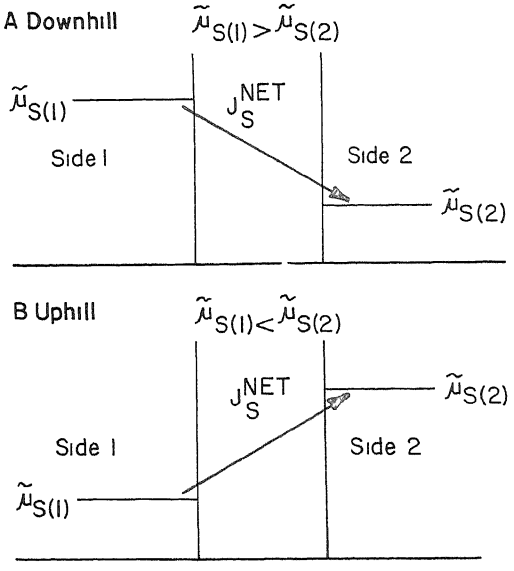

Fig 1 13 If the net flow of a substance is in a direction from higher to lower electrochemical potential it is moving downhill if net flow is from lower to higher electrochemical potential it is moving uphill

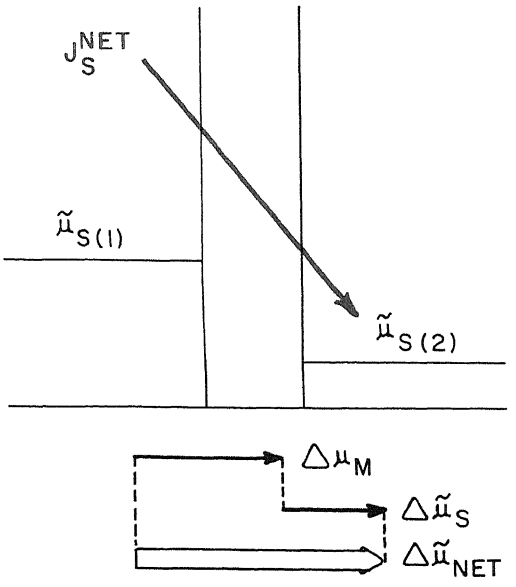

Fig 1 14 Active downhill transport $\Delta\mu_M$ represents the effective input of metabolic energy from the cell for the transport of S This effective input will be less than the free energy available from the coupled metabolic reaction to the extent that the efficiency of coupling between metabolism and transport is less than 100% The metabolic coupling in this scheme is oriented to drive S from side 1 to side 2 $\Delta\tilde{\mu}_S$ is the electrochemical potential difference of S $\Delta\tilde{\mu}_{NET}$ represents the net driving force due to $\Delta\mu_M$ *plus* $\Delta\tilde{\mu}_S$ In this example of active downhill transport both $\Delta\mu_M$ and $\Delta\tilde{\mu}_S$ act to drive S from side 1 to side 2

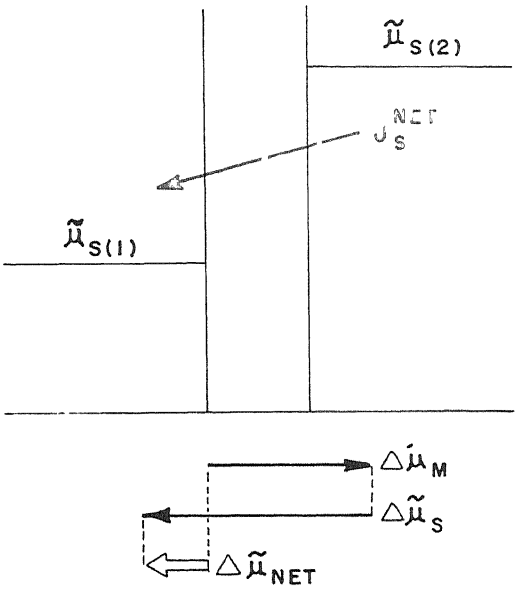

Fig 1 15 Reversed active downhill transport $\Delta\mu_M$ and $\Delta\tilde{\mu}_S$ are oriented to drive S in opposite directions In this example $\Delta\mu_M$ is overwhelmed by $\Delta\mu$ so that $\Delta\tilde{\mu}_{NET}$ is oriented to drive S from side 2 to 1 in the *reverse* of its normal direction of active transport If coupling between the metabolic and transport processes is highly efficient then in principle the reversed downhill transport of S can serve to generate metabolites (e g ATP) from breakdown products (e g ADP *plus* inorganic phosphate)

In all cells there exist mechanisms whereby substances can be transported uphill across membranes from regions of low to regions of high electrochemical potential (Fig 1 13B) These mechanisms are in most cases examples of *active uphill transport* in which a metabolic process (off-equilibrium breakdown of a metabolite) is coupled to and thus provides the energy for the transport process (Fig 1 17) The movement of every mole of substance against its electrochemical potential gradient must be paid for by the expenditure of an amount of energy which depends upon the efficiency of the coupling between the energy-providing process and the transport work accomplished The energy required for active transport is derived from the hydrolysis of substances such as adenosine triphosphate (ATP) If there is no coupling with a metabolic process, transport is passive For example, a substance may move uphill passively if its transport is coupled with the downhill movement of another substance rather than with a metabolic process On the other hand, as we have seen, an

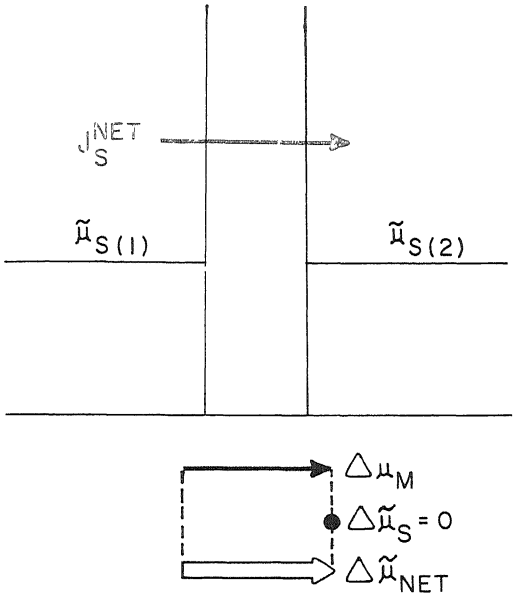

Fig 1 16 Active level flow Only $\Delta\mu_M$ provides the net driving force for the transport of S In undergoing net transport from side 1 to side 2 S neither gains nor loses useful energy ($\tilde{\mu}_S$) The direction of net transport during level flow can be used to define the normal direction of active transport

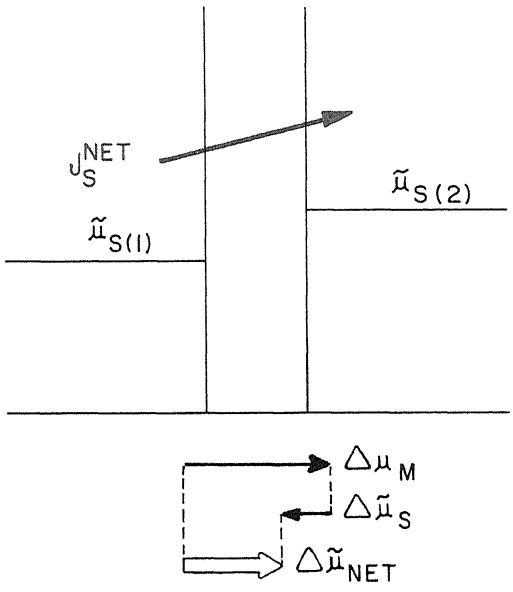

Fig 1 17 Active uphill transport $\Delta\mu_M$ and $\Delta\tilde{\mu}_S$ are oriented to drive S in opposite directions In this example $\Delta\tilde{\mu}_S$ is overwhelmed by $\Delta\mu_M$ so that $\Delta\tilde{\mu}_{NET}$ is oriented to drive S from side 1 to side 2 S gains useful energy during its net transport from side 1 to side 2 In effect the active transport mechanism is responsible for the transfer of energy from metabolites to S

actively transported substance may move uphill, downhill, or remain at a given level with respect to its electrochemical potential, $\tilde{\mu}_S$ Thus, an active transport process is defined, not by demonstrating that flux is thermodynamically uphill, but *only* by demonstrating that flux is coupled to metabolism

In mammalian cells the existence of active transport processes for sodium and potassium ions can be readily inferred from the concentrations of these ions in the intracellular and extracellular fluids (Table 1 1) In general, though with exceptions, the concentration of K^+ is greater in the cell than it is in the extracellular fluid, while the concentration of Na^+ is lower in the cell than it is in the extracellular fluid From the magnitudes of the permeabilities of cell membranes to these ions (Table 1 3) it can be shown that the intra- and extracellular concentrations would equalize by diffusion over a period of several hours It follows that concentration gradients are maintained in vivo across the cell membrane by active processes which pump the ions against the gradients at rates sufficient to offset passive back diffusion (leakage down the gradients)

Active transport is carrier-mediated Therefore the criteria which define it include *1*) saturation, 2) competitive inhibition, *3*) specificity, and *4*) noncompetitive inhibition, however, as noted above, the new criterion which must be added is the requirement for metabolic energy As we have already noted, a substance can be made to move against a concentration gradient only by the expenditure of energy If the energy supply is blocked, active transport ceases As an example we may consider the human erythrocyte which under normal circumstances has a potassium concentration which is higher in the cell than it is in the serum When erythrocytes are refrigerated, active transport ceases and potassium ions slowly leak out of the cells until the intracellular and extracellular potassium concentrations are

Table 1 1
Concentrations (mEq /liter of H_2O) of certain ions in human plasma and erythrocytes

	K^+	Na^+	Ca^{++}	Mg^{++}	Cl	HCO_3
Plasma	5	140	3	1	110	28
Erythrocytes	150	15	Trace	3	70	27
Ratio (*P/E*)	0 03	9	—	0 3	1 6	~1

After Davson, 1964

equal When the blood temperature is returned to 37° C, providing there is an energy source such as glucose in the serum, active transport resumes and the intracellular potassium concentration increases toward normal levels Similar observations have been made in in vitro experiments with muscle tissue, kidney slices, salivary gland slices, etc

A useful model for active transport is shown in Figure 1 18 In addition to the carrier, there is an enzyme, ϵ, and an energy source, W The substance to be transported combines reversibly with a carrier molecule on the extracellular surface of the membrane The substance-carrier complex diffuses to the intracellular side of the cell membrane where the complex dissociates and the substance discharges into the cell In this model the enzyme, ϵ, which is localized on the intracellular side of the membrane, alters the carrier molecule to an inactive form, that is, a form which does not combine with the substance The alteration of the carrier is an enzymatic process which does not require an input of energy The inactivated (unloaded) carrier passes to the extracellular side of the membrane where it is converted to its active form by an energy-requiring process Now it can again combine with the substance to be transported and the cycle then repeats It should be pointed out that there exists no direct evidence for this model The postulated carrier molecule, the inactivating enzyme and the carrier activating system have not yet been isolated or biochemically defined Nevertheless, the model shown in Figure 1 18 is exceedingly helpful in considering a wide range of experimental findings related to active transport It might be thought that active transport should give rise to a continuously increasing concentration gradient This is not the case for the following reasons

1) As the intracellular concentration of the transported substance increases, the dissociation of the substance-carrier complex is opposed by mass action, and therefore, the probability of a loaded carrier molecule returning from the intracellular to the extracellular side increases

2) As the concentration gradient builds up there will be an increase in the passive back diffusion (leak down the gradient in the direction opposite to that of the active transport) so that a steady state is attained in which the rate of active transport equals the rate of back leak

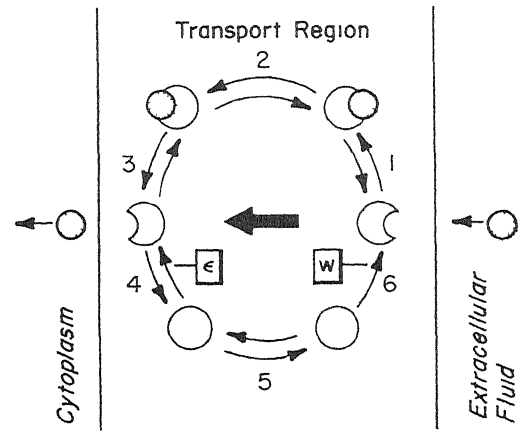

Fig 1 18 Model for active transport The carrier molecules (large circles) are confined to the membrane region There is a net transport of substance (small circles) from the extracellular fluid to the cytoplasm The large arrow indicates the direction of transport

1) Substance combines with carrier

2) Substance-carrier complex passes to cytoplasmic side

3) Substance-carrier complex dissociates Substance discharged into cytoplasm

4) Carrier is enzymatically degraded into an inactive form i e a form which exhibits low affinity for the substance

5) Inactive carrier passes to extracellular side

6) Carrier is activated by an energy requiring process (After Heinz and Walsh, 1958)

Thus, the ratio of the intracellular concentration to the extracellular concentration of the transported substance becomes constant with time

The adaptive value and evolutionary significance of active transport is clear· The total amount of an amino acid in the environment of a microorganism, for example, may be very large though its concentration and rate of entry into the cell may be too small to sustain an adequate level of protein synthesis In the presence of an energy-coupled carrier system the amino acid can be concentrated within the cell. Such a system should not be thought of as operating only between the cell and its outside It can operate at the level of any membrane system—making it possible, for example, for a cell organelle to concentrate a needed constituent This is the case for the mitochondrion in which many ions are accumulated The general features of active transport and facilitated diffusion hold true for a wide range of transport phenomena Active transport processes for amino acids, sugars, and ions (Na^+, K^+, Cl^-,

Mg^{++}, etc) have been demonstrated and referred to by various terms such as the sodium and potassium "pump" of nerve, muscle and erythrocytes, and the active secretion and active reabsorptive processes of the kidney, gastrointestinal tract, and exocrine glands

Unidirectional Fluxes and Net Flux Clearly the net flux across a membrane will be resultant of the two unidirectional fluxes The unidirectional flux of solute, S, from side 1 to 2 ($J_S^{1\to 2}$) can be determined by introducing an isotope S^*, to serve as a tracer for S and then measuring the rate of appearance of S^* on side 2 The unidirectional flux from side 2 to 1 ($J_S^{2\to 1}$) can be determined by introducing a second isotope of S, S^{**}, into side 2 and measuring its rate of appearance on side 1 These operations are depicted schematically in Figure 1 19

Net flux is given by

$$J_S^{i\to j(\text{net})} = J_S^{i\to j} - J_S^{j\to i}$$

If $J_S^{i\to j(\text{net})} > 0$, material S disappears from compartment i and appears in compartment j

Unidirectional flux is of interest because the net flux is often most easily and usefully determined as the difference between the two unidirectional fluxes

Cis- and Trans-. *Cis-* is a prefix referring to the side from which a unidirectional flux originates and *trans-* is a prefix referring to the side to which a unidirectional flux moves

		cis-side	*trans*-side
FLUX	$J_S^{1\to 2}$	1	2
	$J_S^{2\to 1}$	2	1

In general we may represent unidirectional fluxes as follows

cis side *trans*-side

$J_S^{i\to j}$ or $J_S^{cis\to trans}$

It is often important to know whether biologically active agents (drugs, hormones), which modify the transport of a substance, act on one or both unidirectional fluxes and whether such action is from the *cis*-side, the *trans*-side, or both

PINOCYTOSIS

In discussing the relationship between permeability and molecular size it was pointed out that with respect to diffusion the permeability of the cell membrane to large molecules, such as proteins, is negligible Yet the passage of macromolecules into cells is well documented, for example, *1*) the genetic transformation of bacteria by transforming principle (deoxyribonucleic acid), *2*) the infection of cells by viruses, and *3*) the penetration of cells by antibodies One mechanism whereby such macromolecules enter cells is called pinocytosis (cell drinking) a phenomenon related to phagocytosis This phenomenon was noted under the general heading of endocytosis in Chapter 1 In pinocytosis the cell membrane engulfs extracellular fluid and forms a membrane-bounded vacuole (Fig 1 20) The vacuole travels into the interior of the cell The content of the vacuole faces the "outside" surface of the former cell membrane Thus, from the point of view of the asymmetry of the membrane the vacuolar content lies outside the cytoplasm, just as the content of the gastrointestinal tract lies, in reality, outside of an organism However, in pinocytosis, the cell membrane appears to have properties in the cell interior which are different from those which it had on the cell surface The cell membrane of the ameba, for example, is highly impermeable to glucose When pinocytosis is stimulated, however, glucose uptake from the vacuolar fluid becomes considerable It is believed that macromolecules pass from the interior of the pinocytic vacuole into the cytoplasm as a consequence of the breakdown of the vacuolar membrane in the cell interior and the resultant liberation of its contents

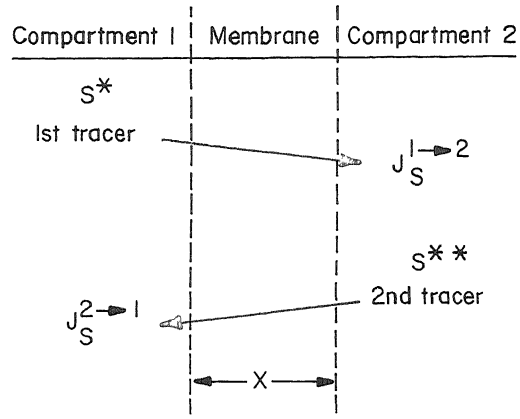

Fig 1 19 Use of tracer isotopes to measure net flux

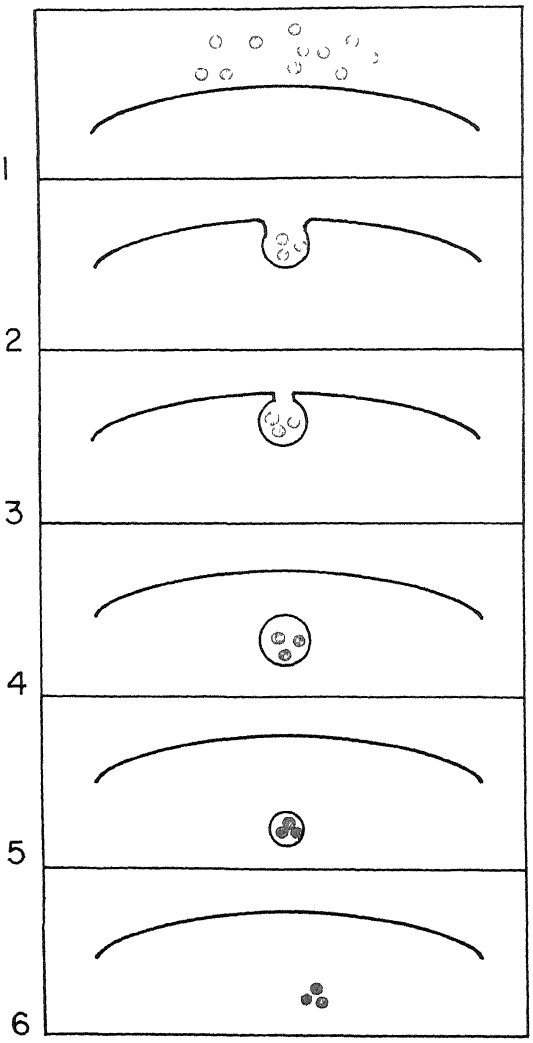

Fig 1 20 Pinocytosis Molecules which stimulate pinocytosis are indicated by dots *1)* Molecules adsorb to the outer surface of the cell membrane *2)* The membrane invaginates in the region of adsorption *3)* A vacuole forms *4)* The vacuole travels inwards *5)* During its inward journey the vacuole shrinks *6)* The membrane disappears and the adsorbed molecules spill into the cytoplasm (After Bennett 1956)

Pinocytosis is not simply the entrapment of a volume of extracellular fluid with the subsequent uptake of solutes from the fluid In the ameba the concentration of protein in the pinocytic vacuole exceeds that in the extracellular fluid This anomaly was explained when it was shown that the protein was adsorbed to the cell membrane prior to the formation of the pinocytic vacuole. It, thus, appears likely that the transport process involved in pinocytosis is primarily one of plasma membrane movement into the interior of the cell and therefore that the ingestion of the extracellular fluid which is trapped in the vacuole is a by product of the process Thus, pinocytosis might be regarded as a transport process in which the carrier is the cell membrane

PHYLOGENETIC VARIABILITY

Thus far we have emphasized the similarity of various biological membranes It is appropriate now to take note of the great diversity of properties manifested by biological membranes In Table 1 2 we note a 100 fold difference in permeability to water of the cell membranes of *Ameba proteus* and the human erythrocyte Even comparisons within the class of erythrocytes show marked differences The permeabilities to glycerol of the cell membranes of erythrocytes of two evolutionary cousins the rat and the ox, differ by a factor of more than 100 We have already considered several generalizations relating the chemical structure of a solute molecule to its permeability coefficient These generalizations were derived largely from studies on plant cells but, with many exceptions, apply also to mammalian cells

Movement of Water Across the Cell Membrane

Because of the special role which water plays in biological systems and because of the unique physical characteristics of this molecule we shall treat the diffusion of water across the cell membrane as a special case Compared to other molecules water diffuses across the cell membrane at a very rapid rate The permeability coefficient of water is 400 times greater than that of urea (Table 1 3) although the latter molecule itself has a very high permeability constant as compared to other molecules of biological significance As a result the water within an erythrocyte exchanges with water from outside the erythrocyte in a small fraction of one second Nevertheless it is important to recognize that the cell membrane is a rather impermeable structure as demonstrated by the fact that a water layer of equal thickness would have a permeability to water molecules 10,000 to 100,000 times larger Thus, when we say that the cell membrane is highly permeable to water we are speaking only in relative terms, that is,

Table 1 2
Permeability to water of some cell membranes

Species	Extracellular Fluid	Permeability (μ^3 water/ μ^2 surface area/atm)
Ameba proteus	Fresh water	0 03
Arbacia egg	Sea water	0 4
Human erythrocyte	Serum	3 0

Prosser and Brown, 1961

Table 1 3
Orders of magnitude of the permeability coefficients of erythrocyte membranes

Substance	Oil/Water Partition Coefficient	Permeability Coefficient (*cm /sec*)	Species
Water	10^{1}	10^{-2}	Ox
Urea	10^{-4}	10^{-4}	Ox
Cl^-	—	10^{-4}	Man
K^+	-	10^{-8}	Man
Na^+	—	10^{-10}	Man

For references see Davson, 1964

we are noting the permeability of the membrane to water as compared with its permeability to other molecules

Osmotic phenomena arise as a consequence of the high rate, as compared to other cell constituents with which water crosses the cell membrane Insight into osmotic phenomena can be most easily obtained by studying a comparable system of deal gases

Consider a container (Fig 1 21*a*) divided into two equal parts by a partition There are an equal number of ideal gas molecules on each side of the partition What distinguishes the two sides is that on the left there are 12 big molecules (marbles) and 4 small molecules (dots), a total of 16 molecules, while on the right there are 16 small molecules (In the biological system the dots correspond to water molecules, the marbles to solute molecules which penetrate the cell membrane very slowly, if at all) Now it is a characteristic of the ideal gas that its pressure depends only on the concentration of particles and *not* on the *nature* (large or small molecules) of the gas Hence, the pressure is the same on each side of the partition Let us now drill holes through the partition of a size that the dots can pass through but the marbles cannot (Fig 1 21*b*)

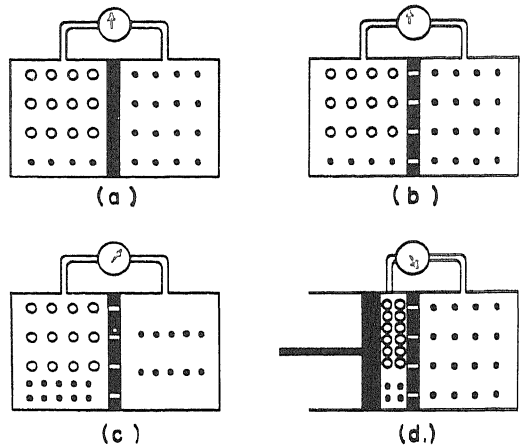

Fig 1 21 Ideal gas model of osmosis

a) An equal number of particles on each side of the partition leads to a zero pressure difference between the two compartments

b) Holes are drilled through the partition These are of such size that the dots but not the marbles can pass from one compartment to the next

c) At equilibrium the concentration of dots is the same on both sides of the partition Due to the presence of the marbles the pressure is higher on the left than it is on the right

d) The net flow of dots from right to left is averted by decreasing the volume of the left compartment and thereby increasing the concentration of dots on the left The pressure difference between the two compartments when the net flow of dots is zero is the osmotic pressure π

What happens next is a consequence of the fact that in a mixture of ideal gases each component behaves as if the other components did not exist Thus, dots migrate through the partition until the number of dots on the left equals the number of dots on the right (Fig 1 21*c*) More generally, we can say that the migration will occur in a direction to equalize the number of dots per unit volume (concentration on both sides of the partition) The migration can be prevented by decreasing the volume on the left side of the chamber so as to equalize the initial concentration of dots on both sides of the *semipermeable* partition (Fig 1 21*d*) The decrease in volume is accompanied by an increase in the pressure of the gas in the left chamber This increase in pressure, π, required to prevent the new flow of "solvent" (dots) between the two chambers is analogous to the *osmotic pressure* of a "solution" (marbles dissolved in dots) with respect to a pure "solvent" (dots)

To transpose this problem back to the cell: the perforated partition corresponds (in its osmotic properties) to the semipermeable cell membrane. (A semipermeable membrane is one which cannot be penetrated by solute molecules or which is very much more readily penetrated by solvent than by solute molecules). The small particles (dots) correspond to the solvent (water), the large particles (marbles) to the solute. As compared to water the marbles represent solute molecules which penetrate the cell membrane slowly, if at all. For an aqueous solution the osmotic pressure, π (in atmospheres), can be estimated from the equation.

$$\pi V = n_0 RT.$$

In this equation V is the volume (in liters) of the solution, n_0 is the number of moles of solute particles in this volume, T is the absolute temperature (°K) and R is the universal gas constant 8.2×10^{-2} (liter·atm.)/(mole·°K). If the extracellular and intracellular fluids have the same osmotic pressure and no solute penetrates the cell membrane, then there is no *net* flow of water across the cell membrane and the cell does not swell or shrink. Mammalian cells do not swell or shrink when placed in a 0.9% NaCl solution. The molecular weight of NaCl is 58.5; therefore the molarity of this solution is 0.15. However, the NaCl is almost completely ionized so that there are approximately 2 osmotically active particles (Na^+ and Cl^-) for every NaCl molecule. Hence, $n_0 = 2 \times 0.15 = 0.3$ moles (per liter), V = 1 liter, T = 310° (at body temperature) and the osmotic pressure of the interior of the mammalian cell is approximately

$$\pi = n_0 RT/V = (0.3)(8.2 \times 10^{-2})(3.1 \times 10^2)/1 = 7.5 \text{ atm.}$$

Any system, such as the cell or the mitochondrion, which is bounded by a semipermeable membrane manifests osmotic properties. In the mammalian organism the osmotic pressure of the blood and extracellular fluids is regulated very precisely and water equilibrates rapidly across the cell membranes. In the ameba, a fresh water organism, there is a constant influx of water into the organism and a continuing energy expenditure on the part of this organism is required to pump the water out again. Thus, the relatively low permeability to water of the ameba as compared with the human erythrocyte (Table 1.2) is an important adaptation for this organism.

3 / EXCITATION, CONDUCTION, AND TRANSMISSION OF THE NERVE IMPULSE

The nervous system is a complex array of specialized structures which serve to receive, store, and transmit information—thereby integrating the activities of spatially separated cells tissues, and organs and making it possible for a multicellular organism to function as a coordinated unit in terms of growth, development, the ability to do work, and to adapt to changes in the environment Our efforts to understand the function of the nervous system involve the concepts and languages of many disciplines ranging from mathematics and physics to the physiology of human beings in all of their complexity In this chapter, however, we will be concerned primarily with the generation and propagation of the impulses which constitute the currency of all neural transactions

The Structure of Nervous Tissue

THE NEURON

The neuron consists of a body (soma, perikaryon), and two types of process—the dendrite and the axon (axis-cylinder process, Fig 1 22A In vertebrates, the bodies of the nerve cells lie within the gray matter of the central nervous system or in outlying ganglia, e g , posterior spinal root, cranial, or autonomic ganglia The white matter of the brain and spinal cord and of the peripheral nerves is composed of bundles of nerve fibers. The core of each nerve fiber is formed by a process of a nerve cell, and many of them are surrounded by a sheath of myelin which gives them a white appearance The gray matter receives a rich blood supply from the vessels of the pia mater; the blood supply to the white substance is much less profuse

There are a number of different types of nerve cell; those in which axon and dendrite arise by a common stem are called unipolar, and those in which the axon and the dendrite or dendrites spring from opposite or at least different parts of the soma are called bipolar or multipolar The cell bodies or somata are of various sizes and forms—stellate, round, pyramidal, fusiform, etc

After fixation and staining by special techniques, various structures are seen in the cytoplasm or perikaryon of the nerve cell body *1)* neurofibrils, *2)* Nissl bodies or tigroid substance, *3)* Golgi apparatus, *4)* mitochondria, *5)* ribosomes, and *6)* the endoplasmic reticulum (see also chap 1) Electron microscopy has revealed much of the detailed structure of these intracellular entities Their structure and function appear to be the same in all cells studied so far Mitochondria, found along the entire length of the axis cylinder, contain all the enzymes required for the respiratory activity of the cell, and are therefore, responsible for those functions dependent upon aerobic metabolism They also participate in protein synthesis but the relationship of this to neural function is not yet clear The neurofibrils appear as fine filaments which stream through the cytoplasm from dendrites to axon (Fig 1 22B), they enter the latter process and extend to its terminations The Nissl bodies composed of ribonucleic acid (RNA) and polysomes are granular masses stainable with basic dyes and occur in the perikaryon and dendrites but not the axon They give a striped or tigroid appearance to the cell They are absent from the region of origin of the axon (axon-hillock) and vary in size and number with the state of the neuron, they undergo disintegration (chromatolysis) in a fatigued or injured cell or in one whose axon has been sectioned This means that the synthetic machinery of the perikaryon is at least partially regulated by events in the peripheral processes of the cell The nature of this feedback control is not known The internal reticular apparatus of Golgi is a coarse network seen within the cells when special methods—e g , impregnation with silver chromate—are employed which leave the Nissl bodies and the neurofibrils invisible

The nucleus of the nerve cell contains one and sometimes two nucleoli but, as a rule, no centrosome The absence of a centrosome indicates that the highly specialized nerve cell has lost its power of division Nerve cells once destroyed are replaced merely by neuroglia

The linking together of neurons to form conducting pathways is effected by the contact (but not union) of the axon terminal of one nerve cell with the body, dendritic process or in some instances, the axon of another Such a junction, without anatomical continuity is called a *synapse*

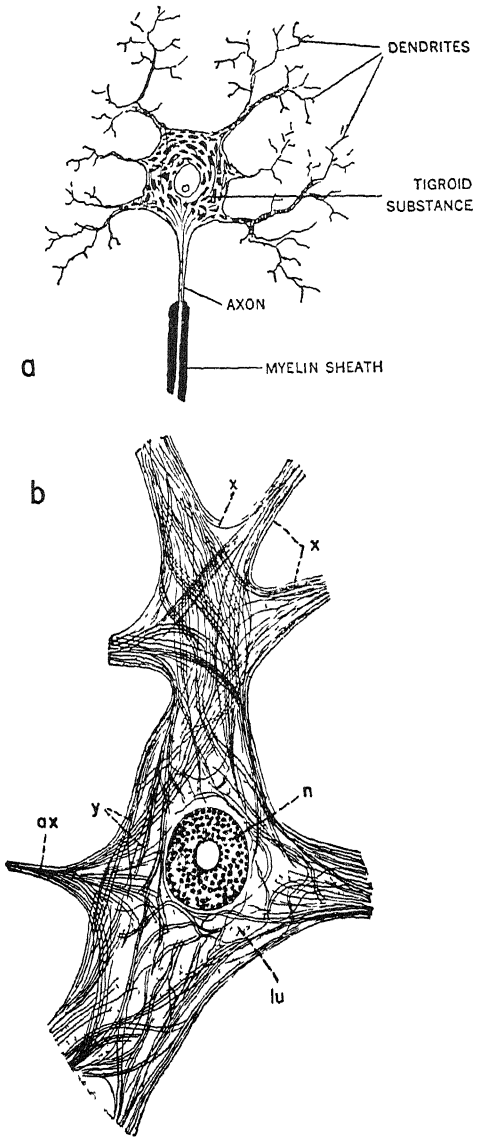

Fig 1 22 **A** Showing different parts of the neuron *B* Showing neurofibrils in a cell from the anterior gray column of the human spinal cord *ax* axon *lu* interfibrillar spaces *n* nucleus *x* neurofibrils passing from one dendrite to another *y* neurofibrils passing through the body of the cell (from Ranson after Bethe and Heidenhain)

Though the nerve cell frequently possesses more than one dendrite the axon is single The axon may be long and contribute to one of the tracts of the central nervous system forming the white matter, or it may terminate as a peripheral nerve fiber Such cells are referred to as Golgi I type In the Golgi II type cell, the axon is short and ends within the gray matter by making contact with another neuron The axon arises from a small elevation on the surface of the cell body, the axon hillock It may give off short collateral branches or run as an unbranched fiber, not dividing until it has reached its destination The dendrite is the receptive process of the neuron, the axon is the discharging process, i e , the former transmits the impulse toward the cell body and the latter away from the cell body Within the central nervous system the dendrite is usually short and possesses many branches, but in the peripheral sensory nerves it is comparable in length with an axon Nerve fibers which carry impulses to the central nervous system are termed *afferent*, those conveying impulses from the central nervous system to the periphery are called *efferent* A mixed nerve contains fibers of both types The fact that conduction is unidirectional is a consequence of the properties of synapses, for nerve fibers per se can be made to conduct in either direction

As with other cells, the cytoplasm of the soma is enveloped by a plasma or unit membrane composed of lipoprotein, a bimolecular leaflet of lipid material covered by a layer of protein This extends over the processes of the nerve cell The electrical properties of nerve depend upon the plasma membrane

THE NERVE FIBER

The white matter of the central nervous system and the peripheral nerves are composed of thousands of individual nerve fibers Within the gray matter the axis cylinders are enclosed only by the plasma membrane; but upon leaving the gray substance they acquire a sheath of lipid material called myelin. The myelin sheath is associated with somatic nerves of large diameter and generally not with any

nerve fibers of small diameter Hence, we speak of myelinated (medullated) or unmyelinated (unmedullated) nerves. Myelinated fibers, usually larger than 1 μ in diameter, conduct faster than the smaller unmyelinated fibers

The myelin sheath of the somatic nerves consists of compressed layers of Schwann cells spiraling concentrically to form a wrapping around the axons The outer layer of the myelin contains the flattened nuclei of the Schwann cells, and is termed the neurilemma or sheath of Schwann Myelinated nerves appear as if constricted at regular intervals along their course This appearance is due to the absence of myelin at these points and the dipping inwards of the neurilemma they are known as the nodes of Ranvier The segments between the nodes vary in length in different nerves, but the usual internodal distance is about 1 mm Each internodal segment of the neurilemma consists of a single Schwann cell The fibers forming the white matter of the central nervous system and optic nerves have no neurilemma, this membrane is replaced by glial cells which produce the myelin sheaths as the Schwann cells do peripherally

Compared with the myelin sheath the neurilemma in the region of the node of Ranvier is highly permeable to ions There is good evidence that the conduction of the impulse along a myelinated nerve is a "leaping" from node to node over the intersegmental regions rather than a continuous process This type of conduction is called saltatory (from the Latin word *saltus*, a leaping)

Myelination of Fiber Tracts in the Central Nervous System The nerve fibers in the various conducting pathways receive their myelin sheaths at different ages and it is generally believed that the myelination of a given tract and the time at which it commences to function coincide. The sensory tracts become myelinated first, those of the posterior columns of the spinal cord between the 4th and 5th months of fetal life (human) The spinocerebellar tracts are myelinated later and the motor paths, e g , corticospinal (pyramidal) tracts, do not begin to be invested with myelin sheaths until the 2nd month of life and are not completely myelinated until about the 2nd year, about the time when the child has learned to walk. The fibers of association paths, for the most part, myelinate at still later dates The function of the myelin sheath is not known, but the high insulating property of myelin suggests that it acts to confine the nerve impulse to individual fibers and thus to prevent cross stimulation of adjacent axons

The neuroglia or "glia" (Greek, glue) is a special type of interstitial tissue Its cells are of three kinds, astrocytes, oligodendrocytes and microglia The microglia appear to have a phagocytic role since they wander into the central nervous system from the meninges and blood vessels, and increase in number during inflammatory processes The astrocytes are found surrounding blood vessels and are thought by some to make up the blood-brain barrier Evidence has been obtained that the oligodendroglia are involved in the formation of the myelin layers around axons within the central nervous system Since it has been shown that the extracellular space of the central nervous system is very small, the glia appear to have permeability properties which enables them to function as a special kind of extracellular "space "

DEGENERATION AND REGENERATION OF NERVE

When a peripheral nerve is cut, the part of the nerve separated from the cell body shows a series of chemical and physical degenerative changes At the same time the fibers of the proximal stump of the nerve, those still attached to their cell bodies, grow distally toward the separated part of the nerve, these changes constitute the process of regeneration (Fig 1 23)

Degeneration. The degenerative period may be divided into an early and late phase Shortly after the nerve has been sectioned, the axis cylinder swells, the myelin sheath begins to form beadlike structures and a series of enlargements (round, fatty fragments) appear)The axon breaks up and its parts are devoured by macrophages. Up to 3 days after section, the distal nerve will continue to conduct an impulse. Changes in the action potential can be observed as early as 2 days after section After the 3rd day, the ability of the nerve to conduct has seriously deteriorated and after the 5th day, an impulse can no longer be evoked.)The first period (3 to 5 days) is one in which the obvious changes in nerve are largely structural Changes in the ultrastructure of the myelin sheath can be shown to occur during this period, as well as

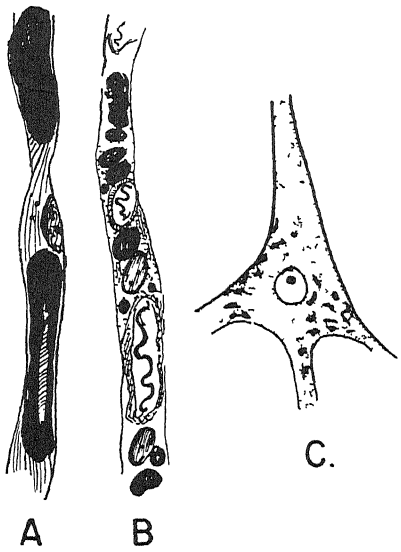

Fig 1 23 Degenerating nerve stained with osmic acid *A* shows appearance of distal segment of nerve fiber 2 days after section note large masses of myelin derived from medullary sheath *B* 5 days after section smaller myelin particles together with droplets of fatty acids and fragmented neurofibrils *C* retrograde degeneration in cell body disintegration of Nissl bodies

changes in the endoplasmic reticulum, mitochondria, neurofibrils, and the plasma membrane

Up to the 8th day, little or no changes in lipid histochemistry may be detected, although changes in nerve cholinesterase and failure in the ability to synthesize acetylcholine have been demonstrated about the 3rd day The lipids appear to maintain their original chemical structure From the 8th to the 32nd day after section, the myelin gradually disappears, while Schwann cells and macrophages have both increased greatly in number Why the myelin breaks down is not clear It has been suggested that the macrophages and Schwann cells secrete enzymes which aid in the destruction of myelin The principal myelin lipids are free cholesterol, and two lipids containing sphingosine cerebroside and sphingomyelin) At the time of the disappearance of the myelin, cholesterol esters appear in large quantities and free cholesterol disappears

The changes just described are generally known as Wallerian degeneration In addition there are other changes that occur in the neuron on the proximal side of the section (retrograde degeneration) The nerve fiber as far centrally as the first node of Ranvier shows changes similar in nature to those just described In the cell body itself swelling of the cytoplasm and nucleus occurs and the Nissl granules undergo disintegration (chromatolysis) Atrophy of the cell body may ultimately result

Regeneration. Following section of a nerve, the fibers in the central stump begin to send out branches consisting of outgrowths of the axon near the cut tip Up to 50 branches may sprout from a cut axon At the same time, there is a rapid proliferation of the Schwann cells If a gap larger than 3 mm exists between the central and peripheral stumps, the fibers tend to intermesh and form a tumor-like swelling called a neuroma In such an event regeneration will probably never occur For this reason it is necessary to join accurately by suture the proximal and peripheral stumps If the neuroma is composed of sensory fibers it may be very painful to pressure, often a troublesome complication following amputation When peripheral degeneration has proceeded for enough time so that the peripheral stump contains only empty neurilemmal tubes, one of the outgrowing sprouts enters a tube and grows to form a new axon Only one of the many sprouts enters an empty tube The ability of axons to grow into a peripheral stump has led some observers to invoke a special chemical attraction between the nerve fiber and the terminal organ This is the doctrine of neurotropism No direct evidence exists for such an attractive force

The rate of growth of regenerating nerve is from 1 to 4 mm /day It has been established, in a variety of experiments, that there is a flow of axoplasm down the normal nerve at about the same rate This axoplasmic flow is accompanied by the movement of protein and nucleoprotein However, it is not known what role axoplasmic flow has in the regeneration of nerve

Principles of Bioelectricity

It will be recalled that the practical unit for quantitation of charge is the coulomb which equals $6\,2 \times 10^{17}$ electrons. A positive charge results from the removal of electrons from a neutral body, as when one electron is removed from the neutral sodium atom to form a sodium ion

An electric field exists in the space around a charge and extends to infinity The strength of this field is measured by the force which would

be exerted on a unit positive charge placed at a point in the field The intensity of the field decreases inversely as the square of the distance from the charge (Coulomb's Law) In order to move a charge in the field, work must be performed against the field Thus, it takes work to move a positive charge up to a region where another positive charge is situated and the potential at any point in the field is defined as the work that must be done on a unit positive charge to move it up to that point from an infinite distance This is the absolute definition of potential which is seldom necessary in practice The significant quantity in experimental work is the difference in potential between two points which is defined as the work necessary to move a unit charge from one point to the other The work is measured in joules The practical unit of potential difference is the volt, i e the potential difference against which 1 joule of work is done in the transfer of 1 coulomb

THE ORIGIN OF POTENTIALS

A difference in potential is associated with a flow of current in a medium (e g , electrons in metal conductors and charge-carrying ions in solutions of electrolytes) The current flow requires energy since it encounters resistance in the medium The relationship between E, the potential difference (in volts), I, the current (in amperes which is the same as coulombs per second) and R, the resistance (in ohms), is given by Ohm's law as follows, $E = IR$ In order to produce electrical currents, special sources of electrical energy are available such as the battery and generator Such sources of energy are said to produce an electromotive force or emf In solutions, electrical energy is produced by chemical reactions which result in the separation of charge at electrodes Other sources of energy produce separation of charge by the flow of ions from solutions of high concentration into solutions of lower concentration, such separation of charge itself constituting a form of stored energy which is manifest as a difference in electrical potential

Two sources of energy are important in understanding the origin of biological potentials, these sources give rise to emfs called *electrode* or *concentration* potentials and *diffusion* or *membrane* potentials. Concentration potentials arise in every measurement of potential difference in solution and are generally to be avoided in biological measurements They arise whenever an electrode consisting of an electrolytic salt is dipped into a solution containing an ion in common with the electrode Thus, an electrode made of silver and coated with silver chloride inserted into a solution of sodium chloride will produce a potential difference between the electrode and the solution The silver dissolves in the solution as silver ion, Ag^+, leaving the electrode negative The positive Ag^+ ion remains at the electrode, forming a double layer of charge with the negative electrode Charge is therefore separated at the electrodes If two such electrodes are set up, each dipping into a different concentration of sodium chloride (a concentration cell) double layers will be set up at each electrode, but the double layer at one electrode will be more densely charged When two such electrodes are connected by a wire, a current will flow The emf produced between the two electrodes can be calculated from the Nernst equation for the concentration cell,

$$E = 2\,303\,(RT/F)\log\,(C_1/C_2)$$

where the electrolyte is univalent R is the gas constant (1 99 cal /mole/°C), T the absolute temperature (°K), F the Faraday, (23,050 cal /v /mole, 96,494 coul /mole), C_1 and C_2 are the concentrations of electrolyte in each solution Note, that according to the formula if the concentrations are equal in each solution, the emf is zero The method of producing a concentration cell is shown in Figure 1 24

Diffusion Potentials. Let us place two solutions containing different amounts of NaCl in contact by means of membrane freely permeable to the electrolyte An emf whose origin is quite different from that of the electrode potentials we have discussed will arise at the membrane The potential difference arises from the

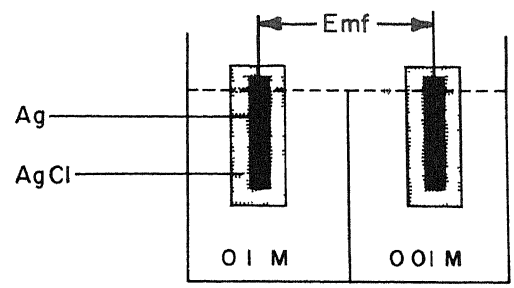

Fig 1 24 A concentration cell Both solutions contain sodium chloride The partition between the compartments is freely permeable to water and salt

diffusion of ions across the membrane or at any junction between such solutions They are therefore called *diffusion*, *membrane* or *junction* potentials The sodium chloride in the solution near the membrane tends to diffuse across into the other solution, the sodium ion diffusing faster than the chloride ion The emf at the membrane depends upon the rates (mobilities) at which the sodium and chloride ions move and the relative concentration of sodium chloride Since Na^+ diffuses faster than Cl^-, a separation of charge is produced, the solution into which a net flow of Na^+ occurs becoming positive At biological membranes, somewhat special hindrances to the movement of ions are present Potassium and chloride usually diffuse at the same rate in solution, however, the ability of chloride to move across the cell membrane is more limited than that of potassium Under these circumstances, potassium diffuses ahead of chloride and an excess of potassium ions appears on one side of the membrane Although the excess is small, it is sufficient to set up an emf or potential difference so that the solution containing the lesser concentration of potassium chloride becomes positive to that containing the higher concentration There is, in effect, a greater loss of potassium from the more concentrated to the less concentrated solution The more concentrated solution becomes negative since it has lost positive charge The concentration of K^+ increases until the emf has become sufficiently negative to keep any further K^+ from diffusing across the membrane The diffusion potential at a membrane is given by a formula similar to the Nernst equation in which the latter has been modified to take into account the mobilities of the ions The equation is

$$E = [(u - v)/(u + v)]\ 2\,303\ (RT/F) \log (C_1/C_2)$$

where the electrolyte is univalent, u and v are the mobilities of the cation and anion respectively, i e , the rates at which the ions move under unit field strength in solution The remaining symbols are the same as those in the Nernst equation Note that when the anion and cation mobilities are equal, $u = v$, and the emf is zero

Transmembrane Potential In recent years, methods have been developed for measuring the potential difference across the cell membrane at rest and during the activity associated with impulse generation and propagation In some cells, such as the giant axon of the squid it is possible to insert an electrode into the body of the axon down its length and by placing another electrode outside the cell to measure the transmembrane potential directly In other cells, where this technique is not feasible, another method is used A glass capillary is drawn out to a fine tip less than 1 μ in diameter The capillary is filled with saturated KCl or NaCl and serves as a microelectrode It is inserted directly into the soma, muscle fiber or even peripheral nerve fiber The potential difference is measured between the microelectrode and a large nonpolarizable electrode (connected via a KCl bridge) located outside the cell, this is the transmembrane potential Such a method always involves the possibility that the injury caused by the puncture will result in a gradual fall in the potential and death of the cell The membrane potentials of a variety of cells are shown in Table 1 4, they range from 61 to 94 mv with the cell interior negative in relation to the external medium

THEORY OF THE MEMBRANE POTENTIAL

The original theory of the membrane potential, largely valid today in broad outline, was first enunciated by Bernstein (1912) at the turn of this century It is well known that the concentration of potassium is much higher inside cells than outside Table 1 5 gives the value of the ratio of inside to outside concentrations for potassium and other important ions in various tissues The ratios for K^+ vary from 23 to 68 Bernstein maintained that the membrane potential was the result of the outward diffusion

Table 1 4

of potassium ions from the cells Since the resting potential is a diffusion potential in which the mobility of the chloride anion was taken as zero and sodium was also presumed to be unable to penetrate the cell, the magnitude of the membrane potential can be calculated from the formula for the diffusion potential in which v 0 The formula reduces to that of Nernst,

$$E \quad 2\ 3\,(RT/F)\log\,(K_{\text{outside}}/K_{\text{inside}})$$

Partial verification for this theory has been obtained by Hodgkin and Huxley (1952b) in several experiments in which the external potassium concentration was varied and resting potential of the squid axon measured It was shown that the resting potential varied directly with the logarithm of the external concentration of potassium over a wide range Table 1 5 shows that the sodium is largely present outside cells The resting potential, V_r, was shown to be independent of the external sodium concentration, $[Na_{outside}]$, in a series of experiments on the squid axon in which $[Na_{outside}]$ was varied over a wide range with no effect on V_r Similar findings have been encountered in experiments on frog cardiac and skeletal muscle

IONIC DISTRIBUTIONS AND THE MEMBRANE POTENTIAL

If no other ion but potassium could penetrate the membrane, the membrane potential would, as noted above, be given by the equation for a diffusion potential in which the anion mobility is zero The resulting equation is then equal to the Nernst equation for a concentration cell Actually, however, potassium does not pass through the membrane alone, there is always some flux of the sodium and chloride ions Two schemes for the membrane potential have been proposed to take into account the flow through the membrane of ions in addition to potassium These are the Goldman equation and the Hodgkin-Huxley equivalent circuit for the resting membrane Tests of these equations are usually made by plotting the membrane potential against the external potassium concentration and observing how closely the equations agree with the experimentally derived curve All the equations, the Nernst relation included, are satisfactory over some range of potassium concentrations .

In order to understand the derivation and significance of the Nernst equation, let us con-

sider the problem of moving an ion in a solution in which a potential difference is present Work must be done with or against two forces, the electrical field, and any concentration difference in the ions Thus, both "electrical" and "concentration" work must be performed The electrical work (in joules) necessary to move 1 mole of a univalent ion (i e , one equivalent) against a potential difference, E (in volts), is given by the expression work = FE, where F is the Faraday (96,494 coul /mole) The concentration work required to move a mole of ion from a concentration C_1 to a higher concentration C_2 is given by the expression work = 2 303 RT log C_2/C_1 where R is the gas constant and T the absolute temperature The total work is given by the sum of the electrical and the concentration work, or work = FE + 2 303 RT log C_2/C_1 When the system is at equilibrium, the work required is zero (this is the definition of thermodynamic equilibrium) and the potential difference is given by the Nernst equation,

$$E = 2\,303\,(RT/F)\log(C_1/C_2)$$

The physical interpretation of this equation is that the tendency of an ion to diffuse down its concentration gradient is countered by the buildup of an electric field at the junction of the two solutions The direction of the field is such as to hold back the ion from further movement Note also that it is only necessary to move a very minute number of ions in order to produce the restraint required to obtain equilibrium of electric and concentration gradients As an example of an application of the Nernst equation, we calculate the transmembrane potential difference which might exist in frog muscle on the assumption that the muscle cell membrane is permeable only to K^+ The internal concentration of potassium is 155 mEq /liter, the external concentration is 4 mEq /liter Substituting these values into the Nernst equation at a temperature of 27° C, we obtain for the potential difference,

$$E = (2.303\ (8\ 2)\ (300)/96{,}500)\log(4/155)$$

$$= -95 \text{ mv}$$

The Goldman equation will not be derived here However, in the derivation, the assumptions are made that the total flow of current through the membrane is zero, that is, that the flow of negative charges is equal to the flow of positive charges, and also that the drop in potential across the membrane is linear Using these assumptions it can be shown that the resting potential will be given by the relation

$$E = 2.303\,\frac{RT}{F}\log\frac{P_K C'_K + P_{Na} C'_{Na} + P_{Cl} C_{Cl}}{P_K C_K + P_{Na} C_{Na} + P_{Cl} C'_{Cl}}$$

In this equation R, T, and F have their usual significance P represents the permeability of the membrane to the ion and the superscript '0' above the concentration i e C' represents the concentration outside the cell, the unlabeled C, the concentration within the cell When the permeabilities to Na^+ and Cl^- are taken to be zero, the equation reduces to the Nernst equation If permeabilities are assumed to have the ratio $P_K : P_{Na} : P_{Cl} = 1 : 0.01 : 0.45$ the emf of the membrane as given by the equation agrees rather well with the value measured in the squid axon, and the resting membrane potential agrees well with the calculated value over a more than 50-fold variation of concentration of external potassium

The Hodgkin-Huxley equivalent circuit constitutes a third approach to the analysis of the nerve cell membrane potential The membrane is assumed to contain separate channels through which each of the ions pass without interference from the others The total electrical current flow through the membrane is again assumed to be zero Each ion, in passing through its channel, encounters resistance to its movement through the membrane Three such channels are shown, one for Na^+, K^+, and Cl^- (Fig 1 25), each is represented by a battery (equilibrium potential) whose emf is calculated from the Nernst relation and whose opposition to current flow is shown as an electrical resistance Often the reciprocal of resistance, the conductance (g), is used to represent the channel permeability If the total current from the membrane is zero, it can be shown that the membrane potential, E, resulting from the three emfs in parallel is given by the equation

$$E = \frac{E_K g_K + E_{Na} g_{Na} + E_{Cl} g_{Cl}}{g_{Na} + g_K + g_{Cl}}$$

The g's represent the conductance of the membrane, they correspond approximately to the permeabilities to each ion. The emfs are the equilibrium potentials for each ion Thus, in frog muscle the equilibrium potential for potassium is −95 mv , for sodium +65 mv , and for chloride −95 mv , values which have been cal-

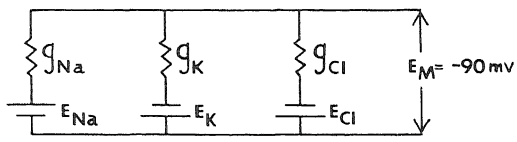

Fig 1 25 The Hodgkin-Huxley equivalent circuit for the membrane The symbols *E* represent the equilibrium potentials as determined for each ion from the Nernst equation The symbol *q* represents the conductance of each ion

culated for each ion from the Nernst equation and the concentration of ions inside and outside the cell Assuming further that the potassium conductance is 100 times greater than the Na and Cl conductances (i e , that $g_K = 100\ g_{Na} = 100\ g_{Cl}$), which is approximately true for frog muscle, we obtain for the emf across the membrane,

$$\frac{-95(g) + 65(g/100) + (-90)\,(g/100)}{g + g/100 + g/100}$$

or −95 mv , a value very close to the actual membrane potential The Hodgkin-Huxley equivalent circuit will prove very important in discussing the mechanism of the action potential in later sections

Excitability and Conductivity of the Nerve Fiber

The generation and transmission of a nerve impulse involves two conceptually independent but operationally related processes, excitation and conduction

When a nerve is stimulated, electrical events which are not propagated occur in the membrane in the vicinity of the electrodes If the local events have particular characteristics (described below), the membrane potential undergoes an abrupt change, termed the *action potential*, which is self-propagated along the axon Excitation refers to the events leading to the generation of an action potential, conduction refers to the propagation of the action potential which proceeds away from the site of excitation, much as a wave travels in a taut string It is fundamental that nerve may be excited anywhere along its length and propagation is away from the point of stimulation in both directions However, when a junction (synapse) intervenes between nerve fibers in the mammalian nervous system, then propagation can only continue in one direction Experimentally many different kinds of stimuli (electrical, thermal, mechanical, chemical) may be utilized to excite nerve or muscle, however, all of those stimuli operate by depolarizing the nerve fiber Since electrical stimuli of any intensity, shape (wave form) and duration may be easily pro duced both accurately and repetitively, this form of stimulation is used universally to study the phenomena of excitation and propagation Moreover, the nerve impulse is electrical in nature and many of its effects as an excitatory agent can be simulated by the electrical stimulus

CHARACTERISTICS OF THE STIMULUS

Nerve responds to electrical stimulation provided that the electrical stimulus fulfills certain specific criteria It must be of sufficient *intensity* and *duration* to reduce the transmembrane potential from its resting value to a critical voltage which, when achieved, results in the development of a propagated impulse This reduction in membrane potential is termed *depolarization*, and the critical voltage required for impulse propagation is termed the *threshold voltage* or *critical firing potential* The relationship between the intensity and duration of the initial stimulus is further discussed below A current just adequate to cause an impulse is called a *threshold* stimulus Intensities below threshold are referred to as *subliminal* Thresholds vary only slightly if the temperature and external ionic composition are maintained constant

Another characteristic of the stimulus is its rate of rise If the current is increased too slowly the nerve will not respond Figure 1 26 shows two linearly rising currents one of which is able to reach threshold The other current rises too slowly and the nerve is able to accommodate to the passage of the current *Accommodation*, therefore, consists of a rise in threshold of the tissue during stimulation To minimize accommodation, it is convenient to employ stimulus currents which rise extremely rapidly Two such stimuli are shown in Figure 1 27, the square wave and the exponential pulse

Even the rapidly rising pulses of Figure 1 27, if too short in duration would not result in an impulse The two properties, intensity and duration obviously interact and it is therefore

important to be aware of the relationship between the threshold stimulus intensity and the duration of the stimulus—the *strength-duration* relationship

For this purpose, the following kind of experiment is usually performed A stimulus of a fixed duration, e g , 1 msec , is applied to a nerve through two electrodes one of which is the cathode (−), the other the anode (+) The threshold stimulus is determined by increasing the current until a response is obtained—at the particular duration selected A series of other durations are selected and the thresholds determined The thresholds obtained at each duration are plotted as a function of the duration The curve so obtained is called the strength-duration relationship for nerve (Fig 1 28)

The curve is accurately described over most of its course by the empirical relationship $I = I_0 (1 - e^{-kt})^{-1}$, where I_0 and k are constants, t is the stimulus duration and I the threshold current For short durations, in which accommodation is presumably slight the relation is approximated by the equation, It = constant

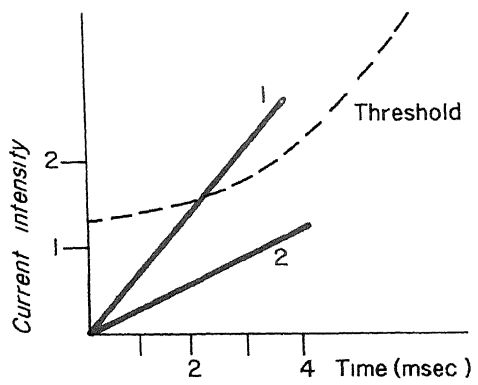

Fig 1 26 A schematic representation of the effect of rate of rise of current Curves 1 and 2 represent two stimuli with different rates of rise Stimulus 2 never reaches threshold (dashed line) Stimulus 1 attains threshold

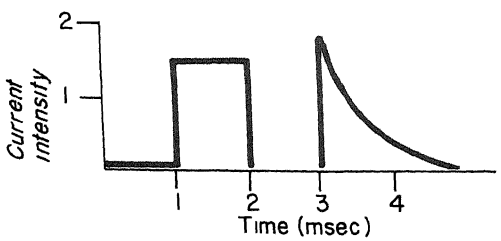

Fig 1 27 Two commonly used stimuli a rectangular pulse (*left*) and an exponential pulse (*right*)

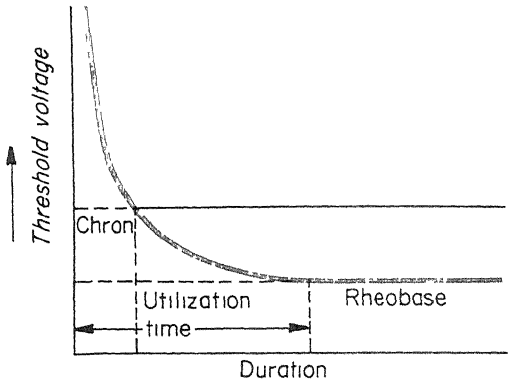

Fig 1 28 Strength duration curve *chron* chronaxie

This relationship may be interpreted as follows The current I is the charge per unit time which is placed on the membrane in a time t The product of the current and time, is therefore equivalent to a constant charge The equation implies that a critical amount of charge must be placed on the membrane, whatever the current or duration

What is the meaning of this critical amount of charge? Placing a charge on the membrane by an appropriately oriented stimulus current reduces the net charge on the membrane, i e , part of the charge on the membrane is neutralized Such a partial neutralization of charge is equivalent to a *depolarization* of the membrane, i e , to a reduction in the membrane potential from its resting negative value toward 0 Increased polarization or *hyperpolarization* results in an increase in the membrane potential, i e , increasing negativity Depolarization decreases the stability of the membrane, hyperpolarization increases its stability

A feature of excitation discovered quite early was the fact that the nerve impulse originated at the cathodal stimulating electrode, i e , at the negative stimulating electrode Figure 1 29 illustrates the lines of current that flow into and out of the electrodes At the cathode, the current flows outward through the membrane, at the anode, where current is flowing inward, excitation is hindered Continuous current flowing into the nerve depolarizes the membrane in the vicinity of the cathode and hyperpolarizes it in the vicinity of the anode Thus, it is easier to stimulate a nerve in the vicinity of the cathode because the membrane potential has been lowered, conversely, at the anode, the membrane potential is increased and higher currents are required to excite the underlying

tissue These effects of direct current on the excitability of nerve and muscle are referred to as electrotonic phenomena, the depolarization at the cathode is referred to as *catelectrotonus*, and the hyperpolarization at the anode *anelectrotonus*

SUMMATION AND THE LOCAL EXCITATORY STATE

The application of a brief subthreshold stimulus has a residual effect on nerve even though an impulse is not elicited This residual effect is revealed by the fact that the application of a second subthreshold stimulus within a millisecond can elicit a response The longer the interval between the two stimuli, the more intense the second stimulus must be to yield a response The important point, however, is the fact that two subthreshold stimuli can sum their effect on the nerve membrane so that a response is evoked The interpretation of this experiment is that the first subthreshold stimulus produces a change in the membrane potential which lasts for a millisecond or more and that this change facilitates the effect of a second stimulus The change in the membrane caused by the first stimulus is referred to as the "local excitatory state" in the vicinity of the electrode It is a nonpropagated response of the membrane which is associated with the depolarization of the membrane in the region of the cathode (see below)

The Local Excitatory State. The experiments on subthreshold summation and the electrotonic properties of nerve led to the expectation that the membrane potential should be decreased in the vicinity of the cathode, and indeed, this expectation has been affirmed by direct experiments in which the changes in membrane potential were measured in the vicinity of the cathode and anode

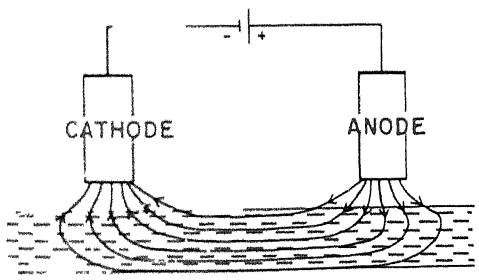

Fig 1.29 Illustrating the passage of direct current through tissue Anode is defined as the electrode which sends current *into* tissue

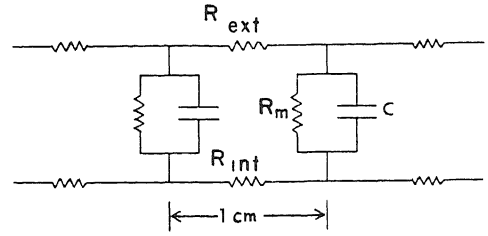

Fig 1 30 Equivalent circuit of a nerve (radius 1 μ) considered as an electric cable R_{ext} is the resistance of 1 cm of the external medium generally low R_{int} is the resistance of 1 cm of the internal axoplasm ($10^7\ \Omega$) and R_m is the resistance of 1 cm of the membrane to radial currents—of the order of $10^{10}\Omega$ The capacity C is 10^{-7} μfd for 1 cm of nerve

It is necessary first to consider the purely passive changes in the membrane potential which result from the fact that nerve has the properties of an electric cable, namely electrical resistance and capacitance (the ability to store charge) The capacitance, C, is defined as the charge, Q, which must be placed on two surfaces in order to produce a unit potential difference, V, between them ($C = Q/V$) The units of C are farads when Q is expressed in coulombs and V in volts The capacitance of the nerve membrane is 1 μf /cm ^{2}

For each unit length of nerve, there is also an external electrical resistance and an internal cytoplasmic resistance The membrane resistance constitutes a third electrical resistance Each unit length of nerve may be considered as an electrical cable (Fig 1 30) consisting of these resistances and a condenser (the capacitance) If a stimulating current is passed through a section of nerve, its condensers will charge but the most distant ones will be least charged since more external and internal resistance is included between them and the source of current If one were to measure the charging process at any moment, the voltage would be highest at the electrodes and would decrease exponentially as one proceeded away from the stimulating electrodes (Fig 1 31) This charging process is almost instantaneous and represents a nonpropagated buildup of charge along the nerve It extends for some distance along the nerve but it is never propagated as a wave

When nerve is stimulated, two electrical events take place The membrane charges passively as a cable and, at the same time, the nerve begins to react physiologically at the cathode Events at the anode are purely passive

and since excitation does not occur there, the time course of charging at the anode may be taken as that for the passive or physical charging of nerve At the cathode, passive charging occurs and, in addition, an active process which we have called the local excitatory process If the passive process at the cathode is subtracted graphically from the overall recorded response, the local excitatory process should be obtained The passive physical process at the anode and cathode are proportional to the stimulating current In order to measure the local responses, an experiment is performed in which the potential difference between electrodes placed at the anode and cathode is measured with respect to a distant electrode Figure 1 32 shows the results of the potential measurements and also the result of subtracting the passive response from the overall response to obtain the local potential which corresponds to an active, nonlinear process at the electrode

The significance of the local potential is that it demonstrates the time course of the depolarization at the cathode When the depolarization at this electrode reaches a critical value an action potential will be initiated which will propagate away from the electrode Such local responses can be found in many tissues For example, receptors must be depolarized before they give rise to an action potential, the potential representing the local excitatory state of the receptor is called the generator potential An active process also occurs at the neuromuscular end-plate which is called the end-plate potential, this depolarization initiates the propagated action potential of muscle At the synapses of neurons, a local, nonpropagated potential called the excitatory postsynaptic potential (EPSP) may be recorded which gives rise to the nerve impulse of the neuron The critical event in the excitation of all these cells is the local, nonpropagated depolarization When this depolarization reaches threshold magnitude, the explosive, propagated change in membrane potential called the nerve impulse or action potential is set off

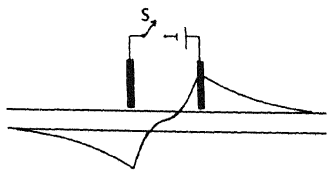

Fig 1 31 Illustrating the passive electrotonic potential along the nerve resulting from the passage of direct current into the nerve

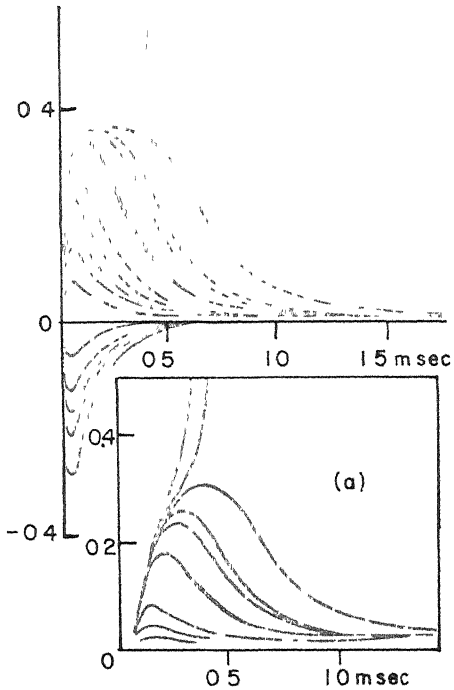

Fig 1 32 Electrical changes at stimulating electrode produced by shocks with relative strengths successively from above 1 00 (upper 6 curves), 0 96 0 85 0 71 0 57 0 43 0 21 0 21, 0 43 0 57 0 71 1 00 The ordinate scale gives the potential as a fraction of the propagated spike which was about 40 mv in amplitude The 0 96 curve is thicker than the others, because the local response has begun to fluctuate very slightly at this strength The width of the line indicates the extent of fluctuation (Inset) Responses produced by shocks with strengths, successively from above, 1 00 (upper 5 curves) 0 96 0 85 0 71 0 57 obtained from curves in upper figure by subtracting anodic changes from corresponding cathodic curves Ordinate as above (From Hodgkin, 1939)

The Nerve Impulse

RECORDING THE ACTION POTENTIAL

The external recorded action potential may be obtained by stimulating a nerve at one end and picking up the responses of the nerve some distance away with two recording electrodes and a recording device Figure 1 33 shows the arrangement by which the action potential of nerve is usually recorded with a cathode ray oscilloscope. Unlike any instrument previously employed for this purpose (e g., the string gal-

vanometer or the capillary electrometer) the moving part of the oscilloscope is a stream of electrons and consequently has virtually no mass, and thus, no inertia It is, therefore, capable of recording very rapid changes in electrical potential The instrument consists of an evacuated tube, an electron stream from a hot cathode strikes a fluorescent screen upon which it produces a spot of light On either side of the electron stream is placed a vertical plate A potential difference is created between the pair of plates, the electric field set up across the path of the stream deflects it horizontally, and sweeps it across the screen The spot of light is converted into a horizontal streak By means of a sweep oscillator the horizontal deflections are repeated many times per second A second pair of horizontal plates is placed one above, the other below, the electron stream It is this latter set of plates into which the nerve action potential is fed so that a vertical deflection of the electron stream results with production of a standing wave which is photographed and a

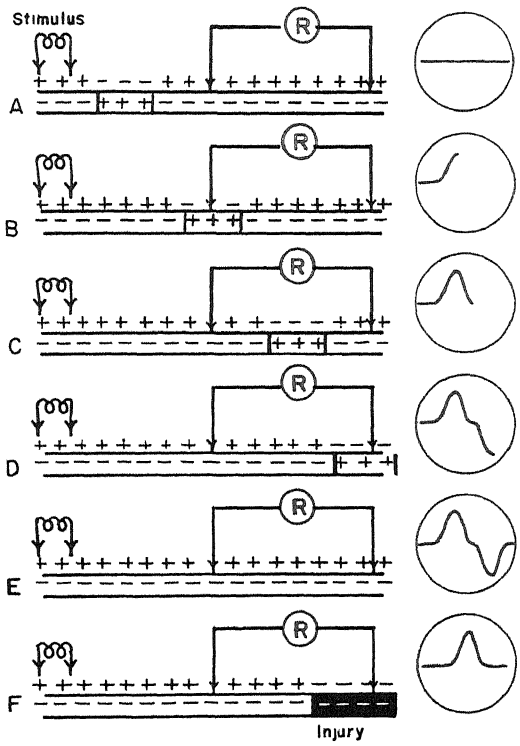

Fig 1 33 Passage of action potential down a nerve Stimulus is applied at left Cathode ray oscilloscope is indicated at *R* The recorded potential is shown at the face of the cathode ray oscilloscope at the extreme right of each figure A monophasic potential is shown in figure *F*

permanent record thus obtained The speed of the horizontal movement of the spot of light enables the time scale to be calculated, this can be varied by altering the potential applied to the horizontal pair of plates The magnitude of the action potential is determined from the height of the wave Before reaching the recording system the action current is amplified several thousand times by passing it through an amplifier This is necessary because the electron stream requires about 50 v to cause a deflection of 1 cm on the face of the tube

The response on the cathode ray oscilloscope shows up as a diphasic variation of potential The cathode ray oscilloscope records the potential under one recording electrode as a function of time with respect to the other recording electrode When the nerve is stimulated, an electrical impulse is generated which travels along the fiber The arrival of this impulse at the first electrode causes the oscilloscope beam to deflect in one direction When the impulse passes between the electrodes, no recorded potential is observed But when the impulse reaches the second electrode, a potential is recorded which is opposite in polarity to the first and accordingly, causes the oscilloscope beam to deflect in the opposite direction We, therefore, say that there are two phases present in the recorded action potential It is quite clear that one can eliminate the second phase from the recording by preventing the negativity of the impulse from reaching the second electrode This can be done by crushing the nerve either in the region between the two electrodes or directly under the second electrode Of course, if the crush is at the first electrode, no potential will be recorded at all, since the action potential cannot pass a dead region of nerve The potential recorded when the nerve is crushed at the second electrode is called a monophasic potential and is shown also in the accompanying figure (Fig 1 33F)

The Compound Nature of the Action Current Recorded from a Nerve Trunk. Erlanger and Gasser (1937) studied the action potential of mixed nerve trunks by means of the cathode ray oscillograph. They showed that the recorded "spike" is actually compounded of the individual spikes of many axons which were classified into three main types of nerve fiber—referred to as the A, B, and C groups (Fig 1 34). Several properties of nerve are correlated with the diameters of the fibers the larger the

fiber diameter, the greater the conduction velocity, the greater the magnitude of electrical response, the lower the threshold of excitation and the shorter the duration of response and the refractory period The relationship of conduction velocity to diameter of the nerve fiber is a linear one (Fig 1 35) The amplitude of the externally recorded potential is also linearly related to the fiber diameter

The A group is composed of the largest fibers, 1 to 20 μ in diameter, with conduction rates from 5 m /sec or less for the smallest fiber to 100 m /sec for the largest The fibers of the A group are all myelinated, are both sensory and motor in function, and are found in such somatic nerves as the sciatic and saphenous nerves

The B fibers are myelinated and have diameters from 1 to 3 μ, and conduction velocities from about 3 m /sec to 14 m /sec The B fibers are found solely in preganglionic autonomic nerves The C group, composed of the smallest fibers (less than 1 μ in diameter), are unmyelinated and have a conduction rate of around 2 m /sec or less, many are found in cutaneous and visceral nerves They have a high threshold, 30-fold that of the A group The A group of fibers make by far the greatest contribution to the compound action potential, and the C group the least The electrical potentials recorded from both A and C fibers exhibit slow variations in potential following the action potential, negative and positive after-potentials, but the B group do not exhibit a negative after-potential with a single response (though a negative after-potential does appear upon repetitive stimulation) The B fibers are the most susceptible to asphyxia, the C fibers, the least so

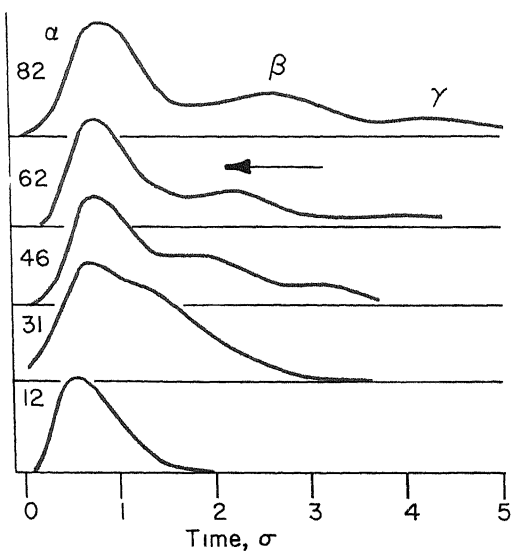

Fig 1 34 Cathode ray oscillograph records of the action currents in the sciatic nerve of the bull-frog after conduction from the point of stimulation through the distances (in millimeters) shown at the left The action potentials might be compared to runners in a race who become separated along the course as the faster contestants outstrip the slower thus in a record at 82 mm from the point of stimulation three waves are shown whereas at 12 mm the potentials are fused and only one large wave appears (Modified from Erlanger Bishop and Gasser)

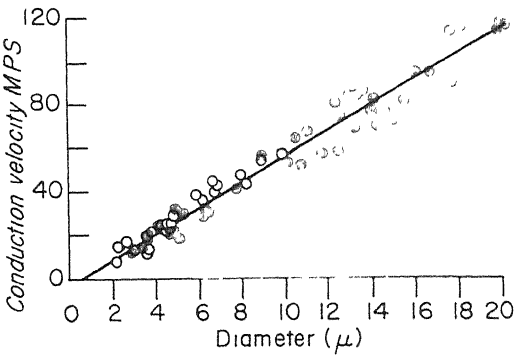

Fig 1 35 Linear relation between diameter and conduction velocity of mammalian nerve fibers Each point represents a determination of the maximum conduction velocity in meters per second and of the diameter in micra of the largest fiber of an individual nerve *Dots* adult nerves *Circles* immature nerves (After Hursh)

The linear relationship between fiber diameter and conduction velocity holds also for growing nerves of young animals During growth the diameters of the nerve fibers enlarge Conduction velocity increases proportionately so that the time taken for an impulse to travel from the toes of a kitten a few days old to the spinal cord is the same as for a full grown cat Thus, the kitten and the cat react to stimulation with about equal promptness

The diameters of the regenerating fibers in a sectioned or crushed nerve also enlarge gradually and conduction velocities increase accordingly, the relationship again being a linear one The maximum conduction velocity is not reached until maximum diameter of the fiber is attained If the axons of the nerve alone are interrupted, the sheaths of the nerve fibers remaining intact, the diameters and conduction velocities may reach those of the normal nerve, this rarely occurs if the nerve has been completely severed

CONDUCTION RATES

The velocity of the nerve impulse varies in different nerve fibers in accordance with their diameters, the thicker fibers conducting more rapidly than the fibers of smaller diameter In the large afferents from muscle spindles of the mammals, the rate is from 80 to 120 m /sec Sensory nerves of the skin being of smaller diameter have slower conduction rates Nonmedullated fibers conduct more slowly than medullated fibers Some of the fibers subserving pain sensation and those of the sympathetic nervous system have a very slow conduction rate

The following table gives the approximate conduction rates in the nerves of several different animals

Medullated nerve, mammal, 37° C 120 m /sec
Medullated nerve, dogfish, 20° C 35 m /sec
Medullated nerve, frog, 20° C 30 m /sec
Nonmedullated nerve, crab, 22° C 1 5 m /sec
Nonmedullated nerve, mammal, 37° C 1 m /sec
Nonmedullated nerve, olfactory of pike 20° C 0 2 m /sec
Nonmedullated nerve, in fishing filament of physalia, 26° C 0 12 m /sec
Nonmedullated nerve, in Anadon 0 05 m /sec
Compare the velocity of sound in air at 0° C 331 m /sec

By an indirect method of measurement the rates of conduction in various human postganglionic sympathetic nerves have been found to be from 0 85 to 2 30 m /sec The lower figures were obtained for the nerves of the leg, the higher ones for the nerves of the chest

Action Currents and Excitation. The externally recorded action potential represents a variation in electrical potential along the nerve An alternative way of looking at the nerve impulse is as a set of currents flowing out of the membrane ahead of the area of greatest depolarization or, more particularly, as the movements of these currents along the nerve (Fig 1 36) The term action current is as appropriate as action potential The advantage of understanding the currents of nerve as well as the potential becomes apparent when one considers how the self-exciting properties of the nerve impulse arise, for it is the currents themselves which act to depolarize the nerve The analogy is often made that the nerve acts like a fuse along which the ignition progresses Action currents leave the nerve ahead of the region of depolarization, acting as a virtual cathode since they have the direction of currents flowing into a cathodal electrode The hypothesis that action currents act to depolarize the region ahead of them was substantiated by experiments in which it was demonstrated that if action currents were allowed to enter but not to excite a region beyond a narcotized stretch of the nerve, then the action currents gave rise to two phenomena beyond the blocked region an increase in excitability and a depolarization of the fiber Neither the increase in excitability nor the depolarization were large enough to set up an impulse, the block diminished the intensity of the currents but it was clear from this experiment that the local currents generated by the action potential (as distinct from the action potential itself) could cause depolarization and, therefore, a change in excitability

Another hypothesis which is a part of the general theory of self-excitation holds that in order for a propagated nerve impulse to be generated, not only is a depolarization necessary, but there must also be an increase in permeability to ions at the depolarized region Thus, depolarization brings about an increased ion flow through the "not yet excited" membrane bordering on the depolarized region In other words, during the action potential a path is opened in the membrane through which the charge from resting membrane can flow Thus, by discharging resting membrane ahead of itself, the action potential becomes self-propagating. Evidence for this characteristic of self-propagating activity was obtained by Curtis and Cole (1938) who showed that there was an increased permeability to ions during activity This was demonstrated as a decrease in transverse resistance of the membrane from a resting value of 1000 Ω/cm^2 to 25 Ω/cm^2 during the rise of the action potential in the squid axon Decreases in membrane resistance have also been demonstrated in other tissues, such as mucle, during propagated activity

THE "ALL-OR-NONE" PRINCIPLE

A stimulus which is just capable of exciting a nerve fiber (threshold stimulus) sets up an impulse which is no different from one set up by a much stronger stimulus The impulse generated by the weak stimulus is conducted just as rapidly and is equal in magnitude to that generated by the strong stimulus when judged by the

action current developed or the mechanical response of the muscle it innervates Thus, the propagated disturbance established in a single nerve fiber cannot be varied by grading the intensity or duration of the stimulus, i e , the nerve fiber under a given set of conditions gives a maximal response or no response at all To make use again of the train of gunpowder analogy—the flame of a match applied to the powder fuse will start a traveling spark no less intense than one started by the flame of a torch The restoration of the strength of the impulse to its original value after passing from a narcotized region into normal nerve also shows the "all-or-none" nature of nervous conduction The well-known fact that a strong stimulus applied to a nerve *trunk* causes a compound action current of greater amplitude, and a greater muscular response than a weaker stimulus is due to the fact that the nerve trunk is composed of many fibers each of which supplies a group of muscle fibers The weak stimulus excites only a proportion of the units of the nerve trunk, whereas, a maximal stimulus excites them all For example, the cutaneous dorsi muscle of the frog is supplied by a nerve which contains only 8 or 9 fibers, each of these innervates about 20 muscle fibers When the nerve was stimulated by shocks of gradually increasing intensity, the muscular responses did not show a similar continuous rise in amplitude, on the contrary the responses of the muscle increased in a series of well-defined steps In other words, increasing the stimulus intensity produced no effect for a time upon the amplitude of the muscular response but then a slight increase in strength of stimulus produced a sudden rise in amplitude The steps which were never greater in number than the number of fibers in the nerve were due to additional fibers becoming excited as the strength of stimulus reached a certain value

It must also be remembered that the "all-or none" principle applies only for the condition of the nerve at the point where, and the moment when, the impulse arises A stimulus which will give rise to a response of a certain magnitude under one condition of the nerve

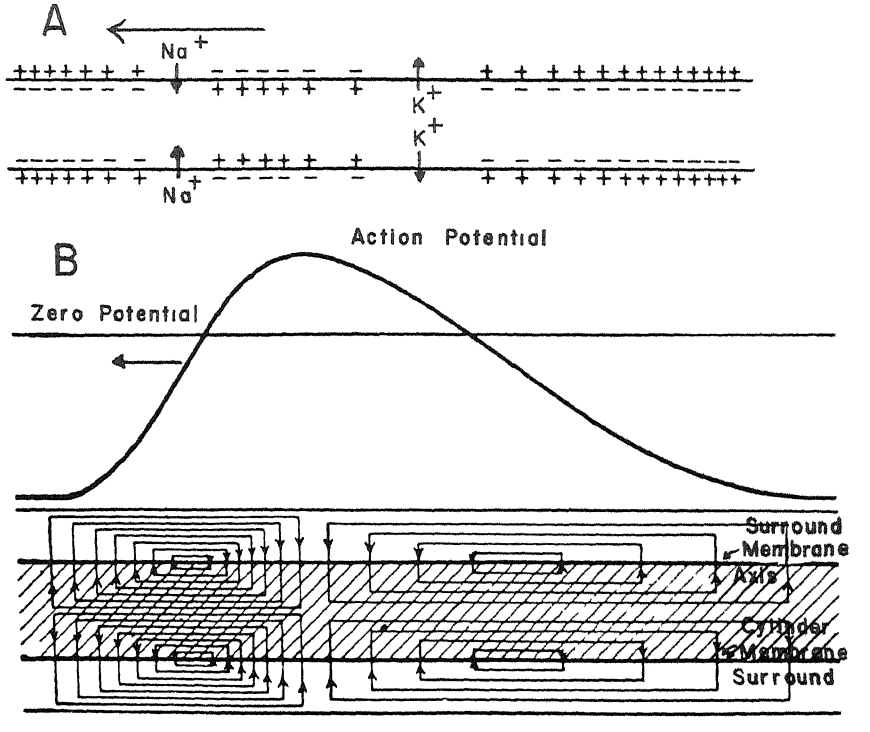

Fig 1 36 *A*) The movement of sodium and potassium during the action potential, travelling in the direction of the arrow The charge in each region is also shown *B*) Upper curve shows the potential distribution of the impulse along the nerve The lower part shows the flow of currents in the external medium and within the fiber There is a reversal of potential during the spike (After Eccles)

may give a much smaller response under other conditions, e g , during the relative refractory period (see below), narcosis, oxygen lack, etc

THE ABSOLUTE AND RELATIVE REFRACTORY PERIODS OF NERVE

For a brief interval following the passage of an impulse along the nerve fiber, a second stimulus, however strong, is unable to evoke a response This interval is called the absolute refractory period In a frog's sciatic nerve at a temperature of about 15° C the absolute refractory period has a duration of between 2 and 3 msec Its duration is roughly the same as the action potential "spike " It is much shorter in mammalian nerve (1 0 to 0 4 msec in large medullated nerve fibers)

The period during which the nerve is absolutely refractory is succeeded by one in which the nerve, though it will not respond to a stimulus of the same strength as it did before the passage of the impulse, will respond to a somewhat stronger one The excitability of the nerve gradually increases and the strength of stimulus necessary for excitation becomes progressively less (Fig 1 37) In the end, the restoration of excitability is complete and the nerve responds to a stimulus of no greater strength than that which is capable of exciting a resting nerve The period following the absolute refractory phase and during which the excitability gradually rises to normal is called the relative refractory period The time required for the excitability of the nerve to return to about 95% of its resting level ranged from 10 to 30 msec (full recovery may not be attained until the lapse of 100 msec) It should be pointed out that the failure of the nerve to conduct a second impulse is not due simply to lowered excitability at the point in the nerve where the original stimulus was applied, for during the absolute refractory period a stimulus applied to any other point upon the nerve likewise fails to set up an impulse The passage of the impulse along the nerve leaves in its wake a change of state in the membrane organization A certain time is required for the changes associated with the passage of the impulse to become reversed and the nerve restored to its resting condition

The refractory period renders a continuous excitatory state of the nerve impossible Fusion or summation of impulses does not occur The refractory period obviously must also set an

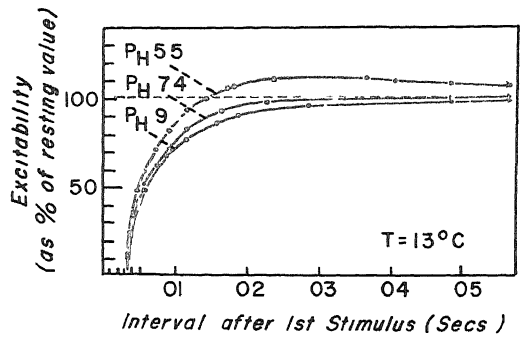

Fig 1 37 Recovery of excitability in nerve perfused with fluids of different pH (After Adrian)

upper limit on the frequency of the impulses In the mammal the absolute refractory period is about 0 5 msec The intervals between impulses cannot be shorter than the absolute refractory period, the maximum impulse frequency is around 1000/sec At this rate the impulses are travelling in the *relative* refractory period of their predecessors and are weaker and more slowly conducted In frog nerve with its refractory period of from 2 to 3 msec , the maximal impulse frequency is between 250 and 300/sec

THE CLASSICAL MECHANISM OF THE ACTION POTENTIAL

The mechanism by which the action potential is produced has not been examined but the role of the currents in exciting a region ahead of the approaching nerve impulse was noted It is now appropriate to consider the origin of the action potential in terms of the prevalent ions, namely, sodium and potassium The resting potential was shown to arise from a diffusion of potassium ions across the cell membrane The action potential has a more complex origin Recent investigations have demonstrated that the action potential results chiefly from the movement of sodium ions into the nerve fiber during the early, rising, part of the nerve impulse and that there is a movement outward of potassium ions, later during the fall of the action potential

At the turn of the century, the action potential was attributed to a complete depolarization of the membrane creating an area more negative than other parts of the nerve into which the ionic currents flowed This concept, first enunciated by Bernstein (1912), could not be tested with the methods and tissues available until 1940 At that time two groups, one in

England, the other in America, performed the critical experiments which led to a re-examination of the Bernstein concept These experiments utilized the giant axon of the squid to make a direct measurement of the transmembrane potential This axon is 0 1 mm or more in diameter so that it is possible to insert one electrode directly into it along its length and to place another electrode outside The resting potential was measured and the nerve stimulated to obtain an action potential The results of such an experiment are illustrated in Figure 1 38 According to the classical concept, the action potential arises from the fall of the membrane potential toward zero, the nerve being completely depolarized when the membrane potential reaches zero In the case of the squid axon instead of a simple depolarization of the membrane, an "overshoot" of the potential past the zero base line was noted Such an overshoot represents a reversal of the potential from the resting state so that during the peak of the action potential, the inside of the cell becomes about 50 to 60 mv positive to the outside (Fig 1 38) This is an astonishing result for, on first consideration, there does not appear to be any mechanism by which the potential difference could invert Bernstein had considered the resting potential a diffusion potential resulting from the permeability of nerve to potassium and the impermeability to sodium and chloride and the electrochemical events during the action potential were attributed to an increased flow of ions other than potassium into the nerve fibers so that the diffusion potential across the membrane disappeared when the sodium and chloride flows were permitted to take place (In a diffusion cell the emf is proportional to the difference of the mobilities of cations and anions and if these are equal, the emf is zero) This hypothesis while showing how the membrane potential could become zero did not appear to contain an explanation of how the reversal might arise

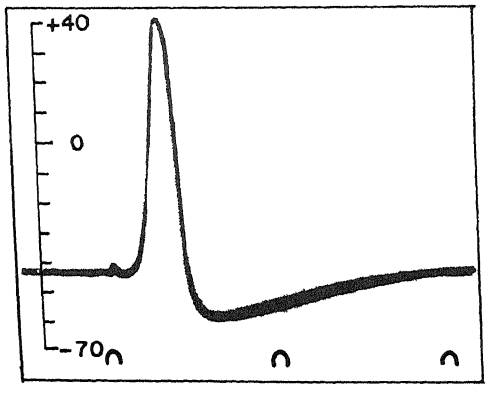

Fig 1 38 Action potential recorded with an internal electrode from a squid giant axon The scale shows the internal potential in millivolts relative to the outside bath Time marks are in 2 msec intervals (After Hodgkin and Huxley)

The Modern Concept of the Action Potential

Closer consideration of the details of ionic flow pointed to sodium as the ion which might give rise to the reversal of potential Since the concentration of sodium is higher outside than inside the nerve a flow of sodium inward would tend to make the inside positive with respect to the outside The experimental result establishing that sodium is the most important cation involved in both the production of the action potential and of the overshoot is simple The squid axon is normally surrounded by sea water osmotically equivalent to a 0 3 M sodium chloride solution If the concentration of the sodium in the sea water is changed so that less sodium is present, the amplitude of the action potential will diminish In such experiments, the resting potential is unaffected by altering the sodium concentration Accordingly it was concluded that sodium is essential to the production of the action potential and, therefore, indirectly of the overshoot Figure 1 39 illustrates the type of result obtained from such substitution experiments Note that in applying half sea water, the osmotic lack of sodium is balanced by substituting an osmotically equivalent amount of a nonelectrolyte such as sucrose or an electrolyte such as choline chloride

A variety of experiments were carried out to determine the dependence of the sodium and potassium ionic currents on the membrane potential Unfortunately, it is not possible to measure one ionic current flow during a depolarization of nerve directly and independently of another The changes in current flow affect the membrane potential which in turn affects the current flow This concept of a mutual influence of current and potential is important for the understanding of the mechanism of the action potential but it is necessary to eliminate the interaction operationally if one wishes to study the effect of a change in membrane potential on the ionic fluxes Such independence

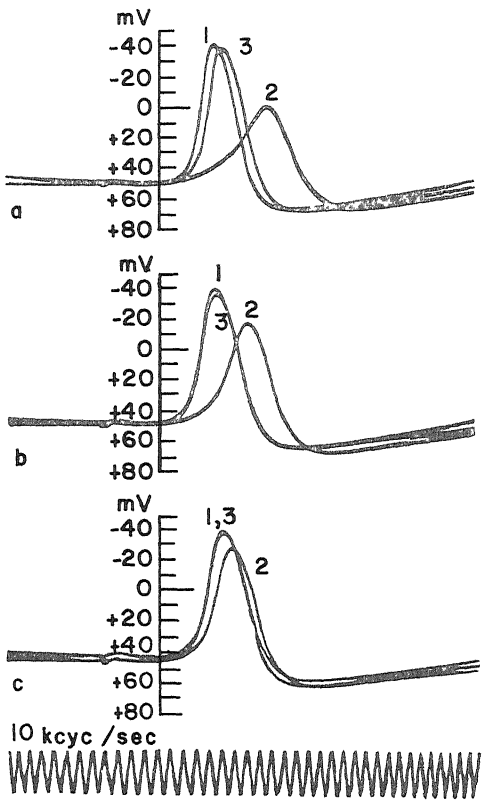

Fig 1 39 Single action potentials recorded from a squid giant axon

1) Normal action potential in sea water

2) Action potential after equilibration in medium with altered sodium *A* is 0 33 times normal *b* is 0 5 times normal and *c* is 0 71 times normal in concentration

3) Action potential after return to normal sodium solu tion

of current and potential is achieved by depolarizing the membrane to a given value and then subsequently maintaining the potential at that value The method is referred to as the *voltage clamp method* because the membrane potential is "clamped" (fixed) at an invariant value Thus, it became possible to investigate the ionic flows resulting from a given step of depolarization Note that once the potential has been clamped there will be no flow of current into the capacitive element of the membrane, since to put charge on a condenser requires a changing potential The current flow is purely resistive and ionic

In such voltage clamp experiments it has been observed that the current may change while the depolarization is being maintained This appears to violate Ohm's law, which states that the current flow in a system depends upon the voltage ($I = E/R$), and the voltage across the membrane is held constant in these experiments The explanation of these findings rests in the fact that the resistance or permeability of the membrane changes during a voltage clamp experiment, and thus, although the potential is constant, extensive changes in current occur

The effect of a small clamp on the current flow through the membrane is shown in Figure 1 40 The depolarizing clamp causes a diphasic current which is first directed inward (into the nerve fiber) and then outward If a solution which lacks sodium is substituted for the outside bath, the initial inward current disappears, but the outward current remains unaffected The early, inward current is, therefore, attributed to sodium inflow The dependence of the sodium current on the amount of depolarization is revealed by the experiments in which progressively greater amounts of depolarization are used (Fig 1 40) As the membrane potential is decreased (greater clamp voltage), the inward current increases With further increases in the depolarization, however, the sodium current decreases in magnitude and ultimately disappears

The results of a brief depolarization or clamp may be outlined as follows *1*) There occurs, initially, a brief inward current resulting from an inward movement of sodium ions, followed by an outward flow of potassium ions *2*) The amount of sodium flowing depends upon the

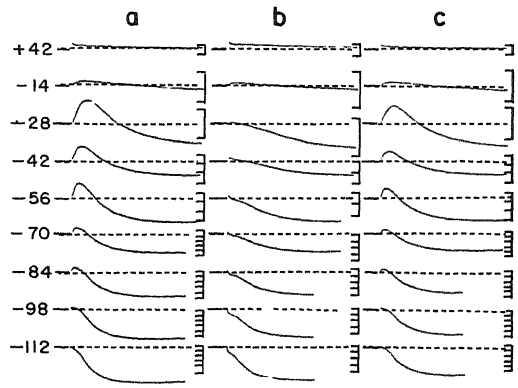

Fig 1 40 Currents flowing through squid giant axon membrane during a steady voltage clamp Figures on left are clamped values of the membrane potential in millivolts relative to resting potential (outside minus inside) Minus values represent depolarizations Columns *a* and *c* axon in sea water Column *b* axon in choline sea water without sodium Vertical scale 1 div = 0 5 ma/cm^2 Time dots are 1 msec apart (After Hodgkin and Huxley)

extent of depolarization, over a rather broad range it is seen that the greater the depolarization, the larger the sodium current .3) The potassium current is relatively unaffected by the depolarization but is greatly affected by a hyperpolarization of the membrane Increasing the membrane potential from, for example, −60 to −80 mv increases the potassium current

To understand the mechanism of the action potential, it is necessary to examine the results of the voltage clamp experiments in terms of a detailed theory—evolved by A Hodgkin (1964) and A F Huxley (1964)—which explains all the known phenomena of excitation and conduction in nerve and muscle According to this theory, the nerve membrane is represented as containing three channels through which sodium, potassium, and chloride ions may move independently The individual ions are forced through the membrane by their electrochemical potential gradients A schematic circuit representing the three channel hypothesis is shown in Figure 1 41 The value of each emf is given by the Nernst equation, the three emf's being equivalent to the three "equilibrium" potentials (as discussed above in the section on the membrane potential) It is important to understand that the network is only an electrical "equivalent" and that the channels are not physically located one next to the other Each of the channels represents a group of many identical channels in a unit area of the membrane

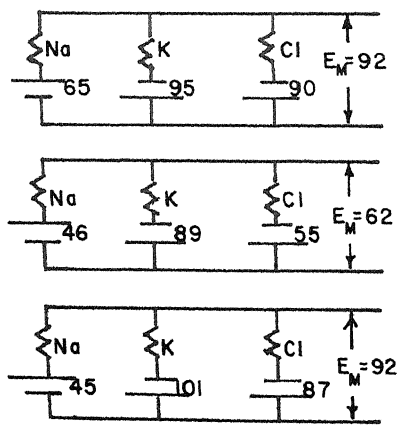

Fig 1 41 Equivalent circuits for three membranes Upper is for mammalian skeletal muscle fiber middle is for squid giant axon and lower is for frog sartorius muscle fiber E_m is resting potential all values are in millivolts

lumped together schematically as one channel The resistance signifies the opposition encountered by each ion in the unit area of membrane The reciprocal of the resistance, the conductance (g), is proportional to the permeability of the membrane to the ion

The sequence of ionic events in an action potential may now be described as follows A depolarizing voltage (stimulus) is applied to the membrane and the sodium influx increases in the direction of its concentration gradient If this Na^+ influx is greater than the flux of potassium and chloride (both of which constitute current flowing in the opposite direction), then the net sodium entry causes a change in the membrane potential But, as noted above, the change in potential across the membrane brings about an increased sodium influx, which in turn leads to a further decrease in the membrane potential Therefore, the influx of sodium builds up quite rapidly This mutual effect of sodium influx and membrane potential constitutes the *regenerative* factor in impulse transmission and is an example of a positive feedback process In terms of the equivalent circuit of Figure 1 41, the action potential develops in the following way The increase in permeability to sodium is essentially a decrease in resistance The potential difference across the membrane, which is the resultant of the three emf's in parallel, will approach that emf which has the lowest resistance in series with it The resistance to potassium and chloride does not change The membrane potential therefore tends to approach the equilibrium potential of the sodium ion which, in volts, is

$$E_{Na} = 0.058 \log (Na_{outside}/Na_{inside})$$

The equilibrium potential of the sodium ion is approximated but never quite reached by the peak of the overshoot It is possible that an increased efflux of potassium and an active process of sodium extrusion accounts for the difference between the experimentally observed peak of the overshoot and the Na equilibrium potential, i e , the theoretically expected peak.

The rapid rise in sodium current does not continue for very long and, as shown by the clamp experiments, the sodium currents are rapidly followed by a potassium efflux from the axon. The sodium influx is terminated by a process called *sodium inactivation* which develops during the increase in sodium flux Evidence for the existance of such an inactivation

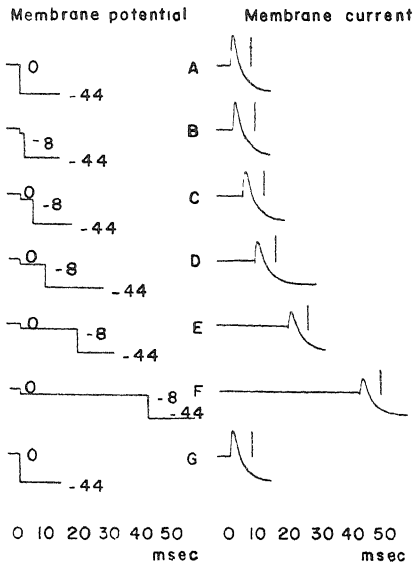

Fig 1 42 Development of inactivation during constant depolarization of 8 mv Left column displacement of membrane potential from the resting value in mv Right column membrane currents as a function of time for the displacement in the left column The vertical lines show the sodium current expected in the absence of the conditioning step (After Hodgkin and Huxley)

process has been adduced in clamp experiments of another type For example, if one applies a clamp of the order of 10 mv , this voltage change is insufficient to cause a sodium influx, yet it can nevertheless set into action the process of inactivation—as demonstrated by the fact that, following the small depolarization, a larger depolarization of about 40 mv does not evoke the magnitude of sodium current that would have developed if the smaller voltage had not been applied initially In other words the small initial voltage clamps rendered the larger subsequent voltage clamp less effective in changing the permeability of the membrane to Na^+ Thus, by following small clamps by larger clamps at various intervals, the time course of development of the inactivation can be ascertained (Fig 1 42) Thus, the inactivation process turns off the sodium current and, thereby contributes toward restoration of the resting state

A second process also aids in the restoration of the resting membrane potential It was noted that a potassium efflux follows the sodium influx The time course of efflux of potassium ions corresponds to the fall of the action potential The increase in conductance to potassium means that the change in potential across the membrane is now being driven by the electrochemical potential due to the potassium gradient This net efflux of cations, the consequence of the increased permeability to potassium ions (sometimes referred to as rectification) tends to restore the membrane potential to its original state of internal negativity Figure 1 43 shows the time course of the increase in conductance of potassium in relation to the sodium inactivation process

Both the sodium and potassium flows during the phase of increased permeability are in the direction of their concentration gradients The flow of ions during the action potential is purely passive and depends upon the concentration gradient The production of a nerve impulse should therefore be independent of metabolism This deduction is substantiated by experiments in which both aerobic and anaerobic processes are blocked by inhibitors Nerves may continue to conduct for hours even when stimulated at high rates under the influence of metabolic inhibitors The increased permeability to sodium and potassium persists although the means for pumping sodium and potassium have been cut off This is not to say that transport processes are not important for maintaining the ionic inequalities If nerve is continually stimulated while being treated with an inhibitor, it fails to pump out the sodium which accumulates inside the nerve both during the resting state and during excitation—and it also fails to reaccumulate potassium to restore its resting intracellular K^+ concentration Ultimately, therefore, the nerve will depolarize as the result of potassium loss and/or sodium influx Thus, the ion pumps and associated metabolic activity which maintains the steady state ionic gradients across the nerve cell membrane

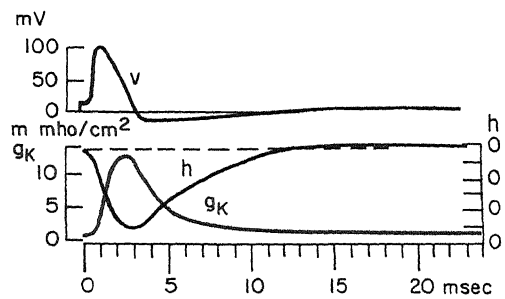

Fig 1 43 Time course of inactivation (h) and potassium conductance (g_K) during a nonpropagated action potential Upper curve is action potential in response to a 15 mv initial depolarization (After Hodgkin and Huxley)

are necessary in the long run, but neither the resting potential nor the action potential depend primarily upon metabolism for their production

How does this theory of the action potential explain other important phenomena of nerve such as refractoriness and accommodation? The absolute refractory period is the result of the inability of nerve to respond to a stimulus no matter how intense This inability corresponds to the period during the action potential when sodium influx is completely inactivated It is impossible to turn on the sodium influx machinery in any degree whatever at the height of the inactivation process During the relative refractory period, the nerve is under the influence of partial sodium inactivation and increased potassium efflux The potassium efflux tends to maintain the membrane potential at the original unexcited level The restorative processes of sodium inactivation and potassium efflux (rectification) must be opposed by very large depolarizations in order to get sufficient sodium influx to start regeneration Similarly, accommodation, which is a rise in threshold during the persistent application of a linearly rising current, may be explained as the result of growth of inactivation at the cathode of an exciting current, much as inactivation developed in the clamp experiments which demonstrated the existence of the process

Little is known concerning the molecular events within the nerve membrane that are triggered by depolarization and then lead to increased sodium conductance It is clear, however, that these events are reversible A hypothesis, advanced by Tasaki (1968), holds that the subunit organization of the membrane may exist in one of two stable states, "resting" or "excited," and that calcium ions within the membrane are critical in regulating a reversible transition between those states In this view, depolarization allows monovalent cations to enter the membrane displacing the divalent calcium ions from their anionic binding sites This displacement of calcium ions permits a transition of the membrane to a state of increased permeability, possibly through alterations in peptide cross-linkages This concept is supported by experiments with barnacle muscle and perfused squid axon in which it has been demonstrated that calcium ions are essential for membrane excitability regardless of which monovalent cations are available to carry current It has also been shown that excitability is preserved in these tissues when sodium ions are perfused internally provided that calcium is present

Nerve Metabolism

INTERMEDIARY METABOLISM

Nerve, like other tissues contains the enzymatic apparatus for glycolysis the citric acid (Krebs) cycle and the electron transport system and, thus, can generate and store energy in the form of adenosine triphosphate (ATP) The pathway of glycolysis is concerned with the breakdown of glucose to pyruvate and/or lactate Only a small amount of ATP is produced in this pathway which is anaerobic The major part of the ATP is produced aerobically in the Krebs cycle and the electron transport system (for details see discussion of the energy generating systems of cells in chap 1

Under anaerobic conditions, e g , in an atmosphere of nitrogen, resting nerve converts glucose to lactate quantitatively However, the nerve at rest produces very little lactic acid aerobically, although recent experiments have shown a clear cut increase in lactic acid production in an oxygen atmosphere (aerobic glycolysis) when the nerve is stimulated at 100/sec

Nerve conduction continues under anaerobic conditions (nitrogen atmosphere), for, as noted previously, the action potential does not depend immediately upon metabolism Ultimately, of course, conduction will fail under anaerobic conditions because of the gradual accumulation of sodium and consequent depolarization of the nerve fiber

Further evidence for the existence of glycolytic systems in nerve comes from the effect of metabolic inhibitors on nerve metabolism Iodoacetic acid, which interferes with glycolysis, causes a decrease in the oxygen consumption of nerve At the same time the effect of the inhibitor may be slowed by the administration of sodium lactate, the latter probably forming pyruvate which is then oxidized The cofactor necessary for the formation of lactic acid from pyruvic acid, diphosphopyridine nucleotide (DPN or nicotinamide adenine dinucleotide, NAD), is found in frog nerve It has also been shown that the administration of glucose partially prevents the loss of potassium and gain of sodium resulting from anoxia of nerve

Evidence for the presence of the Krebs cycle

in nerve comes from the effect of inhibitors on the oxygen consumption of frog nerve Methylfluoracetate, an inhibitor which acts in the Krebs cycle, inhibits the rate of oxygen uptake and ultimately causes a failure of conduction If the nerve is pre-equilibrated with sodium fumarate or sodium succinate, the inhibition is overcome and the nerve regains its ability to conduct and to consume oxygen Fumarate and succinate are intermediates in the Krebs cycle and serve to keep going the portion of the cycle devoted to converting succinate or fumarate to carbon dioxide and water (see energy generating systems, chap 5)

The importance of the electron transport scheme has been demonstrated by experiments in which the cytochrome oxidase of nerve has been inactivated by carbon monoxide When nerve is poisoned with carbon monoxide, the cytochrome oxidase fails to function and molecular oxygen cannot be reduced for its ultimate reaction with metabolically-derived hydrogen to form water The nerve behaves as though it were in nitrogen However, it is possible to dissociate the carbon monoxide from the cytochrome oxidase by shining visible light on the nerve The nerve then regains its ability to consume oxygen and will conduct an action potential

RESTING AND ACTIVE METABOLISM

In the resting state, the oxygen consumption of frog sciatic nerve is quite low, 30 to 40 mm ^{3}/g wet weight/hr in contrast to that of mammalian nerve which ranges from 200 to 300 mm ^{3}/g /hr These values may be compared with those of brain which is of the order of 2000 mm ^{3}/g /hr Corresponding to the consumption of oxygen, there is a resting release of heat by nerve which amounts to 0 15 cal /g /hr for frog sciatic nerve

The oxygen consumption of nerve in vitro is accompanied by a release of carbon dioxide to the extent that the respiratory quotient (moles CO_2/moles O_2) is 0 8 This value indicates that the fuel of nerve may not be exclusively glucose which would yield a respiratory quotient R Q of 1 as indeed proves to be the case when the R Q. of mammalian brain is measured in vivo During excitation the respiratory quotient of the extra oxygen consumption of nerve changes to 0 9, suggesting that the recovery processes following excitation use a different substrate than is used during the resting state

How much of the resting heat production of nerve can be attributed to the heat production of the process pumping Na^+ out of nerve and K^+ into the cell during the resting state? One can calculate the energy required to extrude sodium against both the electrical forces in the membrane and the concentration gradient A similar calculation may be made for potassium uptake If the process is assumed to be inefficient and to produce heat equal to the work done (50% mechanical efficiency) an estimate of the heat production can be obtained In the case of sodium, it is necessary to pump the ion against both the electric field and its concentration gradient since the ion is positive and it must be forced out against the negative attraction of the interior The electric work required is given by EF (ionic flux) The concentration work is obtained from the relationship $RT \log C_1/C_2$, where the symbols have their usual significance Substituting the values for frog nerve of $E = 0\ 070$ v , $F = 23{,}050$ cal /v /mole, $C_1/C_2 = 3$ (sodium) and a sodium flux of 10^{-5} mole/g /hr , one obtains an electrical work of 0 015 cal /g /hr and a concentration work of 0 007 cal /g /hr A similar calculation for potassium shows that the energy necessary to pump this ion into nerve is 0 019 cal /g /hr The work necessary to pump both sodium and potassium is 0 041 cal /g /hr If the pump has a mechanical efficiency of 50% then its operation—complete with inefficiency—accounts for 0 082 cal or about 50% of the total energy consumption of 0 15 cal /g /hr noted above The value of 0 041 cal /g /hr corresponds to 4 1 kcal /mole of Na^+ and K^+ exchanged Thus, taking 8 kcal / mole as the free energy of ATP hydrolysis, it is seen that approximately 2 moles of Na^+ can be exchanged for 2 moles of K^+ for each mole of ATP converted to adenosine diphosphate (ADP) plus P_i

When nerve is stimulated, there is an increase in the oxygen consumption and an increased loss of heat The extra oxygen consumption may double The increase in heat production and oxygen consumption parallel one another and depend upon the frequency of stimulation The increase in oxygen consumption rises gradually with increase in frequency of stimulation, leveling off at about 100 impulses/sec The extra heat which accompanies short tetanic stimulation has been shown by Hill (1938, 1959) and co-workers to consist of two phases, an early one lasting only 2 to 3

sec , called the initial heat which amounts to a few percent of the total extra heat followed by the remainder of the heat production which is called the delayed heat The latter is presumably concerned with the recovery process in nerve involving the pumping of ions The extra oxygen consumption of nerve may be eliminated by inhibitors (azide and methylfluoracetate) which have no effect on the action potential

Abbott, Hill, and Howarth (1958), using improved thermal methods have been able to measure the heat output resulting from a single shock to a crab nerve They found that the initial heat accompanying an action potential occurred in two phases, an early, rapid portion, 1 msec in duration, which was positive (exothermic), and a delayed, negative (endothermic) heat of absorption The actual heats during an impulse were $+14 \times 10^{-16}$ and -12×10^{-16} cal /g /impulse The difference gives the net initial heat production Calculations by Hodgkin indicate that the initial heat can be accounted for by the heat production of the action currents flowing within and without the nerve But other processes such as heat produced by the mixing of sodium entering nerve may also account for the initial heat

Thus, active cation transport may be the major energy-consuming process in specialized tissues such as nerve McIlwain (1966) has shown that electrical pulsation of brain slices in vitro results in cation-dependent respiratory stimulation accompanied by acceleration of active cation fluxes About 30% of the increased respiration may be accounted for by the increased cation flux. The maintenance or restoration of cation gradients in nerve as well as other tissues has been correlated with a sodium-and-potassium-stimulated adenosine triphosphatase present in membranes This enzyme is believed to utilize the chemical bond energy in ATP to translocate Na^+ and K^+ across the membrane against their respective concentration gradients

Synaptic Transmission

In the nervous system of mammals, the formation of conducting pathways does not involve direct anatomical continuity between one neuron and another or between a neuron and a cell of an effector organ An axon gives rise to many expanded terminal branches (presynaptic terminal boutons) The postsynaptic component of the synapse may be formed by any part of the surface of the second neuron with the exception generally of the axon hillocks it usually is a dendrite (axodendritic synapse) but it may be part of the cell body (axosomatic synapse) or part of the membrane of another axon (axoaxonic synapse) A single neuron may be involved in many thousands of synaptic connections but in every case the impulse transmission can occur only in one direction In the mammalian central nervous system there is a cleft of about 20 nm (the *synaptic cleft*) separating the presynaptic axon terminal (the *presynaptic membrane*) and the surface of the postsynaptic component (the *postsynaptic membrane*)

At the sites of opposition, both the presynaptic and postsynaptic membranes exhibit a plaque of electron dense material on their cytoplasmic surfaces Beneath this plaque on the presynaptic membrane and within the presynaptic bouton, there are vesicles ranging in diameter from 10 to 50 nm and often numerous mitochondria

The action potential does not cross the synaptic cleft but instead causes the release of a transmitter substance which is stored in the vesicles of the presynaptic terminals The transmitter substance then crosses the gap, attaches to "*receptors*" on the postsynaptic membrane which is then either *excited* or *inhibited* depending on the precise nature of the permeability changes ensuing after combination of the transmitter and the postsynaptic receptor system (see below)

Chemical transmission was first demonstrated by Otto Loewi in 1920 in a classical experiment in which the heart of a frog was slowed by perfusing it with blood taken from the heart of a second frog that had been slowed as a result of vagal stimulation Loewi (1921) concluded that the vagal stimulation had caused the release of a substance identified as acetylcholine—which altered the excitability of cardiac muscle

THE EXCITATORY POSTSYNAPTIC POTENTIAL (EPSP)

Eccles (1953) and co-workers have inserted finely drawn-out microelectrodes made of glass and filled with KCl or NaCl into the cell body of motoneurons of the spinal cord When the microelectrode is inserted, a resting potential of about 70 mv. is observed, with the interior of the cell negative to the outside If the moto-

neuron is antidromically excited, i e , by stimulating the axon of the motoneuron, the motoneuron is excited without the intervention of the synapse An action potential with an overshoot of about +20 mv appears Thus, antidromic excitation gives rise to an action potential in the postsynaptic cell, the motoneuron, which is no different in its general characteristics than that obtained from squid axon or the muscle fiber The slight inflections which appear on the rise do not enter into the present discussion

The events of interest in synaptic excitation, however, occur when excitation is delivered orthodromically, i e , to the afferent neuron of the dorsal root, so that the presynaptic endings of this neuron are excited In such experiments in which a synapse is present, an additional potential appears in recording from the postsynaptic cell which is a sign of postsynaptic depolarization Figure 1 44 shows the response of the motoneuron to a presynaptic volley The slow potential change which appears just before the action potential is called the excitatory postsynaptic potential or EPSP It consists of a hypopolarization of the membrane which may last for 20 msec and can best be seen when the extent of hypopolarization is insufficient to give rise to an action potential When the membrane potential falls to a critical value of about −60 mv , the motoneuron fires and an action potential appears superimposed on the EPSP Temporal summation of such EPSP's is also possible If two subliminal volleys are sent in over the same nerve, each volley produces an effect which is manifested by an EPSP The EPSP's will then sum and if the critical level of depolarization is reached, an impulse will be set off

The EPSP is monophasic and nonpropagating, it represents a hypopolarization which is localized to the soma of the motoneuron Unlike the action potential, the EPSP is a potential which is not all-or-none in character since it can be augmented simply by increasing the intensity of the input volley Moreover, the EPSP's of different inputs can sum on a postsynaptic cell to produce a greater hypopolarization These characteristics show that the EPSP is produced in a process which is fundamentally different from that of the action potential

Several lines of evidence indicate that the EPSP arises from an influx of all ions through

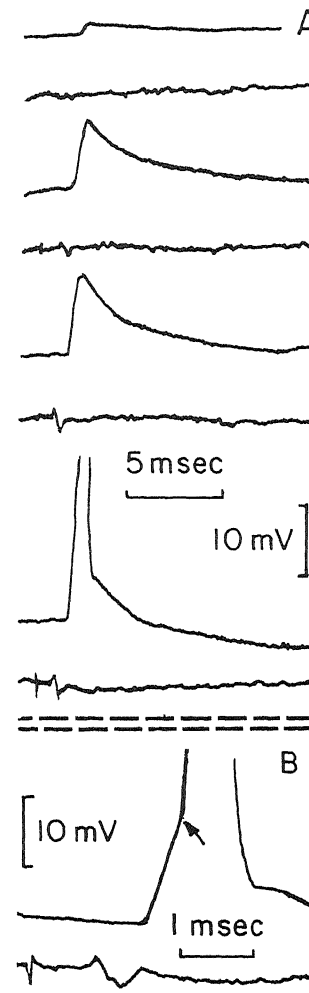

Fig 1 44 Intracellular potentials set up in a biceps-semitendinous neuron by various sizes of volleys in the afferent nerve (lower records) *A* shows synaptic potentials (upper records) of graded size the largest setting up an action potential In *B* a faster record of this response is shown Note spike arising at arrow from more slowly rising synaptic potential (Brock Coombs and Eccles 1952)

the postsynaptic membrane into the cell One group of experiments concerns setting the membrane at a given membrane potential by passing current across the membrane A double-barreled microelectrode was inserted into a motoneuron One electrode was used to hypopolarize or hyperpolarize the neuron with a direct current, the other to record the EPSP When the membrane potential was increased, the amplitude and rate of rise of the EPSP increased Conversely, when the membrane potential was decreased, the EPSP decreased

Reversal of the direction of the EPSP occurred when the membrane potential was set up at zero volts, which is therefore the equilibrium value for the EPSP The explanation of this effect goes back to the experiments on the squid axon It will be recalled that when the axon was clamped at the equilibrium potential of an ion, a reversal of current flow occurred through the membrane above and below this value of clamp voltage We may imagine that the motoneuron membrane contains channels through which ions can flow to cause the development of an EPSP These channels are supposed to be additional to those serving as producers of the action potential A diagram of the equivalent circuit for such channels is shown in Figure 1 45 When the membrane potential is set at zero, the equilibrium potential of the EPSP, a change in resistance of this channel can have no effect on the recorded potential No EPSP will develop Under normal circumstances the membrane potential is determined by the equilibrium potential for potassium but when the EPSP channels decrease in resistance, the potential recorded tends to approach the equilibrium potential for the EPSP Now the only process which can have an equilibrium potential of zero is one in which the membrane is freely permeable to all ions This process will have an equilibrium potential of zero because it is a diffusion potential and the value of the emf developed in a diffusion potential depends directly upon the difference of mobilities of the cations and anions During the production of the EPSP it is presumed that the mobilities are equal so that the process has an equilibrium potential of zero

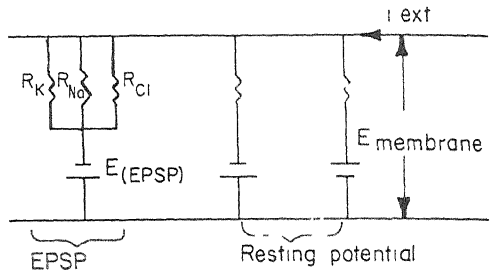

Fig 1 45 Equivalent circuit of motoneuron membrane for EPSP Left circuit represent channels giving rise to EPSP Right circuits represent circuit of polarized membrane

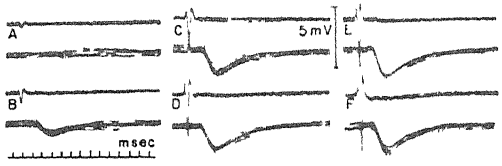

Fig 1 46 Lower records give intracellular responses of a biceps semitendinosus motoneuron to a quadriceps volley of progressively increasing size as is shown by the upper records which are recorded from the L6 dorsal root by a surface electrode (denatured deflection signalling negativity) Note three gradations in the size of the IPSP from A to B from B to C and from D to E Voltage scale gives 5 mv for intracellular records downward deflection indicating membrane hyperpolarization (from Coombs, Eccles and Fatt 1955)

THE INHIBITORY POTENTIALS

If a monosynaptic reflex is evoked by orthodromic excitation, an inhibition of the reflex can be produced by stimulating the afferent nerve from an ipsilateral antagonistic muscle as described more fully in the section on inhibition The effect of the inhibitory stimulus is to cause a hyperpolarization of the motoneuronal postsynaptic membrane in a direction opposite to that of the EPSP (Fig 1 46) This hyperpolarization consequent upon an inhibitory stimulus is called the inhibitory postsynaptic potential or IPSP Its time course is the same as that of EPSP, of the order of 20 msec , and corresponds to the curve of inhibition obtained from reflex studies Indeed the IPSP is a mirror image of the EPSP in the same motoneuron The IPSP being a hyperpolarization of the membrane renders it less excitable Any EPSP which occurs during an IPSP will generate currents which will be less effective in causing excitation of the cell

The problem of determining the nature of the currents responsible for the IPSP has been attacked by the same procedures described for the EPSP Using doubled-barrelled microelectrodes, it is found that setting the membrane potential at −80 mv will cause the disappearance of the IPSP The potential 80 mv. is the average of that determined by potassium (70) and chloride (−90) suggesting that the IPSP results from an increased flow of K^+ and Cl^- making the inside more negative. Further evidence however, points to chloride as the principal ion involved in producing the IPSP The method of electrophoretic injection has been used to demonstrate this One barrel of a double microelectrode is filled with KCl and made negative so that this electrode effectively drives chloride ions into the cell, it is a hyper-

polarizing current since it is internally negative The other barrel electrode records the IPSP It is found that the injection of chloride into the cell converts the IPSP elicited by a group I_a afferent volley from a hyperpolarization to a hypopolarization (EPSP) The injection of chloride caused an increased internal concentration of chloride The transmitter causing inhibition results in an increased permeability to chloride, but the chloride ionic gradient is now opposite to its normal direction so that a hypopolarization will occur instead of a hyperpolarization if the membrane is especially permeable to chloride Chloride now flows out and makes the inside of the cell less negative A number of anions were injected internally and all those with less than a certain hydrated ion diameter caused a reversal of the IPSP to an EPSP Apparently the inhibitory substance opens pores which allow ions below a certain size to pass Since chloride is the only anion which under in vivo conditions exists in a high enough concentration to flow in during such an inhibition, it is presumed that chloride is the main contributor to the inhibitory currents

Types of Inhibition

Some restraint must be placed upon the ability of muscle and neural circuits to respond In reaching for an object, for example, the muscle must be controlled if the movement is to be accurate and the muscle is not to overshoot the mark Certainly reciprocal innervation of some type must often be employed so that when a muscle is activated its antagonist will be inhibited, otherwise persistent opposition of an undesired sort will be encountered These two reasons give some indication of the usefulness of inhibition in motor movement A third less obvious necessity for inhibition arises from the very complexity of neural activity in which some form of "negative feedback" or inhibition is necessary in order to keep the complex neural networks from over-activity An abnormal form of such activity is observed, for example, in strychnine poisoning in which inhibitory neurons have been shown to be inactivated In a strychninized animal any stimulus leads to persistent neural activity and convulsion Again, in the disorder known as Parkinsonism, periodic activity in the form of a tremor of a limb manifests itself, presumably as a result of injury to inhibitory systems which restrain normal motor activity

Three kinds of inhibition have been extensively studied *1)* direct, *2)* presynaptic, and *3)* Renshaw cell or recurrent inhibition A fourth type of inhibition, called indirect inhibition and extensively discussed by Sherrington is not now considered to be inhibition per se but a form of occlusion

DIRECT INHIBITION

The direct form of inhibition can be observed by evoking a monosynaptic reflex and then depressing the amplitude of the reflex by stimulating an ipsilateral skin nerve (type II fibers) It is necessary to stimulate the inhibitory nerve shortly before eliciting the reflex By varying the interval between the inhibitory and excitatory stimulus, the time course of direct inhibition can be obtained The inhibitory nerve is stimulated first A curve of the form of Figure 1 47 is obtained in which maximum inhibition is obtained at an interval of 0 5 msec between the two stimuli and with a delay lasting for about 10 msec The interval 0 5 msec , is equivalent to one synaptic delay so that at least one inhibitory interneuron is interposed between the afferent neuron and the motoneuron It is believed at present that this interneuron in the inhibitory pathway possesses the ability to secrete a substance at its terminals which hyperpolarizes the membrane and leads to an IPSP Thus, a neuron which is normally excitatory to other neurons may exert an inhibitory action by the interposition of an inhibitory neuron

Direct inhibition is very susceptible to strych-

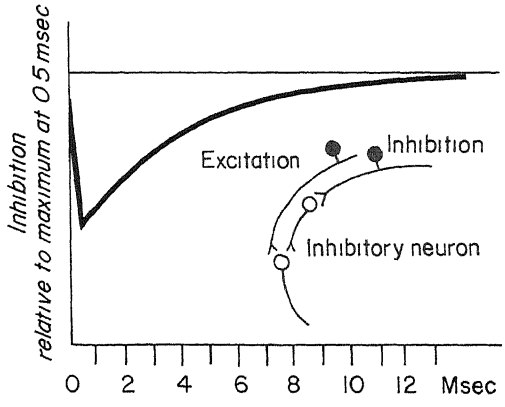

Fig 1 47 Time course of direct inhibition Insert shows circuit containing inhibitory neuron (after Lloyd)

nine injection which can completely abolish it This effect of strychnine is the basis for the explanation of its convulsant activity—all inhibition of the direct type having been removed, the slightest stimulus causes a tremendous extensor response

PRESYNAPTIC INHIBITION

Early in the studies of the electrical responses evoked by reflex action electrodes were placed on the surface of the spinal cord or on dorsal roots, and large potentials which were positive to distant regions, called P waves, were recorded It was suspected that this positivity might be the sign of some inhibitory presynaptic activity going on in the cord To demonstrate presynaptic inhibition, a reflex response is elicited in extensor motoneurons This reflex will be inhibited if it is preceded by stimuli from any nerve entering the cord Group I_a and I_b fibers are most effective in causing the inhibition but groups II and III will also serve The time course of such an inhibition is shown in Figure 1 48 Unlike direct inhibition, maximum inhibition is observed when the inhibitory stimulus precedes the excitatory by about 20 msec The inhibition may endure for as long as 200 to 300 msec and is extremely resistant to strychnine Several lines of evidence indicate that this inhibition is presynaptic Recording within the motoneuron at the time that inhibition is produced shows no changes in the membrane potential Neither a hyperpolarization or a depolarization is produced by an inhibitory volley Instead, it is noted that the magnitude of the EPSP which is set up by the reflex volley is diminished by the inhibitory stimulus and that the magnitude of the EPSP parallels the curve of inhibition (Fig 1 48) It has also been shown that there is a depolarization of the presynaptic fine terminals entering the dorsal region of the cord Microelectrodes are inserted into and just outside a nerve fiber The undesirable potential of neighboring neurons which is recorded inside a nerve fiber together with the membrane potential, may be obviated by subtracting the externally recorded potential from the internally recorded to obtain the true membrane potential It is found that the time course of the depolarization produced by inhibitory volleys parallels the time course of inhibition

Although the mechanism is not clear, depolarization in axo-axonal synapses on presyn

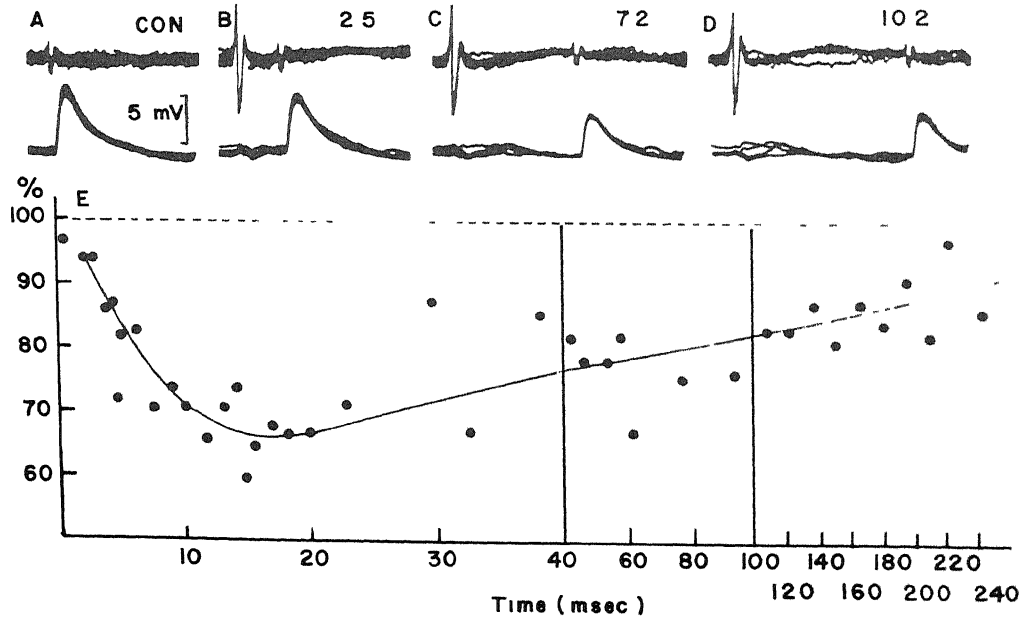

Fig 1 48 Time course of presynaptic inhibition (*E*) Inhibitory stimulus is maximal group I volley in biceps semitendinous nerve Monosynaptic EPSP s were evoked at various intervals after the inhibitory stimulus by stimulating the gastrocnemius-soleus nerve maximally *A* shows control EPSP *B C* and *D* are the EPSP's at intervals marked above the records

aptic terminals may reduce the amount of excitatory transmitter released from the presynaptic terminals, thus decreasing the EPSP amplitude Since long delays are involved in presynaptic inhibition, many interneurons are interposed between the first and last neurons of the chain

RENSHAW CELL INHIBITION

In 1946, Renshaw discovered that a volley of impulses delivered to motor axons causes an inhibition of all types of motoneurons at the segmental level This type of inhibition has therefore been called antidromic because the inhibition may be evoked by firing backwards over the motor roots into the spinal cord When such antidromic excitation was used, an afterdischarge of quite high frequency was observed in microelectrode recordings from the ventral *horn* It was also shown that the discharge did not occur in the motoneuron but in neighboring cells near the motoneuron—in cells which discharge with a high frequency when the antidromic excitation occurs At the same time the motoneuron is inhibited These neighboring cells are therefore believed to cause the inhibition The motoneuron displays a hyperpolarization which has all the characteristics of an inhibitory postsynaptic potential and the IPSP lasts for the period of time corresponding to the discharge in the neighboring cells which are called Renshaw cells An anatomical pathway has been suggested to explain these results (Fig 1 49) The motoneuron gives off a collateral to the Renshaw cells, the Renshaw cell axon returns to the motoneuron and inhibits it

The repetitive discharge of the Renshaw cell is presumed to be caused by an accumulation of acetylcholine at the junction between the motoneuron collateral fiber and the Renshaw cell It has been shown, for example, that the discharge of the Renshaw cell may be prolonged by anticholinesterases which allow acetylcholine to accumulate It is also possible to inhibit the discharge with β-dihydroerythroidine, a substance which blocks the action of acetylcholine The functional significance of this pathway is not clear It appears to serve as a general synaptic inhibitor and may act to limit the frequencies of impulses going to the motor endplate

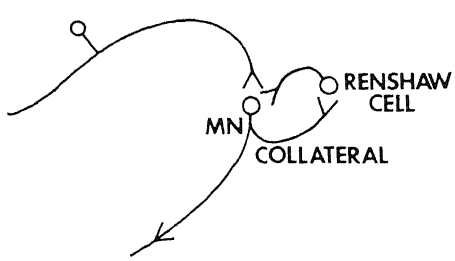

Fig 1 49 Schematic drawing of recurrent inhibition

Electrical and Chemical Transmission

The events at a synapse may be interpreted according to either a chemical or electrical theory of synaptic transmission The chemical theory of transmission attributes the response of the postsynaptic cell to a chemical substance (transmitter) released from the presynaptic nerve terminals The electrical mechanism of transmission presupposes the activation of postsynaptic neurons by electrical currents flowing out from the presynaptic terminals into the postsynaptic cell Examples of each of these types of transmission may be found in various kinds of synapses among vertebrates and invertebrates It may be stated, however, that no firm evidence of electrical transmission at mammalian synapses has as yet been obtained

The present day understanding of chemical transmission is based primarily on studies of the neuromuscular junction because of its accessibility to investigation The chemical mechanism of transmitter release and action may be schematically outlined as in Figure 1 50

The action potential, upon invasion of the presynaptic terminal, causes release of transmitter material In the case of the neuromuscular junction in which the transmitter is acetylcholine, this substance is stored in clear vesicles in the presynaptic nerve terminal In their classical experiments with frog muscle fibers, Fatt and Katz (1952) observed that under certain conditions the muscle end-plate (postsynaptic membrane) exhibited intermittent, spontaneous miniature potentials in a random manner These miniature end-plate potentials (MEPP's), of insufficient amplitude to depolarize the membrane to threshold, were related to random release of acetylcholine packets from the presynaptic vesicles When the external Ca^{++} concentration was reduced, the amplitude of the end-plate potentials decreased in a stepwise manner, under various conditions the

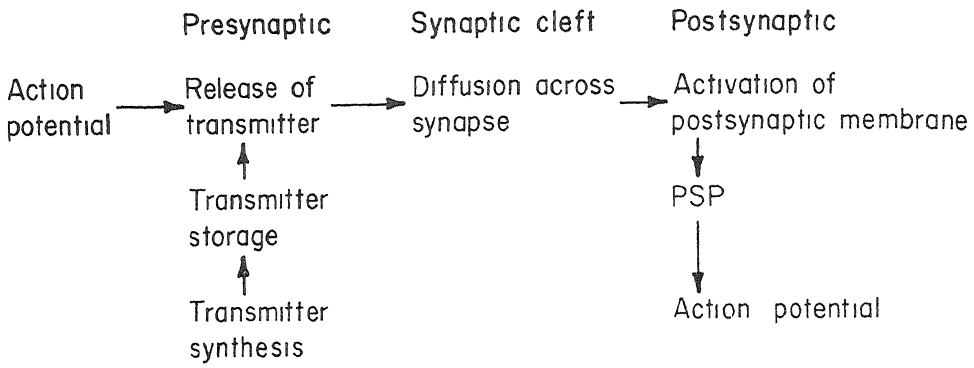

Fig 1 50 Outline of processes involved in storage and release of chemical transmitter

amplitudes were integral multiples of the miniature components However, graded ionophoretic application of acetylcholine directly onto the end-plate produced a continuously graded potential change, thus, indicating that the stepwise electrical changes were not due to the nature of the receptor response, but, rather, to the nature of the transmitter release Their conclusion was that the transmitter is released in quanta or packets of uniform size Depolarization of the presynaptic terminal increased the frequency of quanta release, thus, allowing the MEPP's to summate and reach threshold for firing of an action potential in the postsynaptic cell Other studies have shown that external Ca^{++} is essential for the increased quantal release during the action potential and that external Mg^{++} antagonizes the Ca^{++} action, however, the detailed mechanism for the coupling of excitation to secretion of transmitter is not known

The released acetylcholine diffuses across the synaptic cleft in a very short time (<0.6 msec) to attach to receptor sites on the postsynaptic membrane The mechanism by which this attachment alters the membrane permeability in producing the end-plate potential is not known The action of acetylcholine is terminated by its hydrolysis catalyzed by acetylcholinesterase present at the postsynaptic membrane

Numerous observations indicate that the quantal nature of transmission is applicable to interneuronal synapses in many portions of the vertebrate nervous system and also to other transmitters, for example, norepinephrine In the nervous system, combination of the transmitter with receptor gives rise to the EPSP or IPSP However, direct demonstrations of specific transmitters and their mode of release in the mammalian central nervous system have not yet been achieved

The basis for establishing that chemical transmission occurs involves the following purely chemical criteria A transmitter substance must be found *1*) which is produced presynaptically, that is, the pertinent enzyme systems for its production are present in the presynaptic terminals, *2*) which is released and detected when the presynaptic terminals are stimulated, *3*) the action of which is dissipated by a specific enzyme (as in the case of acetylcholinesterase which destroys acetylcholine) or by reuptake (as in the case of norepinephrine) or by simple diffusion away from the postsynaptic membrane, and *4*) the action of which, when applied directly onto the postsynaptic membrane, mimics the effects of presynaptic nerve stimulation In the case of acetylcholine, the transmitter at the neuromuscular junction, such criteria have been met

Additionally, acetylcholine has been shown to be a transmitter in autonomic ganglia, postganglionic parasympathetic terminals, certain postganglionic sympathetic terminals (sweat glands and vasodilator fibers), and in motoneuron collateral-Renshaw cell synapses in the spinal cord Not all the criteria have as yet been fulfilled to firmly establish acetylcholine as a synaptic transmitter in the vertebrate central nervous system Examples of some of the evidence bearing on the role of acetylcholine as a transmitter in the central nervous system are *1*) choline acetylase and vesicles containing acetylcholine are present in nerve endings from many nuclei of the nervous system; *2*) acetylcholinesterase is abundantly present in neural

tissue, 3) acetylcholine release has been detected from the cerebral cortex after excitation of a sensory nerve, but only in eserinized preparations in which acetylcholine cannot be destroyed, and 4) injection of acetylcholine either directly or electrophoretically will activate many cells in the nervous system

There is substantial evidence that norepinephrine is the transmitter released at postganglionic sympathetic nerve terminals The inactivation of norepinephrine action involves reuptake into the presynaptic terminal Within the central nervous system norepinephrine is found abundantly in the hypothalamus and brainstem reticular formation where it may have a transmitter role On the other hand, dopamine, a precursor of norepinephrine, is abundant in the corpus striatum where it is thought to act as a transmitter Histochemical fluorescent studies have shown that dopamine is present in nerve terminals within the corpus striatum that derive from cell bodies located in the substantia nigra In Parkinson's disease which is associated with symptoms of basal ganglia dysfunction, there is degeneration of this biochemically-defined nigra-striatal path and depletion of dopamine in the corpus striatum Administration of L-dopa, which is decarboxylated to form dopamine in vivo ameliorates the symptoms of Parkinsonism Both catecholamines, dopamine and norepinephrine, are stored in granular vesicles in presynaptic nerve terminals

A number of other substances have been suggested as possible synaptic transmitters and inhibitors Serotonergic axons extend from median raphe nuclei in the brainstem to many areas of the brain, but particularly to the hypothalamus Evidence is accumulating that γ-aminobutyric acid is an inhibitory transmitter in portions of the central nervous system, particularly the cerebellum, and that glycine acts as an inhibitory transmitter in the spinal cord Glutamic acid has been suggested as an important excitatory transmitter It is as effective as acetylcholine in activating neurons when injected into the cells electrophoretically Unfortunately, direct evidence of release has not as yet been obtained for most of the substances alleged to have transmitter or inhibitory activity in the vertebrate central nervous system

There are other indications that chemical transmission takes place at mammalian synapses Some synaptic delay would be anticipated if the release, diffusion, and attachment of a substance were factors important in transmission Thus, the finding of a synaptic delay at vertebrate synapses of 0 5 msec is consistent with a chemical theory A second phenomenon which is consistent with the chemical theory is the fatiguability of synapses when rates of stimulation are increased At 40 or 50 impulses/sec , many synapses within the nervous system fail to transmit an impulse According to the chemical theory, such a failure would be in accord with the expectation that there will be a frequency of stimulation above which the synthesis of transmitter is unable to keep pace with its release from the terminals At such high frequencies, the amount of transmitter released per impulse would decrease and fail to activate the postsynaptic membrane A third, well-known observation is the susceptibility of synapses to anoxia and metabolic inhibitors Thus, cutting off the supply of oxygen interferes with the synthesis of ATP and other chemical materials necessary for the manufacture of the transmitter substance The supply of transmitter diminishes and the amount released per impulse again becomes inadequate to activate the postsynaptic membrane A fourth phenomenon is the repetitive discharge of neurons as noted in the case of the Renshaw cell where a repetitive discharge ensues from a single shock This repetitive discharge is the result of a prolonged depolarization lasting more than 100 msec The prolonged depolarization is attributable to the accumulation of the transmitter substance at the synapse

Criteria for the presence of electrical transmission are essentially the opposite of those for chemical tranmission Thus, a system which transmits impulses across junctions at high frequencies with no delay and in which anoxia and metabolic inhibitors have little or no effect is presumed to be an electrical synapse Such systems behave, indeed, as though no junction were present, although there may be an anatomical junction with little or no space between the presynaptic and the postsynaptic membranes Such electrical junctions have not yet been discovered in the mammalian nervous system but artificial synapses called "ephapses" have been created at junctions between nerve fibers so that an incoming electrical impulse will either modify the excitability in a contig-

uous nerve or actually set off an action potential. Among the invertebrates, several examples of purely electrical junctions have been discovered. The giant motor synapses of the crayfish are designed to transmit electrically in one direction only. Simultaneous recording from both presynaptic and postsynaptic cells has demonstrated that practically no delay (about 0.1 msec.) occurs. The postsynaptic response has the shape of an EPSP and spikes may be generated from sufficiently strong EPSP's. Such synapses appear to act as rectifiers, i.e., they pass current more easily in one direction than the other.

4 / EXCITATION AND CONTRACTION OF MUSCLE

General Characteristics of Muscle Tissue

The functions of muscle tissue are development of tension and shortening Mechanical work is accomplished when the load is not excessive so that the muscle can shorten against it Muscular contraction under physiological conditions depends on the stimulation of muscle tissue through motor nerves In experimental conditions muscular contraction can be elicited by electric or chemical stimulation applied directly to the tissue

Between contractions, muscle tissue assumes a relaxed state characterized by a low resistance to stretch Muscle is elastic but there are changes in its elastic modulus during the transition between the relaxed and the contracted states

The tension developed by a muscle in the body is graded and adjusted to the load If contraction is associated with shortening, the tension is adjusted both to the load and to the velocity of the shortening The graded response of muscle is due to variation in the degree of activation of the tissue through the motor nerves

Through nervous control, the activity of different parts of the muscle tissue of the body is coordinated to produce useful movements and postures The effect of muscle activity is transferred to the skeleton by means of tendons, the translational displacements between various parts of the muscle mass, displacements that are associated with movement, are facilitated by the interposition of connective tissue, either as thin or thick layers of connective tissue or as compact connective tissue septa The latter structures are present at places where the translational displacements are most pronounced

The activity of muscle tissue depends on a supply of energy primarily through breakdown of carbohydrates For highest efficiency and sustained activity, this breakdown is oxidative, which implies a constant supply of oxygen via an efficient blood circulation The transport of oxygen through the blood vessels by means of streaming is supplemented by diffusion from the capillaries through the muscle tissue The dense arrangement of narrow capillaries allowing rapid streaming of the blood secures a fairly short mean distance for the diffusion of oxygen and the maintenance of a high concentration gradient between the capillary lumen and the oxygen-consuming structures, the mitochondria

The activation of the contractile apparatus in muscle tissue depends on events which serve in effect to transfer the nerve stimulus from the motor nerve endings to the contractile machinery Furthermore, the activity of the muscle tissue depends on a precise ionic milieu which is different from that of blood plasma

MICROSCOPIC AND MOLECULAR ORGANIZATION OF MUSCLE

The elongated cells of skeletal muscle (referred to frequently as skeletal muscle fibers or, simply, *myofibers*) are delimited by a plasma membrane, the *sarcolemma* The selective permeability and transport properties of the sarcolemma facilitate the control of the medium in which the contractile machinery is immersed and also contribute to the propagation of impulses that serve to activate the contractile process Skeletal muscle fibers vary in diameter from 10 to 100 μm , and in length from a few micrometers (in the case of insect flight muscle) to several feet (in the case of the long muscles in the giraffe) Despite the great difference in length the mucles of an insect and a giraffe both have the same basic structure Under the light microscope skeletal muscle shows a repeating pattern that has given rise to the designation *striated muscle* Under the electron microscope the subcellular structure of

the skeletal muscle fiber is seen to be composed of smaller fibrous structures 1 μm in diameter *myofibrils*, which are separated by cytoplasm *sarcoplasm*, and arranged in parallel fashion along the long axis of the cell On more detailed examination each myofibril is composed of fibrous substructures, the *myofilaments*, which are of two types, thin myofilaments (approximately 50 Å in width in mammals) composed of a protein called *actin*, and thick filaments (approximately 100 to 120 Å in width) composed of a protein called *myosin*

The arrangement of the myosin and the actin filaments is responsible for the cross-striated appearance of the muscle The cross-striations depend on a regular repetition of one structural pattern consisting of dense cross bands (1 5 μm in width) separated by less dense segments The dense cross bands, referred to as A bands because they are strongly anisotropic, contain the thick myosin filaments arranged neatly in parallel (Fig 1 51) When myosin is extracted from intact muscle, thick filaments can no longer be detected microscopically

The myosin filaments have a characteristic appearance which reflects the mode of aggregation of the myosin molecules within the filaments With the exception of a middle section of the filaments, a series of lateral projections extends from the approximately 100-Å-thick trunk of the filaments Similar filaments can be made artificially by allowing myosin in solution to aggregate Under such conditions the gradual growth of filaments is reflected in the distribution of sizes of reconstituted filaments The morphology of the filaments agrees with the assumption that the myosin molecules aggregate with their globular ends directed towards the ends of the filaments The middle smooth shaft corresponds to a close packing of the rod-shaped part of the molecules and the series of projections corresponds to their globular ends (Fig 1 52)

Such a polar arrangement of the myosin molecules could secure a definite direction of the force developed in connection with a configurational change of the myosin molecules whether the latter change is minimal or extensive

The smooth shaft of the filament shows a somewhat thicker segment located exactly in the middle of the filament, contributing to a dense line, the M band, extending across the middle of the sarcomere

The actin filaments in intact muscle show

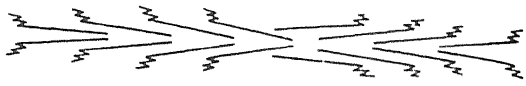

Fig 1 51 Schematic presentation of the likely arrangement of myosin molecules in the myosin filaments

great similarities to fibrous actin (F actin) filaments that are formed in vitro by polymerization of globular actin (G actin) although the axial periodicity is slightly greater (406 to 411 Å) for the natural than for the artificial filaments (350 Å) Recent analyses of electron micrographs of F actin and isolated thin filaments indicate the presence in the latter of additional proteins This additional material probably reflects the presence in the thin filament of the tropomyosin troponin complex as does the 406 to 411 Å periodicity (vide infra)

The less dense segments the *I bands*, contain the actin filaments which extend symmetrically in opposite directions from a dense thin line, the *Z line* (Fig 1 53A) The Z line appears in embryonic muscle before the actin filaments develop and is comprised of a lattice like protein This protein is intertwined with the actin (thin) filaments which extend perpendicularly from the Z line for about 1 μ on either side When actin is extracted from intact muscle the thin filaments can no longer be observed microscopically The term I band is based on the fact that this zone was originally considered to be isotropic Although it is now recognized to be weakly birefringent, it is very much less birefringent than the A band. The width of the I band varies with the degree of stretch or shortening of the muscle fiber Since the length of the individual actin filaments is about 1 μm and there are two sets of such filaments extending from the Z line, the total width of the Z line-actin filament complex will be about 2 μm The Z-line structure contributes toward keeping the actin filaments arranged in register and with a regular spacing The gap between the terminations of the actin filaments is called the H zone and, as noted above, the M line is the darker area in the center of the H zone The M line is particularly pronounced during contraction

The term *sarcomere* defines the repeating unit of this striated structure as the region between two consecutive Z lines, thus, this unit consists of one A band and one-half I band at each end of the A band The sarcomere is the

Fig 1 52 Electron micrographs of negatively stained preparations of (*left*) natural thick filaments prepared directly from homogenized muscle (*middle*) synthetic filament formed by aggregation of purified myosin in 0 1 M KCl and (*right*) synthetic filament formed by aggregation of light meromyosin (vide infra) in 0 1 M KCl Projecting cross-bridges can be seen on the natural and synthetic filaments in which whole myosin is present—that is in which both the heavy- and light-meromyosin parts of the myosin molecule are represented The filaments containing light-meromyosin alone have no projections (about × 162 000) (Huxley 1969)

fundamental contractile unit of muscle Its length at rest varies from 10 to 15 μm in crab muscle and between 2 and 2 5 μm in frog and mammalian (including human) muscle

At the rest-length of muscle, which here is defined as the normal length of the muscle in situ, the two sets of filaments in most muscles interdigitate with a rather extensive zone of overlap at each end of the A band In the rabbit psoas muscle the sarcomere length at rest-length is about 2 8 μm If the muscle is stretched, the zone of overlap decreases in width in proportion to the increase in half-width of the I band The zone in the middle of the A band bounded by the two zones of overlap, the H zone, also increases in width, this increase corresponding to the decrease in width of both zones of overlap This means that when a muscle is stretched, the actin filaments are being pulled out of the A band, while the length of both the myosin filaments and the actin filaments remains constant (Fig 1 56 *B* and *C*) At a sarcomere length of about 3 5 μ, the actin filaments have been pulled out completely, and the two sets of filaments appear now in an end-to-end arrangement At further stretching, the two sets of filaments become separated by a gap, in which filaments consid-

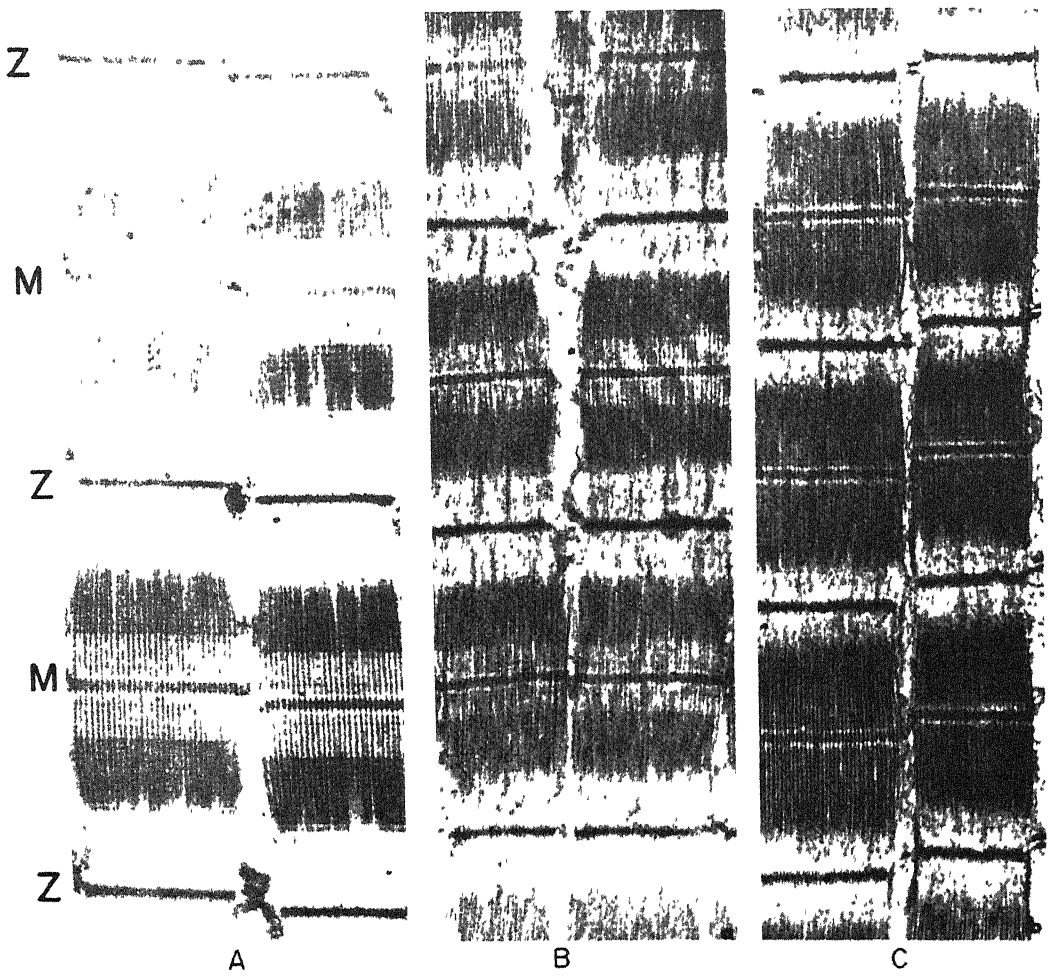

Fig 1 53 *A* Frog sartorius muscle (thick section) showing periodicity in both thin filaments (as seen in I bands) and in thick filaments (as seen within the entire width of the H-zone) Periodicity is best seen by viewing pictures of the fibrils obliquely from the side The two periods differ by 5 to 10% (their probable values being 410 Å and 435 Å) Near the edges of the H-zone the periods show strongly in the overlap region where they are more or less in register but as they get progressively further and further out of register the vernier effect blurs out the pattern The M line structure (3 dense lines, about 200 Å apart running across the fibril and probably corresponding to the cross bridges between thick filaments seen in the M-region in cross-section) shows up rather clearly The less dense region immediately on either side represents the remainder of the central region of the thick filaments from which the cross bridges are absent (× 32 400) *B* Frog sartorius muscle (live) fixed in gluteraldehyde during direct electrical stimulation and whilst it was shortening against a load postfixed in osmium tetroxide stained with PTA in absolute alcohol, araldite embedding Only surface fibers used Specimen shown had only shortened very slightly, and quite a wide H-zone is still visible (× 19 200) *C* As in *B* but allowed to shorten further so that a very short H zone (and a shorter I band) is visible (× 19 200) (Huxley 1964)

erably thinner than the actin filaments can be seen extending between the ends of the myosin and the actin filaments

If a muscle is allowed to shorten, either passively or through an active contraction, and the structure is analyzed after the muscle has acquired a new length, the relationship between the half-width of the I bands, the width of the overlap zone and the width of the H band is the same as described above At sarcomere lengths less than 2 μ, that is, less than the sum of the lengths of the two sets of actin filaments in the sarcomere, a somewhat more dense zone appears in the middle of the A band This phenomenon is due to a double overlap of the actin filaments (Fig 1 56 D)

When the sarcomere length has decreased to 1 5 μ or less, the Z lines cause the ends of the thick filaments to crumple, giving rise to zones with irregularly arranged filaments Such zones are referred to as contraction bands Contraction bands at this sarcomere length involve a rather random arrangement of thin actin filaments as well as thin filaments derived from the myosin filaments as a consequence of the splitting of the latter into filamentous subunits

In accord with the above considerations the microscopic patterns seen in cross sections of muscle fibers depend on the level of the section (Fig 1 54) For instance, near the Z band, only actin fibers are observed (Fig 1 55*A*) whereas at the site of overlap of actin and myosin filaments, each thick filament is surrounded by six thin filaments and each thin filament by 3 thick filaments (Fig 1 55*B*)

The sarcolemmal membrane of the myofibers has the general double layer structure of most biological membranes Besides shielding the muscle fiber, the sarcolemma imparts a characteristic resistance to stretch for the muscle as a whole Because this resistance is anatomically disposed in parallel with the contractile elements, it is usually lumped together with the resistance contributed by the connective tissue surrounding the muscle fibers and both are referred to as *parallel elastic elements*

Skeletal muscle fibers are multinucleated In embryonic tissue the nuclei are located in the center of the fiber, however, in the course of differentiation they come to occupy a peripheral position

Skeletal muscle has a rich supply of mitochondria and microsomes dispersed along the length of the myofiber These subcellular structures, as in other tissues, are supportive components of the muscle fiber, the myofiber is the smallest metabolically autonomous unit

PROTEINS OF THE CONTRACTILE ELEMENTS

1) **Actin.** With recent advances in the purification of muscle constituents it has become apparent that actin comprises a major portion but not all of the thin filament (I band) Actin molecules exist in two states G-actin, a globular monomer, which is stable in solutions of low ionic strength, and F-actin, a fibrous polymer, which is formed when salts are added to G-actin The polymerization of G-actin to form F-actin (referred to as the G-F polymerization) is accompanied by an increase in the viscosity of the protein solution The conformation of the F-actin polymer is that of a double-stranded helix

A bound nucleotide and a bound divalent cation are necessary for polymerization of globular actin In the in vitro preparations, 1 mole of adenosine triphosphate (ATP) and 1 mole of

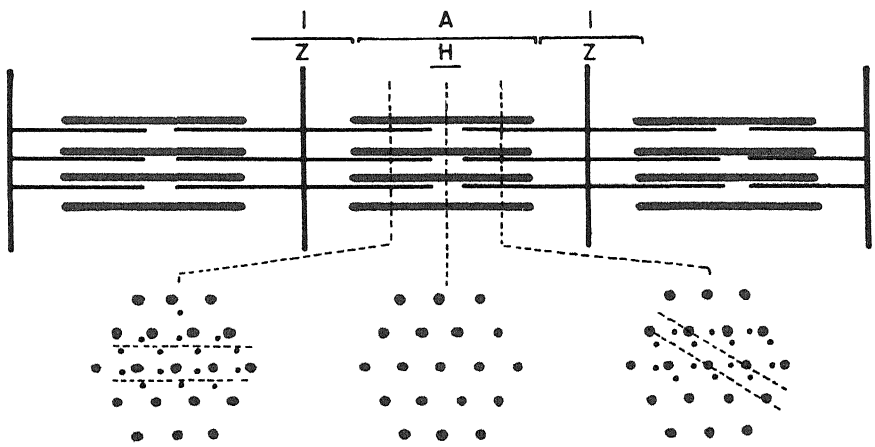

Fig 1 54 Diagram illustrating the arrangement of the two kinds of protein filaments in a myofibril At the top are three sarcomeres drawn as they would appear in longitudinal section Below are transverse sections taken through the H zone (center) and through the other parts of the A band (right and left) where the arrays of thick and thin filaments interdigitate If a longitudinal section were cut in the plane which is indicated by dotted lines in the left-hand transverse section it would appear as in the electron micrograph in Figure 1 52 and as in the diagram here, and it would show (apparently) one thin filament between each two thick ones If it were cut in the other plane (dotted lines in right-hand transverse section) it would show two thin filaments between each two thick ones (From Huxley and Hanson 1960)

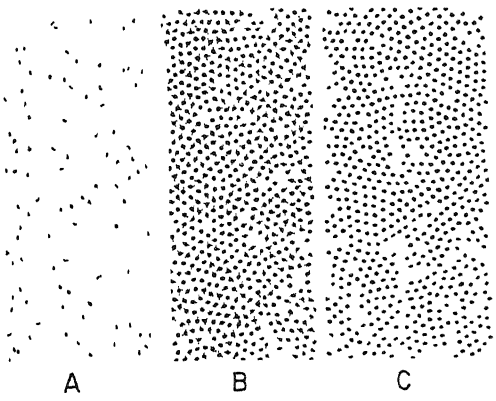

Fig 1 55 *A* Cross section of muscle fiber near Z band showing only actin fibers *B* In region of overlap both thick and thin filaments are seen *C* In the H zone only myosin filaments appear

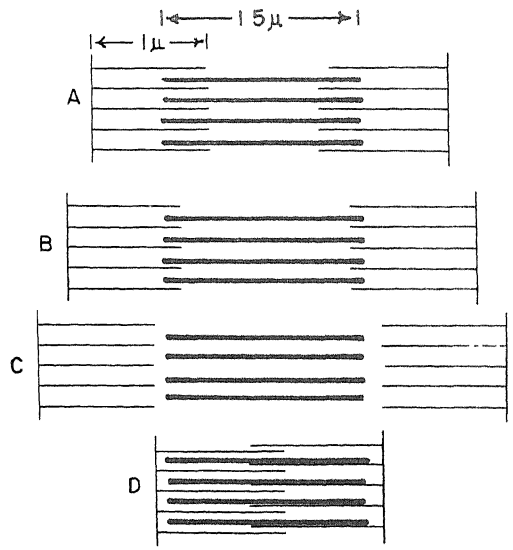

Fig 1 56 Schematic illustration of the arrangement of thick myosin filaments and thin actin filaments in the sarcomere at various degrees of stretch and shortening *A* and *B* show different degrees of overlap of the two types of filaments *C* illustrates the case when the actin filaments have been completely pulled out from the A band with a gap between A band and the actin filaments In the extensively shortened sarcomere in *D* a zone of double overlap of actin filaments has developed in the center of the A band

Ca^{++} have been found to be associated with 1 mole of G-actin Nucleotides other than ATP can also bind with G-actin, although with lower affinity Mg^{++} and Mn^{++} can replace Ca^{++} but also with the affinity that is four times less than the affinity of Ca^{++} for actin

The nucleotide (ATP) bound to G-actin is readily exchangeable, however during polymerization to F-actin, the terminal phosphate of ATP is split off and the resulting adenosine diphosphate (ADP) formed remains bound to F-actin and is not exchangeable Addition of inorganic phosphate (P_i) per se will not reverse the reaction of G-F polymerization to restore G-actin and ATP in fact such a depolymerization requires ATP

The molecular weight of skeletal G actin is generally accepted to be approximately 47 000 based on viscosity measurements, sedimentation equilibrium studies, amino acid analysis, and ATP content

2) **Tropomyosin.** Tropomyosin is a protein which constitutes 10 to 12% of skeletal myofibrillar protein Although it was purified in 1948 its role in the machinery of the contractile process had escaped attention until recently It is now believed to react with troponin to form a complex which is implicated in the processes by which excitation is coupled to contraction The molecular weight of tropomyosin is approximately 70,000 Tropomyosin is a coiled coil (two alpha helices wound around each other), which by itself has no known biological activity When bound to actin, however, tropomyosin can modify the interaction between actin and myosin

The presently available evidence does not support a previous suggestion to the effect that tropomyosin comprises the structural protein of the Z line Antibodies against tropomyosin show very weak binding to the Z-line proteins and ammonium sulfate extracts of tropomyosin fail to restore the Z band to rabbit muscles from which the Z line had been previously extracted with glycerin

3) **Troponin.** This protein was isolated recently It has been studied extensively because it is linked with the important regulatory action of calcium in the contractile process Its salient feature is a high affinity Ca^{++} binding site, 2 moles of Ca^{++} are bound to approximately 100,000 g of troponin Recent work indicates that troponin consists of two or three distinct components, one of these, designated as troponin A, possesses the specific (high affinity) binding site for Ca^{++} Another component, designated as troponin B, inhibits the Mg^{++}-activated interaction of actin and myosin which constitutes the quintessential biochemical event in the contractile process (vide infra) Troponin molecules complexed with

tropomyosin are believed to be distributed along the thin (actin) filaments at intervals of 406 to 411 Å to form reactive sites which are important in the contraction process Antibodies to troponin are not found on the Z band and it may therefore be concluded that troponin, like tropomyosin, is probably limited only to the thin filaments

4) **Myosin** This protein is the chief constituent of the thick filaments which, as has been noted, disappear after myosin has been extracted from muscle fibers When purified myosin molecules are allowed to aggregate, the resulting polymers are virtually indistinguishable from the thick filaments Myosin is a large protein with a molecular weight between 450,000 and 500,000

The physicochemical properties of myosin indicate a high degree of molecular assymmetry One end of the molecule is globular, the other end is rodlike Optical rotatory dispersion measurements indicate that between 54 to 60% of the peptide chain in the native molecule exists in the α helical configuration The extremely large size of the myosin molecule suggested a complex structure, and indeed it was found that treatment of myosin with proteolytic enzymes such as trypsin splits the protein into two components, light meromyosin (LMM), which consists of most of the rodlike part of the native molecule, and heavy meromyosin (HMM) the primarily globular end of the native molecule, to which is attached a short piece of the rodlike portion

Myosin possesses adenosine triphosphatase (ATPase) activity which is associated with the HMM component, LMM being totally inert in this respect

Unlike trypsin, papain cleaves myosin at a point of the globular end of the molecule splitting off two identical HMM components These HMM components are held together and attached to LMM by a peptide stem at a locus which is not susceptible to the action of trypsin (Fig 1 57) When myosin is treated with 12 M urea or 5 M guanidine, it can be resolved into two heavy fragments and two or three light fragments The functions of the latter are unknown, however, differences in electrophoretic mobilities of light myosin fragments, when they have been prepared from different muscle types, suggest but do not prove that the nature of the light myosin fragments may determine myosin ATPase activity

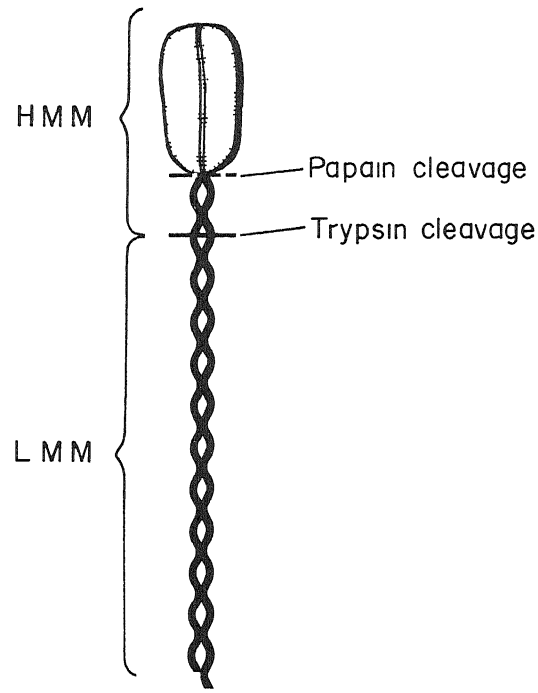

Fig 1 57 Sites of cleavage of the myosin molecule by papain and trypain

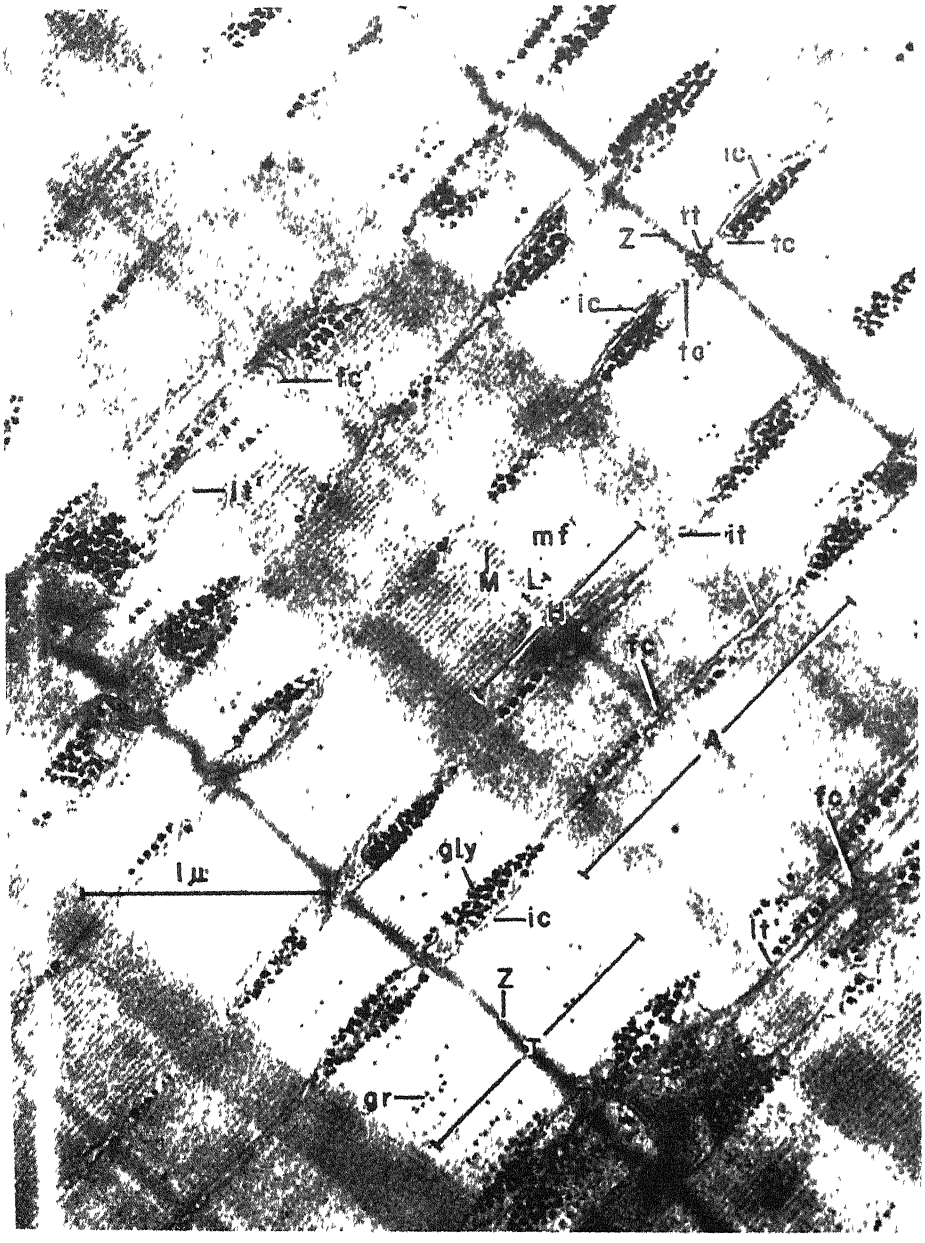
LMM exists in a highly ordered structure Like tropomyosin, LMM consists of two coiled parallel peptide chains each in the form of an α helix HMM, on the other hand, exists primarily in globular form with a short highly helical fibrous rodlike extension Acid treatment of HMM releases both the rod and the globular head of the molecule, the latter in the form of its two subunits each of which retains ATPase activity and the ability to combine with actin

Myosin can be split into subunits by 12 M urea and 5 M guanidine (as noted above) and also by other agents such as alkali and succinic anhydride The light subunit appears to be associated with the ATPase activity and the species specificty of myosin However, variants of the whole myosin molecule with characteristic amino acid sequences can be found in different muscles of the same animal and also in the same muscle at various developmental stages (vide infra)

The molecular weight of skeletal HMM is approximately 350,000 and that of LMM is approximately 150,000 The estimated molecular weight of the heavy fragments of myosin is between 112,000 and 180,000 whereas the



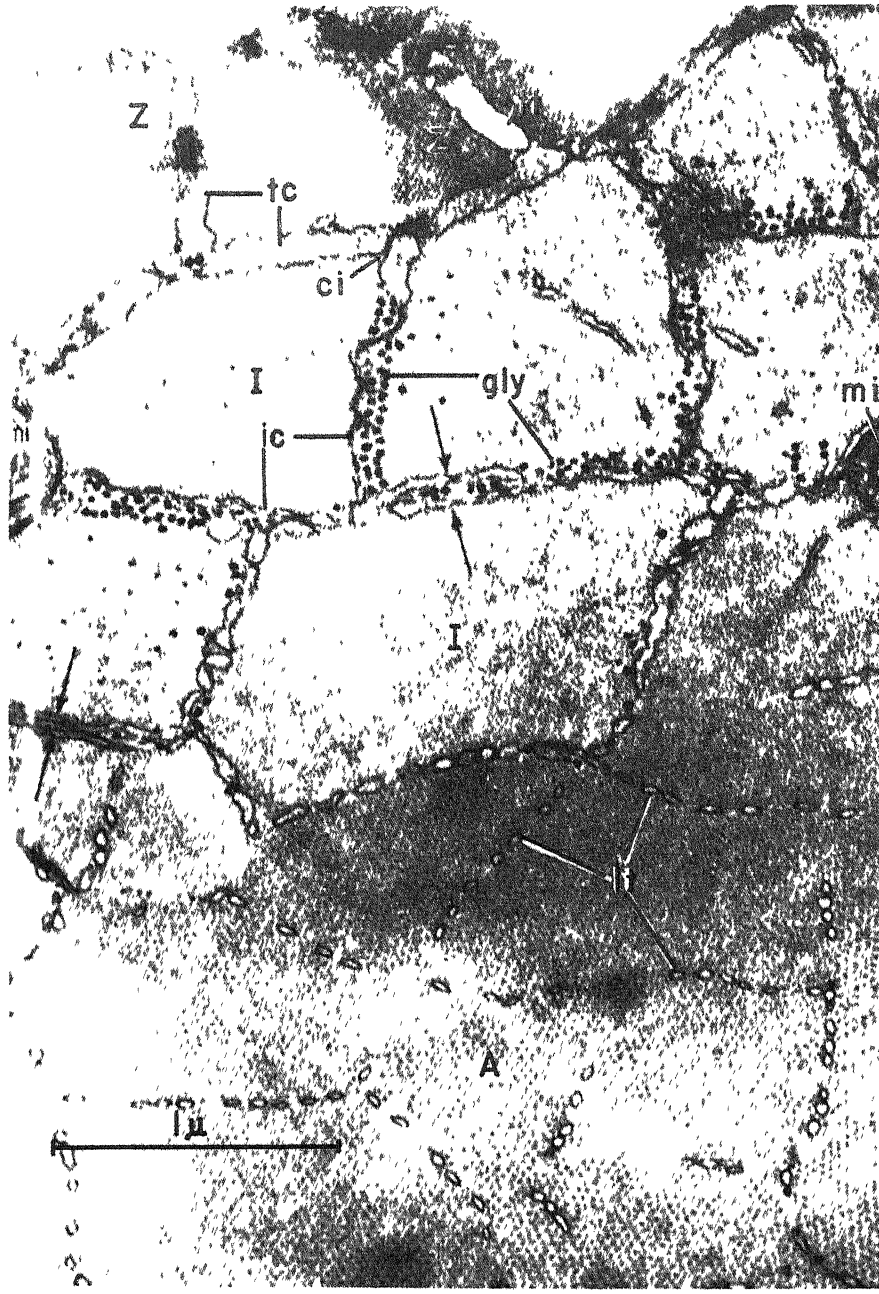


Fig 1 58 ***A*** Longitudinal section oriented with the long axis of the fiber extending from lower left to upper right in the figure The myofibrils (*mf*) show a typical transverse banding pattern with dense Z lines (*Z*) spaced about 3 μ apart at the centers of the light I bands (*I*) The A bands (*A*) have a central light H zone (*H*) and denser outer regions where primary and secondary filaments overlap At the center of each A band is a light L zone (*L*) with a dark M line (*M*) down its middle Triads consisting of two terminal cisternae (*te*) and a centrally located transverse tubule (*tt*) are seen adjacent to the Z lines (*Z*) of the myofibrils Connecting in the terminal cisternae are the intermediate cisternae (*ic*) Adjacent to the myofibrillar A bands elongated profiles of the longitudinal tubules (*lt*) and oval profiles of the fenestrated collar (*fc*) are seen These latter structures are also seen overlying the myofibrils at two places where the section grazes the surface of the myofibril (*fc'* and *lt'*) The large, densely stained granules are glycogen (*gly*) Smaller granules (*gr*) are found within the I bands (× 36 000) ***B*** Very thin, slightly oblique transverse section showing a Z line (*Z*) as dark patches with a square pattern at the upper left corner of the figure The I band (*I*) appears as the lighter areas around and below the Z line patches The A band (*A*) is at the bottom of the figure Near the Z

line and for about one-third of the I band the fibrils are completely surrounded by wide membrane-bounded elements of the triads Dark patches within these elements are interpreted as regions where the membranes of the central portion of the triad (transverse tubule and flattened ends of terminal cisternae) lie within the section The triad elements that are filled with granular material are the terminal cisternae (*tc*) and the very light patches (*tt*) are interpreted as areas where only the transverse tubule lies within the section, implying that the section thickness in this region is somewhat less than 300 A One interruption in lateral continuity of the terminal cisternae is indicated (*ci*) Below these elements in the figure but still within the I bands are found the narrower profiles of the intermediate cisternae (*ic*) These are found alongside and sometimes flanking both sides of the glycogen (*gly*) masses (see arrows) The intermediate cisternae extend as far as the edge of the I band Beyond this within the A band roughly circular profiles of the longitudinal tubules (*lt*) are seen Parts of two mitochondria (*ml*) appear in this figure (× 45 000)

myosin light fragments have molecular weights of approximately 20 000

5) Other Proteins of the Contractile Machinery In addition to actin and myosin and their derivative subunits, other proteins have been isolated from myofibrils One of these proteins appears to have been derived from the M line Another, of unknown derivation, modifies the aggregation of myosin However, at the present time the role of these proteins in the contraction-relaxation cycle of muscle is not known

A protein designated as α-actinin often isolated with actin, is found to increase the ATPase activity of myosin When bound to F-actin, the α-actinin-actin complex forms a gel The significance of α-actinin in muscular contraction however, remains in dispute

α-actinin has three distinct components, the lightest of which (6S component) has a molecular weight of 160,000, has been localized on the Z lines and can be displaced by troponin

β actinin, another protein associated with the contractile system of muscle, is probably an important determinant of the structure of the thin filament inasmuch as it has been shown to *1*) bind stoichiometrically to F-actin, *2*) inhibit the network formation of F-actin, and *3*) induce the formation in vitro of 1 μ filaments similar to actin filaments

THE SARCOPLASMIC RETICULUM

In 1902, Veratti observed a lattice or network structure in the muscle cytoplasm (sarcoplasm) similar to what is now recognized as the endoplasmic reticulum Veratti proposed that this newwork may be a continuation of nerve endings which function to convey the excitation process to the contractile elements These prescient observations and suggestions were ignored for over 50 years until the recent era of detailed, critical study of cellular ultrastructure

The ultrastructure of the sarcoplasmic reticulum (Fig 1 58) was first described by Bennett (1955) and by Porter and Palade (1957). They observed an elaborately anastomosing tubular network running parallel to the myofilaments The diameter of this tubular system was approximately 5 μ The slender tubules often extended the full length of the sarcomere and were closed at each end (terminal cisternae), the separation of two such adjoining cisternae taking place at the level of the Z line and amounting to 500 Å A third vesicular structure the transverse or T tubule was also identified in the gap between two adjourning terminal cisternae This *triad* of structures T tubule and two terminal cisternae were observed to repeat regularly in the I band at the level of the Z line or at the junction of the A-I band or at both sites depending on the type of muscle studied and the species from which it was obtained The regularly repeating pattern of the network (Fig 1 59) suggested from the outset that the sarcoplasmic reticular system in general and the triad in particular were intimately related to the function of the contractile elements

Recent studies of the embryonic development of muscle have shown that the sarcoplasmic reticulum (SR) originates from the nuclear membrane before the differentiation of myofila-

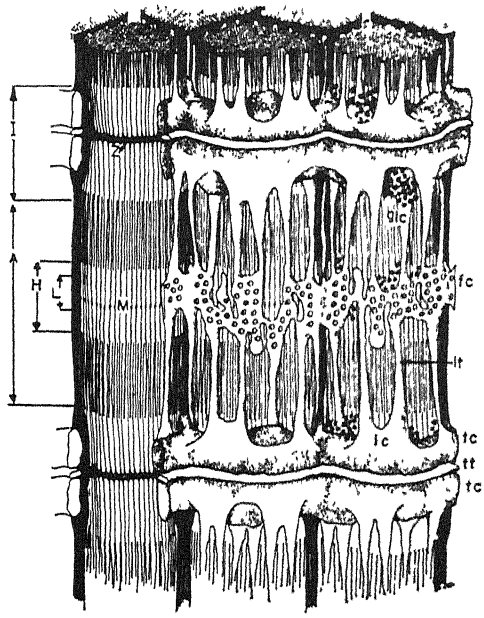

Fig 1 59 A three dimensional schematic diagram illustrating the sarcoplasmic reticulum and its relationship to the myofibrils The myofibrils show the light band (*I*) with the dense Z line (*Z*) at its center The A bands (*A*) have a central light H zone (*H*) and denser outer regions where primary and secondary filaments overlap At the center of each A band is a light zone (*L*) with a dark line (*M*) in its center Triads consisting of two terminal cisternae (*tc*) and a centrally located transverse tubule (*tt*) are seen adjacent to the Z lines of the myofibrils Connecting to the terminal cysternae are the intermediate cysternae (*ic*) and adjacent to the A bands they form the longitudinal tubules (*lt*) In the vicinity of the H zone in the center of A band the longitudinal tubules join the fenestrated collar (*fc*) *glc* glycogen granules (From Peachey 1965)

ments takes place and also that the SR lays the foundation for formation of the Z lines Other lines of evidence indicate that the central component of the triad (the T tubule) is an invagination of the sarcolemmal membrane which penetrates deep inside the fiber (Fig 1 60) For instance, it has been shown that if muscle is incubated with ferritin, the granules can be later found inside the T tubules It was also shown by Huxley and Taylor in frog and fish skeletal muscle, that following exploratory stimulation with minute electrical currents applied with a microelectrode at intervals of 1 μ along the length of the sarcolemmal membrane, a local contraction was elicited *only* when the stimulatory microelectrode was placed at the level of the Z line

In a similar experiment in crab muscle, a local contraction was elicited only at the A-I junction which, *in this species*, is the site in the sarcomere at which the T tubules are located These findings revealed an important relationship between the T tubules and the adjoining cisternae of the triad and also between the triad as a whole and the contractile elements (myofilaments) of the myofiber

More recently it has been shown *1*) that the T tubules of frog skeletal muscle can be shattered and converted into vesicles by soaking the tissue for about 2 hr in hyperosmotic Ringer's solution containing 20 to 50% glycerol and then subjecting the tissue to osmotic shock by returning the tissue abruptly to normal Ringer's solution, and *2*) that following this disruption of the T system it was not possible to elicit a contractile response even though an action potential could be recorded after electrical stimulation Thus, it was demonstrated that an in-

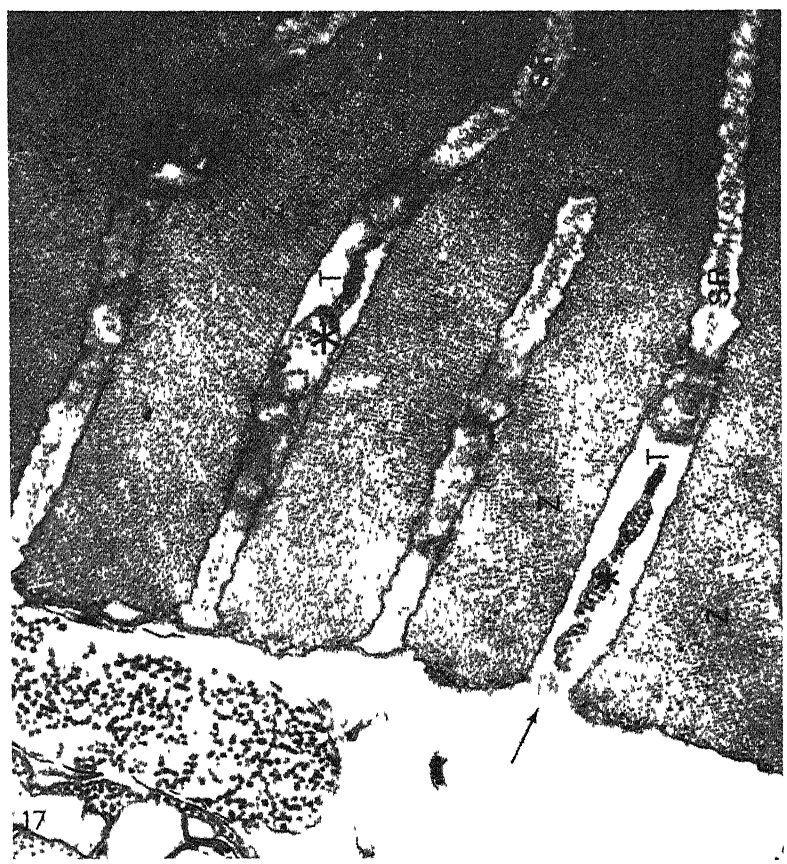

Fig 1 60 Transverse section of a glutaraldehyde-fixed muscle fiber to show the form and disposition of the T system The section cuts across the Z line (*Z*) and so includes the middle of the T system cisterna Openings or orifices of the T system (*T*) to the outside are shown at the arrow Strands of sarcoplasm (asterisk) which penetrate into the T system from neighboring fibers may be observed *SR* sarcoplasmic reticulum Original magnification × 38 000 (From Franzini-Armstrong and Porter 1964)

tact T tubular-triadic system is necessary for the electrical excitation of muscle to become translated into a contractile response

Theories of Contraction

FOLDING PROTEIN THEORY

There have been two concepts regarding the structural changes occurring during shortening According to an older concept, the contraction of muscle is associated with a splitting up of the compact myosin filaments at their ends into a number of subunits possibly consisting of individual myosin molecules, an interaction of these subunits with the actin filaments resulting in bonds being formed between the subunits and the actin, yielding drastic changes in the myosin subunits from the originally extended configuration to a compact configuration This would involve extensive conformational changes in the myosin molecules and would result in a pulling in of the actin filaments toward the center of the A band since the myosin subunits remain attached to the myosin filaments at the end which is located toward the center of the sarcomere The splitting up of the end regions of the myosin filaments would be an important first step since it would allow active sites on the myosin molecules to be exposed In the compact arrangement of myosin in the thick filaments these sites would be shielded from interaction with actin

THE SLIDING FILAMENT THEORY

According to the other concept of muscle contraction, the "sliding model," there are no extensive configurational changes occurring during contraction The actin filaments slide along the surfaces of the myosin filaments due to oscillatory, minute movements of the lateral process of the latter filaments with repeated alternative formation and breaking of bonds between myosin and actin The bonds are formed in the oscillatory cycle when the processes are in a position closest to the Z line, the bonds are broken when the processes have swung to their extreme position furthest from the Z line and closest to the center of the A band

The first evidence that led to the sliding filament theory came from electron microscopic observations which showed that cross-bridges link the actin and myosin filaments together across a gap of about 130 Å The bridges are seen as projections on the myosin filaments even in places where no actin filaments lie alongside them (for example in the H zone of stretched sarcomeres) but they do not project from the actin filaments in the portion of the I band which does not overlap with the thick (myosin) filaments Therefore it seems clear that the cross-bridges are permanent parts of the myosin filament structure On the basis of the above observations it was suggested that cross-bridge structures were the mechanical links between the thick and thin filaments It was also suggested that cross bridges probably represented the heavy meromyosin subunits of the myosin molecule Because the ATPase activity and the actin binding properties of myosin reside on the heavy meromyosin it is reasonable to regard this enzymatic activity as a built-in feature of the structure of the cross-bridges and to assume that the cross bridges have a special affinity for sites on the actin molecules

During a twitch, the frog sartorius sarcomere, which typically has a length of 2.5 μ, shortens by about 30%, the actin and myosin filaments sliding past each other by 0.375 μ in each half sarcomere

Huxley (1964) observed that variations in orientation of the cross-bridges can be seen in electronmicrographs of resting and contracted muscle The distal ends of the cross bridges never seem to be displaced by more than about 100 Å from the position they would occupy if the bridges were exactly perpendicular to the thick filaments Therefore, he proposed that, in order to produce the much larger overall sliding movement, some type of repetitive interaction of the cross-bridges with the actin filaments is necessary and he suggested two possible mechanisms for this interaction *1)* the cross-bridges move to and fro in a cyclic manner, first attaching to the actin filaments and pulling them toward the center of the A band in the initial phase of the cycle and then detaching again prior to their return stroke—similar to the action of a ratchet, *2)* the cross-bridges might remain rigidly fixed in position on the myosin filament while repetitive cyclic changes occur at fixed intervals along the actin filaments causing the latter to attach and then detach from the fixed cross-bridges, thus, moving to the center of the sarcomere (H zone) In either case, the central idea is that

the cross-bridges are attached to actin filaments while force is being developed and the cross-bridges serve as the agents through which the mechanical force is transmitted

From the known free energy of hydrolysis of ATP, it seems possible that splitting of 1 molecule of ATP per cross-bridge can provide enough energy for the actin and myosin filaments to slide past each other for a distance of 50 to 100 Å during a maximal shortening This is consistent with a model in which 1 molecule of ATP is split at each cross-bridge during one tension-generating cycle and in which each cross-bridge can go through its cycle only once during a relative movement of the filaments over a distance of 50 to 100 Å

In this context, there will be neither tension development nor significant energy release (ATP-cleavage) when this "make and break" filament cycle is not completed Thus, chemical energy release in muscle can be controlled *1)* by the tension developed (which is proportional to the number of cross-bridges that had time to attach themselves to the actin filaments at any given shortening velocity), and *2)* by the distance shortened (which would be proportional to the number of "make and break" cycles) This kind of system would release energy efficiently and in proportion to the work done

Strong evidence supporting the notion that the cross-bridges represent the heavy meromyosin end of the myosin molecules came from a comparison of the filamentous aggregates of light meromyosin (formed at physiological ionic strength) with aggregates formed under similar conditions by intact myosin molecules (Fig 1 52) The light meromyosin filaments were seen to consist of needle-shaped structures many microns long and of variable widths up to several thousand angstrom units, the surfaces of these filaments were perfectly smooth On the other hand, the filaments formed by aggregation of whole myosin molecules had a large number of projections on their surfaces over most of their length These latter filaments varied in thickness but were usually less than 200 Å in diameter and shorter than the light meromyosin filaments These synthetic myosin filaments were very similar in their appearance to the natural myosin filaments prepared from disrupted muscle It is therefore apparent that the cross-bridges observed by negative staining methods are equivalent to the cross-bridges in the sectioned material and, since they do not appear in the light meromyosin preparations noted above, they must be associated with the heavy meromyosin part of the molecule Their dimensions closely approximate those of the sectioned cross-bridges (40 to 50 Å by 120 Å) if shrinkage (ca 20%) of the sectioned preparations is taken into consideration

The width of isolated heavy meromyosin (determined by shadow casting technique) is about 40 to 50 Å in the globular region which is attached to a short tail approximately 400 Å long From the above observations it is concluded that the cross-bridges consist of the globular head of the heavy meromyosin, supported by an α-helical tail which lies in an approximately parallel position along the backbone of the myosin filament to which it ultimately attaches Myosin molecules are arranged in the thick filaments with a definite structural polarity so that the heads of the molecules are always directed away from the midpoint of the filaments Thus, all cross-bridges in one half of an A band have the same orientation (polarity) This polarity is reversed in the opposite half of the A band The actin monomers are also oriented oppositely on either side of their attachments to the Z line Thus, during contraction the sets of actin filaments in each half sarcomere are drawn toward the center of the A band and subjected to sliding forces oriented in opposite directions This polar organization of both the myosin and actin filaments is a fundamental condition of sliding filament theory

Accepting the evidence that the cross-bridges attach to active sites on the actin filaments in order to develop force, it is reasonable to link this interaction to the hydrolysis of ATP and the release of energy The fact that actomyosin has considerably greater ATPase activity than does myosin alone supports this idea It is not known whether ATP is split before, during, or after the combination of actin with heavy meromyosin (cross-bridges), however, there is no doubt that this force-generating interaction requires the transformation of energy from ATP into mechanical work Conversely, it is important to recognize that the chemomechanical transformations of muscle also *control* the release of energy from ATP (Fenn effect, vide infra)

The contribution of each cross-bridge to the force generated by contracting muscle will be considered in the discussion of the length-tension relationship At first it was assumed that cross-bridges undergo specific structural

changes when they interact with actin and split ATP However, measurements of the spacing between actin and myosin at different sarcomere lengths revealed that the filaments move closer together as the muscle is stretched and further apart when the muscle returns to rest length, the separation varying inversely with the square root of the muscle length Thus, as the sarcomere shortens from 2 8 to 2 0 μ, the side spacing increases by about 18% of its original value In absolute terms it has been estimated that the center to center distance between actin and myosin filaments may increase by 40 Å as the sarcomere shortens from 2 8 μ to 2 0 μ For contact to be made between actin and myosin filaments during contraction, the cross-bridges must adapt to these changes in spacing between the filaments without any qualitative alteration in function

The technique of negative staining has helped to elucidate some of the puzzling aspects of the actomyosin interaction For example, this technique has revealed significant irregularities in the repeating subunit of the actomyosin filaments The double helical structure of G-actin units remain clearly visible (Fig 1 61), whereas, no trace of an ordered structure (helix) can be seen in the projection of the myosin filaments However, when heavy meromyosin is reacted with actin, a clear regularly repeating pattern of arrowhead-like structures bound to the actin filament can be observed (Fig 1 62), these arrowhead-like structures represent myosin bound to the sites on actin at which the cross-bridges link It is not known why the sites of attachment of the head of the cross-bridges on the thin (actin) filaments are more orderly than the sites of attachment of the tail of the cross-bridges on the thick (myosin) filaments, however it is possible that the cross-bridges are more rigidly bonded to the actin filament than to the myosin backbone

Using x-ray diffraction Huxley had initially predicted that the contractile components (later identified as actin and myosin) must have different structures Further study of x-ray diffraction patterns indicated that in striated muscle of vertebrates the cross-bridge projections on the thick filaments are arranged on a two-stranded helix with three pairs of cross-bridges per 360° turn of the helix (6/2 helix) Each pair of bridges project out from the myosin backbone in opposite directions so that the two bridges in any pair form an angle of 180° with each other, i e , any pair of cross-bridges form a straight line at any given level. Taking any pair of cross-bridges as a reference, the nearest neighbor pair of bridges on either side occurs at a distance of 143 Å and is rotated relative to the reference pair by 120° This arrangement continues so that the full pattern repeats itself at intervals of 3 × 143 Å or 429 Å. (Fig 1 63)

On the basis of these observations a model

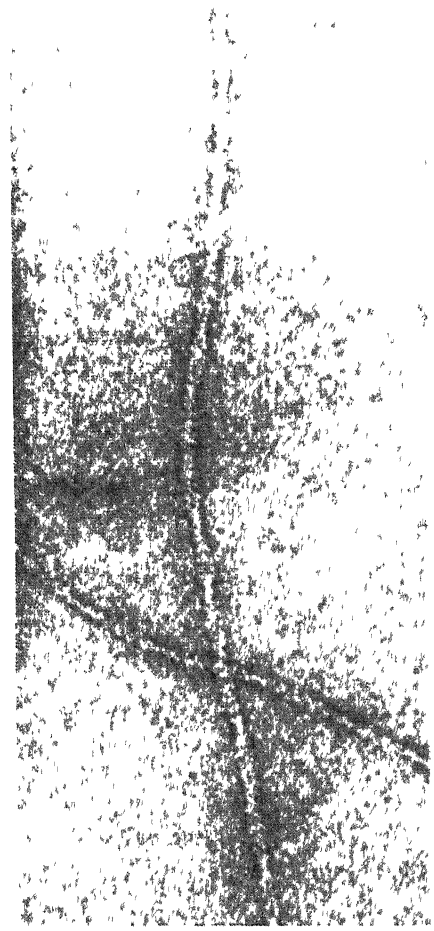

Fig 1 61 Electron micrograph of negatively stained actin filament, showing the double helical arrangement of two chains of globular subunits twisted around each other The subunit repeat in each chain is about 55 Å and the cross-over points of the two chains are 360 to 370 Å apart (Huxley, 1969)

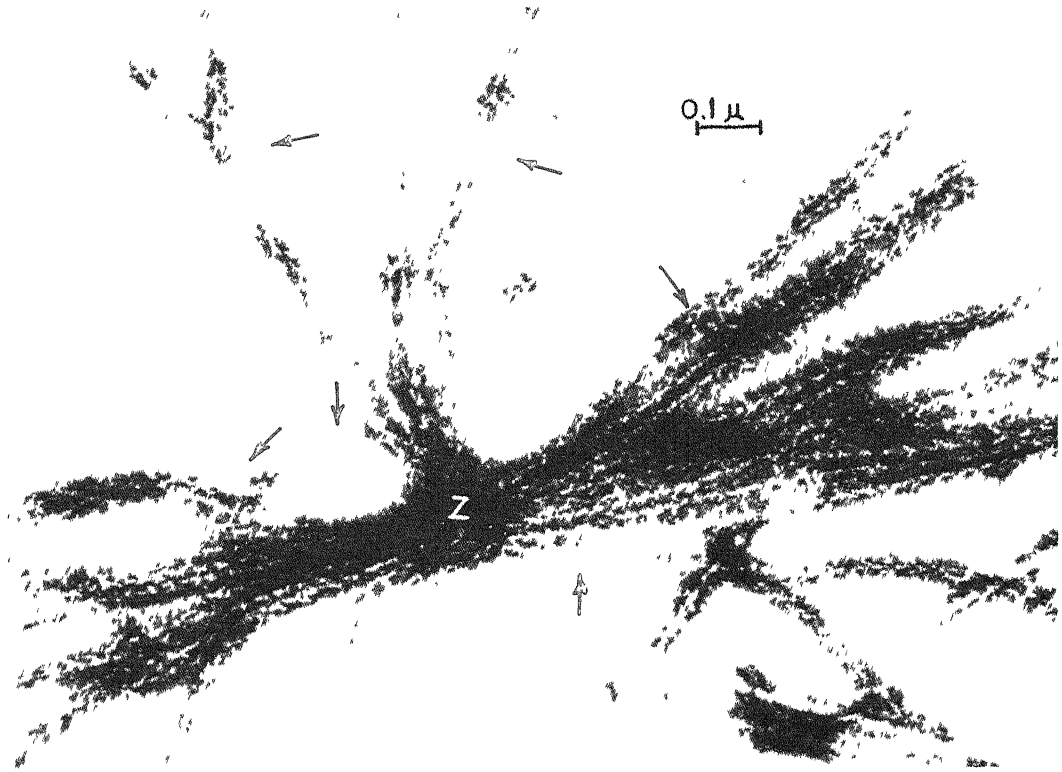

Fig 1 62 An isolated I segment has been treated with heavy meromyosin which attaches to the thin filaments producing arrowhead-like structures (note places indicated by arrows) These are polarized and point outward from either side of the Z line Segment prepared by blending glycerol-extracted muscle in a medium which separates thick and thin filaments (From Huxley 1963)

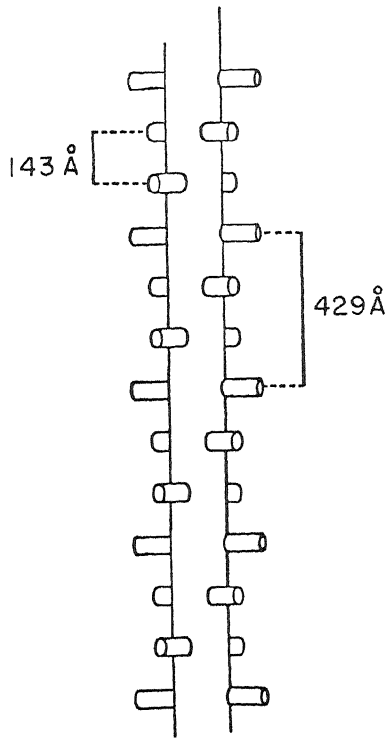
(Fig 1 64) has been suggested in which the cross-bridge projections are attached to the backbone of the myosin filaments at a distance of 60 Å from the center of the thick filaments and then extended outward beyond the myosin backbone for an additional 70 Å, thus, the total projection from the center of the myosin backbone is 130 Å The distance between the center of the thick filament and the surface of the actin filament is about 190 Å in a muscle at rest length Thus, these observations indicate that, at rest, cross-bridges do not reach the actin filaments It has also been noted that, at rest, the cross-bridges are not precisely fixed in position on the thick filaments

The x-ray diffraction patterns of the actin filaments show a nonintegral double helical structure, with subunits repeating at 54 6 Å intervals along both strands but the position of any subunit on one strand is staggered relative to the position of its nearest neighbor subunit on the other strand by half a subunit period (27 3 Å) The chains twist around each other with cross-over points at 360 to 370 Å intervals so that the pitch of the helix formed by either of the two chains is 720 to 740 Å (Fig 1 65) Off meridional reflections from both actin and myosin filaments indicate that the helices in the filaments may be able to twist and untwist to some extent, but the axial repeat of the subunits remains rather constant

When all the ATP in the muscle is lost and the muscle goes into rigor, it is believed that a major portion if not all of the cross-bridges become attached to actin filaments Since the subunit repeat of the actin and the spacing of the cross-bridges are entirely different, a matching of the cross-bridge and its binding site on the actin monomer occurs only once every several thousand angstrom units along the filaments, therefore, bonding of the cross-bridge to actin requires a change in conformation of the actin and/or cross-bridge molecules in going from the resting to the contractile state. Thus, x-ray diffraction studies of muscle in rigor reveal marked changes in the attach-



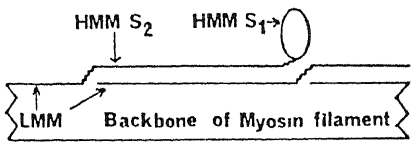


Fig 1 63 Diagram of cross-bridge arrangement on thick myosin-containing filaments of frog sartorius muscle which would account for the observed x-ray pattern (From Huxley 1969)

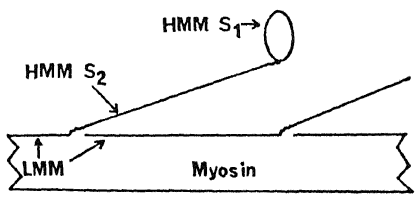

Fig 1 64 Suggested behavior of myosin molecules in the thick filaments The light-meromyosin (*LMM*) part of the molecule is bonded into the backbone of the filament while the linear portion of the heavy-meromyosin (*HMM*) component can tilt further out from the filament (by bending at the HMM-LMM junction) allowing the globular part of HMM (that is the S_1 fragment) to attach to actin over a range of different side-spacings while maintaining the same orientation (From Huxley, 1969)

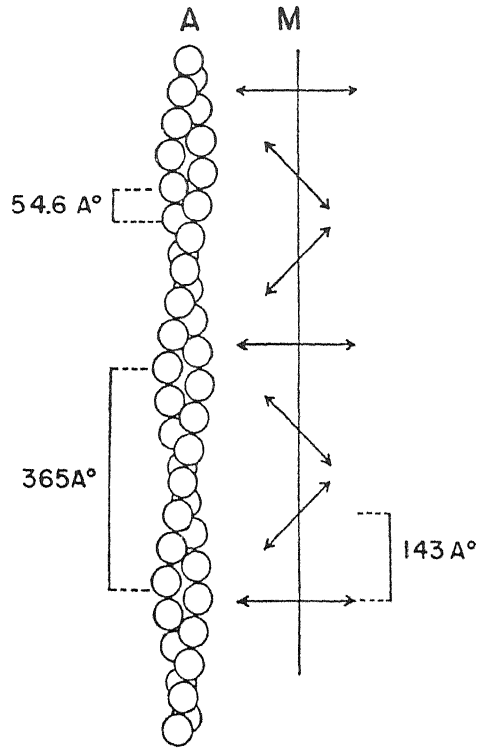

Fig 1 65 Diagram of the arrangement of G actin monomers in actin (*A*) filaments derived from x ray diffraction and electron microscope observations Both the pitch of the helix and the subunit repeat differ from those of the myosin (*M*) filaments indicated schematically alongside Thus cross-bridges between filaments would act asynchronously and a sequence of them would develop a fairly steady force as the filaments moved (From Huxley 1969)

ment of the cross-bridges to actin but no change in the actin filaments per se The 429 Å repeat pattern of the cross-bridges disappears completely indicating that a large portion of the cross-bridge structure is displaced from the position it normally occupies during rest The pattern observed in rigor indicates a helical pitch of 720 Å which approximates the helical pitch of the actin filaments This observation confirms that, in rigor, a high proportion of the cross-bridges attach to the actin filaments.

The axial separation of the cross-bridges remains unchanged at 143 Å during rigor although the bridges rotate away from the myosin backbone, and thus extend more perpendicularly toward the actin filaments. With this reorientation a span of 5 cross-bridges (5 × 143 Å) closely matches the 720 Å pitch of the

actin filaments permitting an increase in the number of bonds formed

The Myosin Filament Model Huxley has suggested that cross-bridges are attached at their bases to the backbone of the myosin filaments by a short subunit tail which is soluble in physiological solutions This tail (approximately 400 Å in length) is attached to the thick filament only at one end This type of attachment makes it possible for the cross-bridges to move away from the backbone toward the actin filament As noted above the attachment of the heavy meromyosin (HMM) tail to the light meromyosin (LMM) of the thick filament backbone is susceptible to trypsin digestion and, therefore, probably represents a less than helical, flexible region of the molecule Similarly, the junction between the linear part of the HMM tail with the globular head is also susceptible to enzymatic digestion (with papain) and this site of attachment probably also constitutes a flexible site Therefore, the presence of two flexible points on the tail of the cross-bridge would give the HMM head the mobility needed for it to become properly oriented towards the actin filament during contraction (Fig 1 66*A*, *B*, and *C*)

On the basis of both mechanical and biochemical considerations, the flexible tail of the cross-bridge cannot itself account for the development of tension during contraction inasmuch as the ATPase activity of HMM remains with the globular head after the linear tail is removed by enzymatic treatment However, the orientation of the linear tail to the thick filament backbone suggests that the tail serves to sustain the tension which is developed by the globular end of the HMM cross-bridge Observations of interactions between cross-bridges and actin filaments indicate that globular HMM binds tightly to actin at least during part of the contraction cycle, therefore, Huxley has suggested that the linkage of the globular HMM to actin is the most stable and rigid (al-

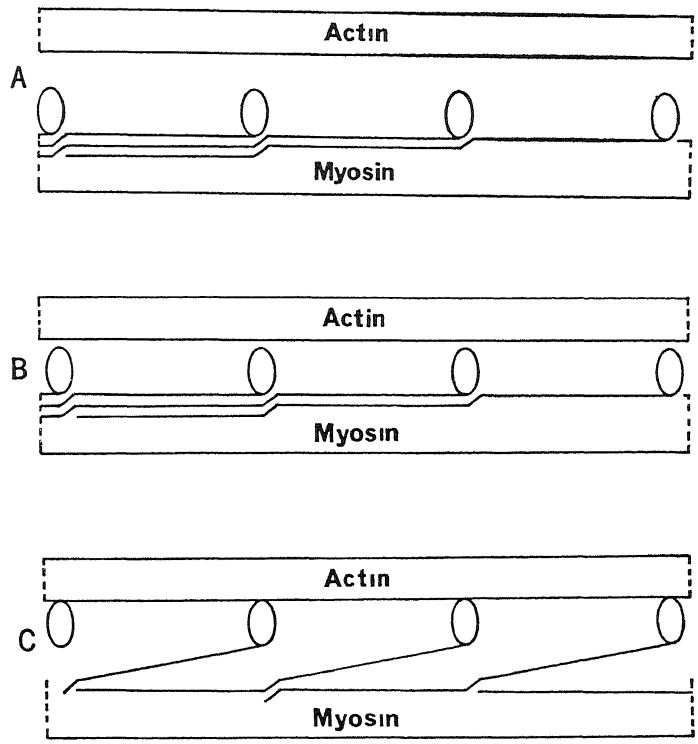

Fig 1 66 Diagram showing relative positions A of filaments and cross-bridges at two different interfilament spacings [(*A*) 250 Å and (*B*) 200 Å] corresponding, in frog sartorius muscle to sarcomere lengths of ~2 0 and ~3 1 μ The x-ray diagram (not shown) suggests that in a relaxed muscle the cross-bridges do not project very far toward the actin filaments During contraction or in rigor the cross-bridges could attach to the actin filaments by bending at two flexible junctions as shown in (*C*) (From Huxley 1969)

belt temporary) attachment between the thick and thin filaments In this hypothesis, tilting of the globular HMM head of the cross-bridge at the site of attachment to the actin would initiate the sliding of the actin filament along the myosin filament (Fig 1 67*A*) In an alternative hypothesis, a similar sliding of the actin filament is initiated by a mechanism involving oppositely directed movements of the paired subunits in each globular head of the cross-bridges (Fig 1 67*B*)

In summary, *1*) the ATPase activity of myosin and the high affinity of the cross-bridges for actin is associated with the globular HMM head of the cross-bridge, and 2) the sliding of the thin (actin) filament along the thick (myosin) filament depends on a characteristic cycle of attachment, movement, and separation of the HMM head of the cross-bridge to successive sites along the actin filament as well as on the adaptability of the long (400 Å) flexible HMM tail of the cross-bridge

Davies (1963) has advanced an hypothesis of muscle contraction based on the molecular structure of the contractile elements This theory has the following assumptions *1*) the ATP-binding site is located at the end of a mobile polypeptide which is a component of the HMM cross-bridge The bound ATP is held by three electrostatic positive charges (probably Mg^{++} ions linked to negative charges on the protein) *2*) There is a fixed negative charge (perhaps phosphorylserine) inside the HMM, near the mobile polypeptide which repels the negatively charged ionized ATP so that during rest the assymmetric polypeptide chain is uncoiled *3*) When the muscle is activated, the depolarization of the sarcoplasmic reticulum liberates enough calcium to make chelate links between the bound ATP of the extended HMM polypeptide and the bound ADP of the F actin This step provides the link for electrostatic bond formation between the actin and myosin filaments and neutralizes the negative charge on the terminal phosphate resulting in the abolition of the repulsive force within the HMM Thus the extended polypeptide recoils and forms an α helix by twisting and forming hydrogen bonds as well as hydrophobic bonds If the magnitude of the force thus created is great enough to overcome the resistance of the series elastic elements, actin molecules will be pulled along the myosin filament and the muscle will shorten *4*) The ATPase activity of HMM is inside the cross-bridge with no access to free cytoplasmic ATP When the polypeptide chain coils, bound ATP is moved within the range of activity of the HMM ATPase, which then hydrolyzes the ATP and breaks the link between

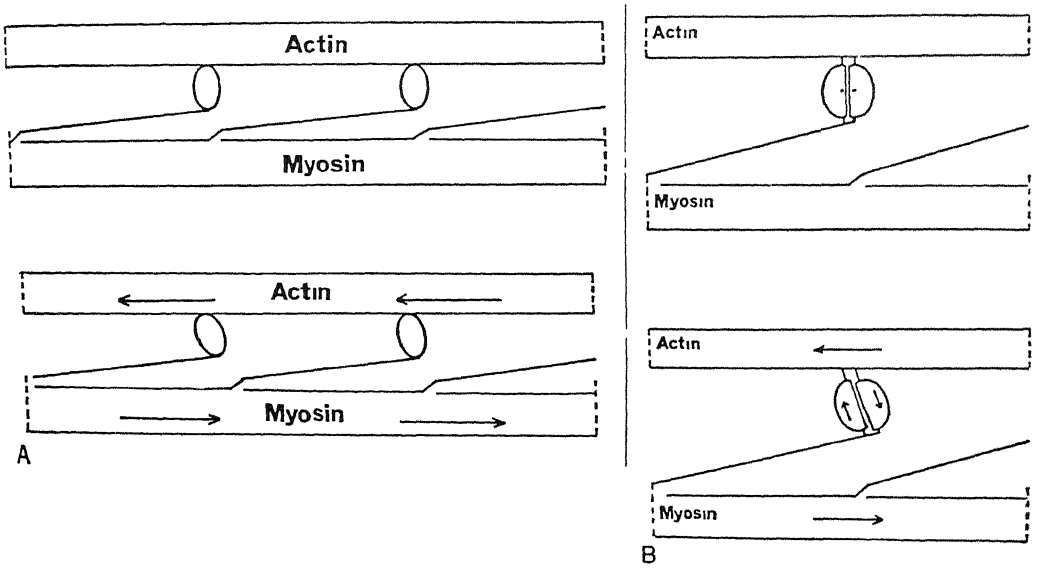

Fig 1 67 Diagram illustrating possible mechanisms for producing relative sliding movement by tilting of cross bridges *A* If separation of filaments is maintained by electrostatic force-balance, tilting must give rise to movement of filaments past each other *B* A small relative movement between two subunits of myosin could give rise to a large change in tilt by the mechanism shown (From Huxley 1969)

actin and myosin ADP bound to the cross-bridge is rephosphorylated in the next step by cytoplasmic creatine phosphate

ADP may also slowly exchange with cytoplasmic ATP The formation of ADP would thus serve to inhibit the activity of ATPase When ATP is regenerated, its negative charge will repulse the negative charge inside HMM so that the latter is extended along the actin filament 5) This process repeats itself as long as Ca^{++} ions are present However, because Ca^{++} ions are quickly sequestered by the sarcoplasmic reticulum, this active state is soon ended The sequestration of Ca^{++}, being an active process, is also accomplished with the energy derived from ATP According to Davies the energy for contraction is provided by the formation of hydrogen bonds which had been previously split by the action of ATP

On the basis of the above theory, Davies has suggested a number of explanations for many of the phenomena of muscle contraction, i e, *1*) the number of Ca^{++} ions required for maximal contraction must be equal to the number of cross-bridges, *2*) the length of latent period is equal to the time it takes the released Ca^{++} ions to reach the sites of linkage between actin and myosin (the latent period also includes the time taken up by the events leading up to the release of Ca^{++} and by the actual activation of actomyosin to contract), *3*) following stimulation, the early volume alteration of muscle (first increase and then decrease) and the phenomenon of latency relaxation may be associated with differences in electrostriction between the states of Ca^{++} tightly bound in the sarcoplasmic reticulum, in free solution in the sarcoplasm, and in the postulated bond between the nucleotides, *4*) the increase in the resistance to stretch following stimulation is associated with Ca^{++} chelate links which form prior to contraction, *5*) activation heat may be due to the dissociation of Ca^{++} from their tightly bound sites in the sarcoplasmic reticulum

The Single Muscle Twitch

MECHANICAL CHARACTERISTICS OF MUSCLE

A relaxed, unstimulated muscle is elastic and offers little resistance to stretch The force needed to stretch the muscle increases, however, as the muscle is being extended The tension developed in the muscle as a consequence of stretching does not increase linearly but approximately exponentially as the length of the muscle increases (Fig 1 68)

If resting muscle is exposed to a small load its elasticity is "rubber-like," that is, it shortens when warmed and lengthens when cooled At greater load, i e at greater initial length, the elasticity is normal and not "rubber-like "

The elasticity of the resting muscle has been ascribed to properties of the contractile material itself or to the sarcolemma which involves the plasma membrane of the muscle fiber, the "basement membrane" material coating the outer surface of the plasma membrane and connective tissue elements associated with the muscle fiber surface At moderate degrees of stretch it is unlikely that the sarcolemma would contribute substantially to the elasticity of the muscle

When a muscle or a single muscle fiber is stimulated by a single stimulus while extended by a moderate load, there is a brief lag between the arrival of the stimulus and the initiation of tension development This lag is referred to as the *latent period* (2 to 3 msec in the frog sartorius muscle) When the tension has reached a value exceeding the stretching force exerted by the load, the muscle shortens rapidly This development of contractile force is transient, and as the contractile force decreases, the muscle lengthens and returns to its relaxed condition (Fig 1 69)

If a muscle is allowed to shorten freely under a given load (isotonic contraction) and this experiment is repeated applying different

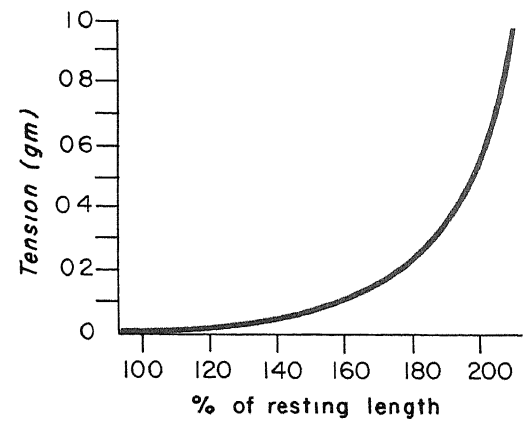

Fig 1 68 Static length-tension diagram of isolated single muscle fiber at rest (From Buchthal et al, 1951)

loads, the degree of shortening as well as the velocity of shortening are found to be dependent on the load With increasing load, the amount of shortening and the velocity of shortening decrease and the latency period increases

If the stimulus is repeated at a sufficiently high rate the muscle will not relax between each stimulation but rather will remain in a contracted state which is referred to as *tetanus* The plateau of such a tetanic contraction exceeds the peak of a single twitch and, in fact, represents the maximum contractility of which the muscle is capable This plateau is maintained until the muscle begins to fatigue at which time it relaxes gradually However, if stimulation is discontinued prior to the onset of fatigue the tetanized muscle relaxes immediately (Fig 1 70)

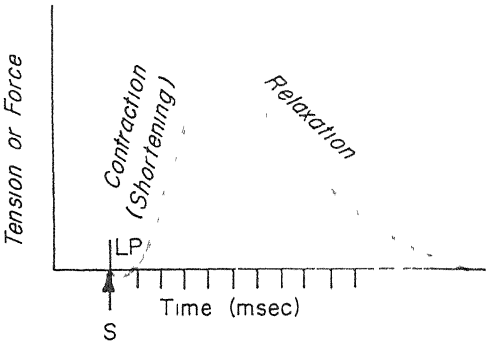

Fig 1 69 Simple muscle twitch *S* stimulus *LP* latent period

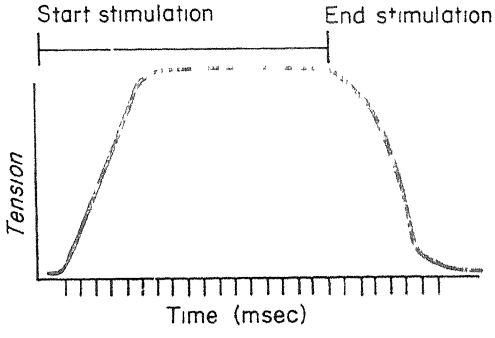

Fig 1 70 Tetanic tension in response to high frequency stimulation skeletal muscle develops and sustains a level of tension greater than that of the simple twitch

CHANGES IN THE EXCITABILITY OF THE MUSCLE DURING THE CONTRACTION-RELAXATION CYCLE

As noted above, a simple muscle twitch is characterized by a short period during which tension is being developed, the contraction phase, followed by a relaxation phase during which the muscle returns to a resting condition If an initial single effective (threshold or suprathreshold) stimulus is followed by a second stimulus of the same or greater intensity, the muscle will or will not respond to the latter stimulus depending on the time interval between the first and second stimulus In other words, there is a brief period following stimulation during which a second stimulus cannot elicit a response (Fig 1.71) This period of inexcitability is referred to as the absolute refractory period (ARP) or as the effective refractory period (ERP) The duration of this period of inexcitability varies from 5 to 50 msec in various skeletal muscles Then the excitability of the muscle returns gradually so that stimuli of greater than threshold intensity will evoke a response although threshold stimuli are ineffective This period is called the "relative refractory period" (RRP)

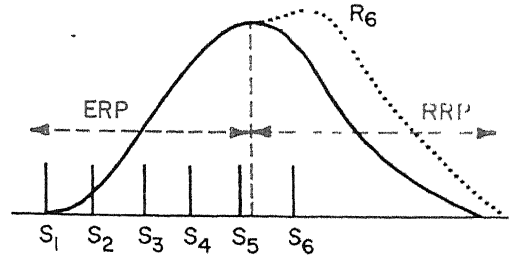

Fig 1 71 Effective and relative refractory periods *S*, stimuli given to the muscle at intervals *R* response of the muscle (a twitch), R_6 shows response to stimulus S_6 *ERP*, effective refractory period *RRP* relative refractory period

The duration of the effective and relative refractory period varies from muscle to muscle (Fig 1 72) In fast muscles, the ERP and RRP are much shorter, therefore, fast muscles can respond to higher frequencies of stimulation For example, the insect flight muscle, which has a total response time (i e , the time required to complete one full cycle of contraction and relaxation) of 2 to 3 msec , can twitch so rapidly that it literally flutters (at a frequency of approximately 300/min)

THE MOTOR UNIT

In normal skeletal muscles, fibers probably never contract as isolated individuals. Instead several of them contract at almost the same

moment, all being supplied by branches of the axon of one spinal motor neuron In other words, when the motor neuron is excited by a stimulus at or above threshold, all muscle fibers innervated by the neuron will be activated The single motor neuron and the group of muscle fibers which it innervates is called a *motor unit* (Fig 1 73), this is the smallest part of the muscle that can be made to contract independently The number of muscle fibers in this unit varies in different muscles, from 2 to 3 to more than 1000, the size of the unit is correlated with the precision with which the tension developed by the muscle is graded (see below)

The gradation of the tension developed by a muscle depends on variation in the number of motor units activated as well as on the frequency at which each unit is stimulated

OTHER CHARACTERISTICS OF A SINGLE TWITCH

All-or-None Response Stimulation at threshold intensity (minimum effective stimulation) evokes a minimal twitch tension There is one response to one stimulus If the intensity of the stimulus is increased stepwise the amplitude of the twitch tension will likewise increase However, with continued increase in the intensity of stimulation, a maximal contractile response is attained after which further stimulation no longer results in a change in the amplitude of the twitch tension (Fig 1 74)

The explanation for these responses lies in the fact that with low intensity stimuli, only the most excitable nerve fibers respond and activate their respective motor units, but as the intensity of the stimuli is increased, more motor units are recruited until finally all motor units are responding at which time the twitch tension is maximal and, therefore, an increase in the intensity of the stimuli can no longer elicit an increased response It is to be noted that the *individual* motor unit responds in the classical "all-or-none" manner Recently, it has been possible to tease single muscle fibers and record their tension, in such preparations the "all-or-none" law is clearly demonstrated

The Series Elastic Element. If a muscle is rapidly stretched during the early part of a contraction, or even during the latter part of the latency period, it can be demonstrated that it is capable of developing a considerably greater tension than that recorded under normal conditions (i e , without stretching) at the same time after stimulation This observation has been interpreted to reveal the presence in the muscle of an elastic element coupled in series with the contractile elements Following stimulation, the shortening of muscle is delayed because the

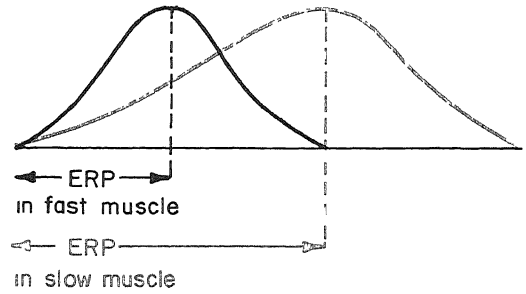

Fig 1 72 Relative duration of effective refractory period (*ERP*) in fast and slow muscles

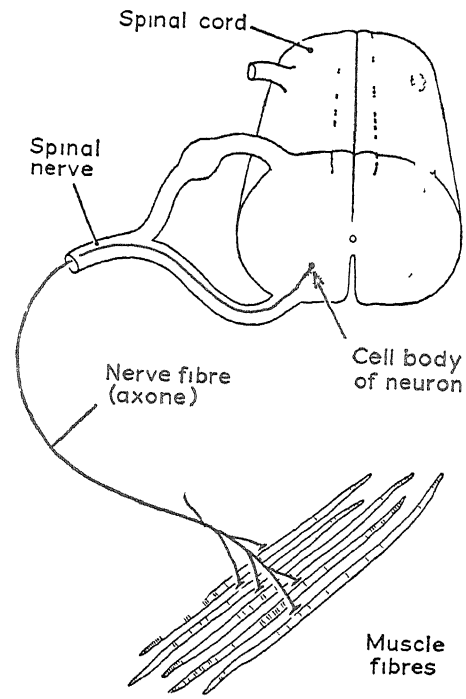

Fig 1 73 Diagram of a motor unit

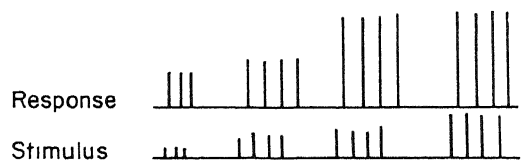

Fig 1 74 Recruitment of motor units with increasing stimulus intensity The response of the individual unit is 'all-or-none but the threshold of excitability varies among the units

contractile elements must first stretch the series elastic elements before a tension can be recorded externally

The quick-stretching experiments also show that the contractile machinery is activated already during the latency period and that this activation, the "active state," very rapidly reaches a maximum which is maintained at a constant level for only a short period of time

The existence of a series elastic element can be demonstrated in an obvious way by quickly releasing one point of fixation of an isometrically contracting muscle and allowing it to shorten to a new equilibrium length The tension then falls to zero before a new level of tension develops which is characteristic for the newly established length This instantaneous fall in tension has been ascribed to the undamped series elastic element

It is likely that at least part (about half) of the series elastic element resides in the contractile system itself and more specifically in the filamentous structure in which the main muscle proteins are arranged, although the suggestion has also been raised that the Z line structure is the site of the series elastic element

Resting Tension. It has been observed that muscle which is neither stimulated nor stretched beyond the normal body length still maintains some degree of tension, a phenomenon which is revealed by the simple fact that if a tendon is cut in vivo its associated muscle shortens Recently, Hill (1970) has adduced evidence that resting tension is due to residual long-lasting interactions between actin and myosin filaments and that it increases with rising ambient temperature

Latency Relaxation. When a loaded muscle is stimulated, the first mechanical response which appears during the latent period is a slight lengthening which is referred to as latency relaxation This phenomenon, which must be due at least in part to the release of resting tension, begins about 1 0 to 1 5 msec after stimulation (frog sartorius) and lasts for about 2 msec

It is likely that latency relaxation reflects the disruption of long-lasting cross-bridge bonding between myosin and actin filaments just prior to the initiation of the more rapid "make and break" cross-bridge bonding associated with the sliding process

Latency relaxation is most marked at longer lengths of muscle and is not at all evident when the muscle length is substantially (10% or more) below the normal body length

ISOMETRIC CONTRACTION

When the two ends of a muscle are held at fixed points, stimulation causes the development of force without change in muscle length (isometric tension) If adequate stimulation is delivered so that all muscle fibers are synchronously contracting, the isometric tension following a single stimulus changes as shown in Figure 1 69 If multiple stimuli of increasing frequency are delivered, the isometric tension follows the same curve as the single twitch however, tension increases until it reaches a maximum level which is maintained until the stimulation is discontinued This sustained maximal isometric tension, as in the case of sustained isotonic contraction is referred to as *tetanus*, and constitutes the maximum tension that the muscle can develop Tetanic tension will decline shortly after the stimuli have ceased and the muscle then relaxes with a characteristic time course Isometric tension is also dependent on the length at which the muscle is kept during the experiment The length tension relationship for isometric contraction (Fig 1 75 *A* and *B*) shows a maximum tension at a length slightly less than the length of the muscle in the body This amounts to about 3 5 kg /cm ^{2} It is important to recognize that the curve 3 in Figure 1 75 *B* is a composite of active and resting tension If the component of resting tension (curve 1, Fig 1 75 *B*) is subtracted, the curve of residual active tension vs time will rise and fall (curve 2, Fig 1 75 *B*) indicating that active tension declines as the muscle is stretched beyond normal body length These length-tension relationships can be explained in terms of the sliding filament theory of muscle contraction When tension is minimal, the length of the muscle is referred to as initial length (L_i) With the muscle length at L_i (considerably less than body length) the actin filaments overlap each other in the center of the sarcomere (Fig 1 56 *D*) to such an extent as to reduce the number of active sites available for interaction with myosin As the sarcomere is stretched, the "abnormal" overlap of the actin filaments is progressively reduced and accordingly, more active sites become available for linkage to the myosin cross-bridges. As the

muscle approaches the normal body length, the length at which tension becomes maximal is defined as optimal length (L_o) In this condition the position of the actin and myosin filaments is such as to provide a maximum number of active sites for interaction (Fig 1 56 *B*) As the muscle is further stretched beyond the optimal length the overlap of actin and myosin filaments is again progressively reduced and contractile tension diminishes until a point is reached at which there is no overlap (Fig 1 56 *C*) and, consequently, no active tension can be developed At this point the muscle is at maximal length (L_{max})

In isometric contraction the shortening of any contractile element is minute and a moderate configurational change associated with the lateral projections (cross-bridges) of the myosin filaments can account for the development of tension This would imply that, during isometric contraction, a large number of subunits in the myosin filaments could interact synchronously to develop tension, the number depending on the degree of overlap The highest isometric tension has been recorded when the zone of overlap extends the entire length of the myosin filaments over which cross-bridges are present This implies that the development of maximum tension during isometric contraction is related to the condition allowing maximal interaction between myosin and actin During isometric contraction, how-

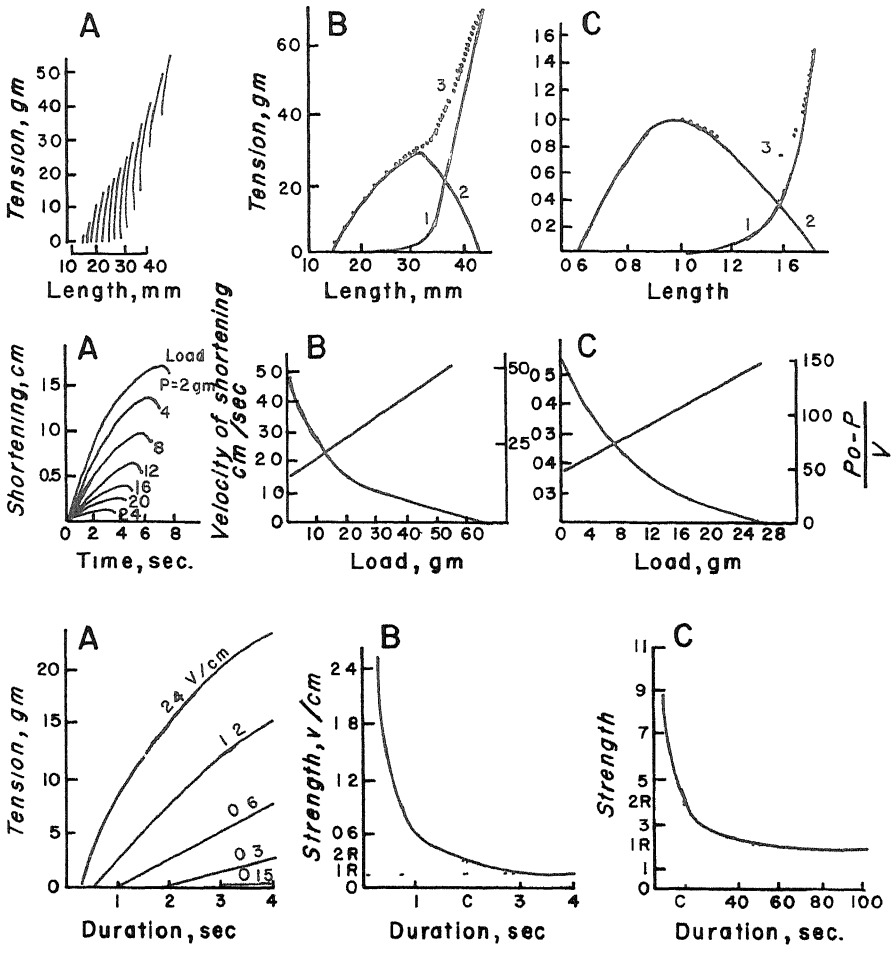

Fig 1 75 The length-tension load-shortening velocity and strength-duration relations of the frog sartorius and the rabbit uterus The first picture in each row is an original record from an experiment with the uterus the second is a plot from the first record to be compared with the third in each row illustrating the same experiment with the frog sartorius Note the general similarities between the frog sartorius and the rabbit uterus in each of the three relations (Csapo 1960)

ever, the conditions for interaction between myosin and actin can be restricted, since it is mainly the subunits located at the ends of the myosin filaments which are involved, and since the length of the sarcomere determines the number of actin-myosin interactions

ISOTONIC CONTRACTION

When one end of the muscle is free, it shortens while exerting a constant force The curve of isotonic contraction begins with a short period of increased rate of shortening which is followed by a "linear period," i e , a period of shortening at a constant rate during which the force of muscular contraction just overcomes the gravitational force The degree of shortening of a muscle bears a direct relationship to the load upon which it exerts force A progressive increase in the frequency of stimulation (at suprathreshold levels) will evoke a partial and then a complete state of tetanus which, under conditions of isotonic contraction, is characterized by sustained maximal shortening (Fig 1 70) The additional shortening observed during tetanus as compared with the shortening observed during a single twitch indicates that in the latter circumstance the muscle is not fully activated

FORCE-VELOCITY RELATIONSHIP

If a muscle is contracting isotonically (i e , shortening against a load), the velocity of contraction is inversely related to the load which the muscle is lifting If the muscle is unloaded it shortens with maximum velocity and as the load increases, the velocity of shortening declines When the load reaches a maximum (which is equal to the maximum isometric tension the muscle can develop), the muscle no longer shortens The relationship between load and the velocity of shortening is hyperbolic except at the extremes as shown in Figure 1.76 Hill (1970) and co-workers adduced the following empirical equation on the basis of data obtained from frog sartorius muscle tested at 0° C

$$(P + a)(V + b) = \text{constant} \qquad (1)$$

where P is the load applied to the muscle, V is the velocity of shortening and a and b are constants with dimensions of force and velocity, respectively It can be seen from Figure 1 76 that when $P = P_o$, $V = 0$, P_o being defined as

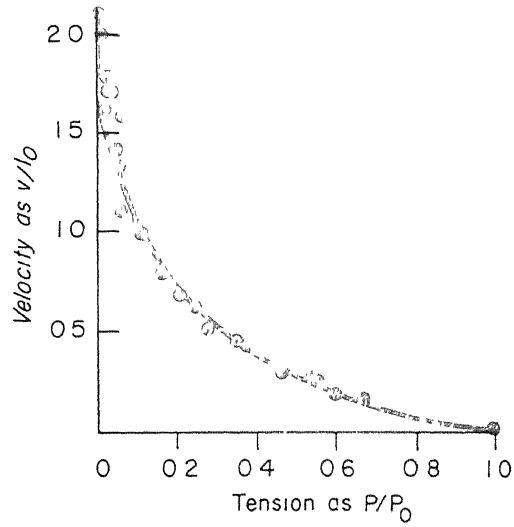

Fig 1 76 Force velocity relation, derived from experiments made with velocity as the independent variable Velocity as v/l_o, force as P/P_o Twenty four measurements in three experiments are shown as circles The curve was drawn from the usual equation with constants given in the text (From Hill 1970)

the maximum isometric tension that the muscle can develop, therefore

$$(P_o + a)b \quad \text{constant} \qquad (2)$$

Therefore

$$(P + a)(V + b) \quad (P_o + a)b \qquad (3)$$

Equation 3 can be rearranged to take the following form

$$(P + a)V \quad (P_o \quad P)b$$

This equation states that the rate of extra energy liberation during contraction (over and above the energy used for activation and maintenance of tension) is inversely and linearly proportional to load This follows because both P and a have dimensions of force and $V \quad dx/dt$, the rate of change in length. Thus, $(P + a)V$ is the rate of release of energy (force x distance) with time The right hand term $(P_o - P)b$ increases as load (P) decreases, b being a constant of proportionality The significance of this observation was recognized long before the advent of sliding-filament theory by Hill (1938) who postulated "that the inverse dependence of energy release upon load could be explained if each active point in the molecular machinery (i e , those sites which generate tension and effect shortening) could exist in one of the two following states *1)* in combi-

nation with each other and thereby developing tension or 2) uncombined or free, and thereby able to take part in chemical transformations At any instant the distribution of the active points between those two states would be determined by the load which the muscle bears If the ends of the muscle are fixed, so that no external shortening occurs and the tension developed is at its maximum (isometric contraction), all active points would tend to be in the combined state Thus, P_o (maximal tension, P at zero velocity) should be determined by the total *number* of active points With lighter loads fewer points would be in the "cimbined" state and more in the "free" state, until both shortening velocity and the rate of energy release are maximal when the muscle shortens freely at zero load Here, because essentially all active points are in the free state, the maximal shortening velocity (V_{max}) will be determined by the intrinsic rate at which the active points are able to undergo cyclic position changes which effect shortening As a result, the limiting *rate* at which the active points of the contractile machinery couple and uncouple should determine both V_{max} and the maximal rate of energy release"

If the term "active point" is replaced by the phrase "actin-myosin interaction", Hill's entire analysis can be translated into present day concepts of the contractile process including the correlation of V_{max} and the rate of myosin ATPase activity (Bárány, 1967)

Hill observed that the constant, a, was independent of temperature and had a value of 15 g when the maximum isometric tension (P_o) was 60 g Therefore, he postulated that in general the value of the fraction, a/P_o, was equal to 0 25

From (3) it follows that when

$$P = 0 \text{ and } V = V_{max}, \text{ then}$$

$$a\ V_{max} = b\ P_o$$

and, rearranging,

$$V_{max} = b/a\ P_o \qquad (4)$$

Thus, substituting Hill's values (P_o = 60 g , a = 15 g)

$$V_{max} = 4b \qquad (5)$$

Unlike a, b is temperature dependent exhibiting a Q_{10} ranging from 2 to 2 5 Thus, b appears to be related to chemical processes underlying the mechanism of shortening The value of b varies from muscle to muscle

Further experiments involving the velocity of contraction, load, heat production and work performed by muscle provided independent data supporting the validity of the constants, a and b, as employed in the Hill equation In these experiments the apparatus used to measure the generation of heat by muscle consisted of an elaborate system of thermocouples (referred to as a thermopile) connected to an ultrasensitive galvanometer (Fig 1 77)

HEAT PRODUCTION DURING THE CONTRACTION-RELAXATION CYCLE

Muscle contraction is associated with heat production, a sign of the chemical and physical events associated with contraction A rise of temperature in muscle can be measured to within about 10^{-5} ° C, and the time-course of heat liberation can be resolved within a few milliseconds with the thermoelectric method, a technique which provides the only means to follow the rapid internal physical and chemical changes occurring during and after a contraction

The heat production of unstimulated muscle amounts to 0 0002 cal /g min and is referred to as "resting heat " The heat produced during a single muscle twitch is about 0 003 cal /g and appears as *1*) an initial very rapid heat production which starts before any shortening has occurred, and *2*) heat liberated during shortening in proportion to the amount of shortening of the muscle If the muscle performs

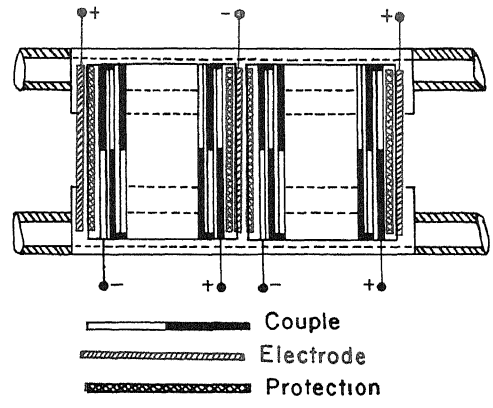

Fig 1 77 The pile consists of two identical frames supporting three thermocouples connected with indifferent electrodes The couples are isolated by a thin sheet of mica (Aubert 1956)

work, additional heat is liberated in proportion to the work done (see Fenn effect below) The initial heat liberation has been associated with the development of the active state, it is independent of the extent of shortening of load, of the velocity of shortening, of temperature of oxygen supply, and of work done—and is referred to as "activation heat "

In the second stage of heat liberation the amount of heat released during shortening (Figs 1 78 and 1 79)—referred to as the "shortening heat"—is proportional to the degree of shortening

$$H_s \quad \alpha x \tag{6}$$

where α is the coefficient of the heat of shortening and x is the distance representing the decrease in length of the shorteed muscle

In evaluating the total energy expenditure of muscle, one must consider the mechanical work accomplished as well as the heat produced Thus, the rate of release of energy during shortening is

$$(d/dt)\, E_s = (d/dt)\, (H_s + W) \tag{7}$$

where E_s is the total energy expenditure involved in the overall shortening process, H_s is the heat of shortening and W is the work done on shortening W equals Px where P is the load applied to the muscle and x, as defined above, is the amount of shortening Substituting for heat and work in equation (7) we have

$$(d/dt)\, E_s = (d/dt)\, (\alpha x + Px) \tag{8}$$

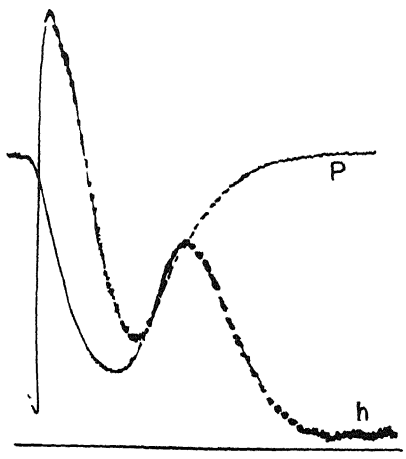

Fig 1 78 Simultaneous oscilloscopic recording of mechanical tension (*P*) and heat production (*h*) during an isometric twitch (Aubert 1956) Note that in this recording increasing tension corresponds to a downward deflection

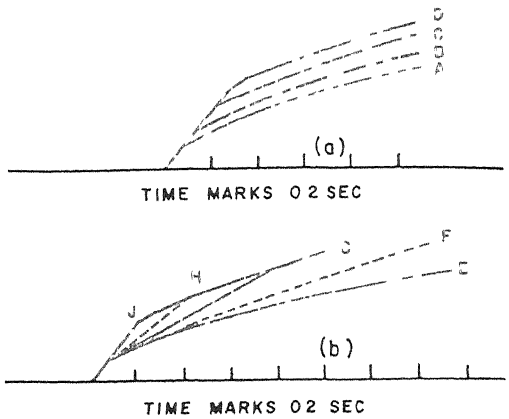

Fig 1 79 Heat production during isotonic shortening (tetanus 0° C) (*a*) shortening different distances under constant load of 1 9 g (*A* 0 0 mm isometric) (*B*) 3 4 mm (*C*) 6 5 mm (*D*) 9 6 mm (*b*) shortening constant distance 6 5 mm under various loads (*E*) isometric (*F*) 31 9 g (*G*) 23 7 g (*H*) 13 8 g (*J*) 1 9 g The ordinate represents total heat produced (Hill 1938)

When P is constant

$$(d/dt)\, E_s \quad [dx/dt]\, (\alpha \quad P) \tag{9}$$

But dx/dt equals V, the velocity of contraction, therefore

$$(d/dt)\, E_s \quad V\, (\alpha + P) \tag{10}$$

When energy expenditure was measured at loads ranging from 0 to P_o, $(d/dt)\, E_s$ was found to be inversely proportional to load as follows

$$(d/dt)\, E_s \quad \beta\, (P_o \quad P) \tag{11}$$

The constants a and b of equations (1) to (3) were estimated by analysis of the relationship between load and the velocity of shortening, whereas, the constants α and β of equations (10) and (11) were calculated from heat production measurements The value for a proved to be 0 25 P_o, whereas, the value for α varied with load as follows $\alpha = 0\ 18\ P_o + 0\ 16\ P$, thus, α proved to be dependent on changes in P which may range between 0 and P_o Accordingly α has a lower limit of 0 18 P_o (when P 0) and an upper limit of 0.34 P_o (when P P_o) The constant, a, and α both have the dimension of force

The Fenn Effect. Fenn (1923, 1924) observed that the total energy released by a muscle (work + heat) increases as muscle work increases This fundamental observation revolutionized the concept of muscular contraction because, previously, it had been believed that when a muscle contracts a preset amount of

additional energy is fed into the contractile machinery (in association with the assumption by the muscle of new elastic characteristics), and that this present increment of energy could be proportioned between work and heat, the total amount of energy (work + heat) remaining constant irrespective of the amount of work performed by the muscle In other words, it was believed that when the muscle assumes new properties associated with the contractile state, the total energy made available to it for release as work and/or heat was determined by the activation process Fenn's finding indicated that the energy release is determined not only by the activation process but also by the work load imposed on the muscle Thus the mechanical function was shown to control chemical reactions in muscle cells, the molecular mechanism being finely attuned to the work demand, (i e , the performance of a given increment of muscular work calls for the generation and delivery of a commensurate increment of energy)

There is no heat liberated during relaxation except when a load stretches muscle In this case the liberated heat corresponds to the work done by the muscle during shortening, this work is degraded into heat as the muscle is stretched

Further heat is liberated during recovery This "recovery heat" is associated with oxidative chemical synthetic processes The recovery heat is about equal to the total of the initial energy consisting of activation heat, shortening heat and work Since about half this initial energy is derived from chemical reactions that are reversed during recovery it appears that about half the energy associated with the recovery reactions is wasted as heat

From a knowledge of the energetics of muscle contraction it is possible to estimate the mechanical efficiency of a muscle, that is, the fraction of the chemical energy liberated during contraction and recovery that is turned into mechanical work This efficiency is generally not higher than 20 to 25%, part of the energy being wasted during contraction and part during recovery

THE ACTIVE STATE

The active state of muscle which develops following an adequate stimulus commences with the onset of latency relaxation The intensity of the active state (I_{as}) is defined as the "maximal isometric tension which contractile components can develop " Only a part of this maximal tension is actually manifest in a twitch because of the damping effect of series elastic elements, i e , the "spring-like" quality of the series elastic elements initially absorbs the energy developed during the onset of the active state as in the sarcomere

I_{as} can be determined at various times after stimulation by measuring the maximum load that a muscle can sustain after a small quick stretch Shortly after a muscle starts to contract (about 20 msec after stimulation for frog muscle), a quick stretch demonstrates that, in fact, the load-bearing capacity of the contractile element has reached its peak Thereafter I_{as} declines exponentially and by the time the muscle has developed peak tension, I_{as} has subsided substantially

I_{as} is affected by the nature and concentration of ions in the medium in which the muscle is immersed and by drugs such as epinephrine, caffeine, nitrate, and quinine The duration of the active state is inversely related to temperature ($Q_{10} \simeq 2$)

Gasser and Hill (1924) had observed that the properties of frog sartorius muscle change drastically soon after it is stimulated For instance, stimulated muscle develops a resistance to stretch which is not observed at rest Furthermore, as noted above, if the muscle is briefly stretched shortly after stimulation it develops maximum tension, however, if the muscle is briefly stretched at progressively lengthening intervals following stimulation it develops increasingly lesser levels of tension Conversely, if a muscle is stretched prior to stimulation and then released to the resting length at various intervals after the stimulation, it can be observed that quick release causes an initial loss of tension which is followed by a secondary development of tension However, the amplitude of this redeveloped tension is dependent on the exact time interval after stimulation that the muscle is subjected to the quick release maneuver These early observations provided the basis for the formulation of the concept of the "active state" by Hill (1927) Because maximal tension (in a quick stretch experiment) is always observed almost immediately after stimulation, Hill postulated that in the simple twitch response all the contractile elements undergo a rapid transition from a fully resting state to a fully activated state which persists

for a variable period of time, and then declines before peak contractile tension is reached (Fig 1 80)

The quick stretch and quick release experiments of Hill have been confirmed and extended by several other investigators Initially the results of these experiments were explained in terms of "viscous and elastic" components of muscle However, with the advent of electron microscopy and the new insights gained into the subcellular structure of the contractile elements, less significance has been ascribed to the role of the "viscous" elements of muscle in the contraction process It also has become apparent that the instrumentation used initially to map the contour of the active state was rather insensitive Therefore, Hill (1970) has repeated his early experiments and revised his concept of the active state on the basis of the sliding filament theory of muscle contraction, as well as the newer data obtained with improved recording techniques For example, the early data suggested that the active state attained maximum intensity instantaneously and then remained at a plateau for 10 msec or longer It is now known that the active state requires approximately one-third to one-half of the contraction time (i e , time elapsing between initiation of tension development and attainment of peak tension) to reach maximal intensity and that it is not maintained at a plateau but instead declines immediately with a characteristic time dependence

Using repetitive stimuli the contour of the active state can be mapped by measuring the distance between the peak and trough of consecutive twitches With this technique it has been observed that the amplitude (intensity) of the active state is dependent on the resting length of the muscle, that maximal contractile

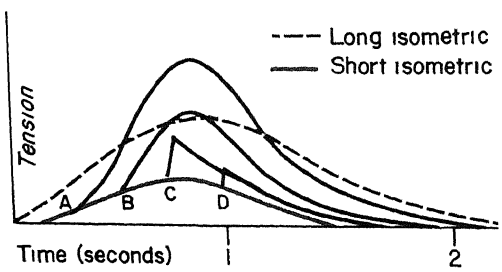

Fig 1 80 Diagram of the effect on the tension developed of stretching a muscle at various instants (*A B, C D*) during a twitch copied from records (From Hill, 1970)

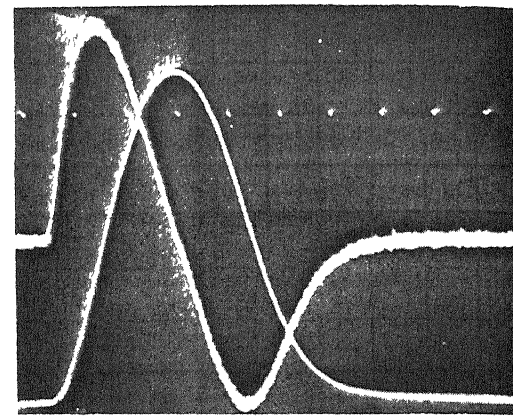

Fig 1 81 A technique for mapping the contour of the active state The monophasic curve is a recording of isometric tension and the biphasic curve is a recording of *dp/dt* the rate of change in the development and release of tension (From the records of one of the authors Penefsky)

tension is obtained at a sarcomere length of 2 4 to 2 5 μ and that various agents which alter the contour of the active state may also alter the contour of the action potential

The quick stretch and quick release methods for mapping the time course of the active state interrupt the instantaneous changes and provide only discontinuous "steady state" glimpses of the total time course Therefore, a new technique has been developed which does not require any manipulation of the muscle and provides a continuous map of the active state contour In this technique, tension is transduced into an electrical signal which, in turn, is differentiated so that the change in muscle tension as a function of time, dP/dt, can be recorded for a muscle twitching isometrically (Fig. 1 81) Inasmuch as the stretching of the elastic elements (which develops the isometric tension) is a reflection of the state of activity of the contractile elements, the dP/dt curve in effect indicates the instantaneous changes in the contour of the active state Observations recorded by this "continuous" technique have confirmed *1*) that the maximum intensity of the active state is not developed instantaneously but requires a measurable period of time, *2*) that after attaining maximum intensity, the active state declines immediately, *3*) that the intensity of the active state depends on the initial length of the muscle prior to stimulation, and *4*) that various conditions which increase contractile tension affect either the peak or the duration of the active state.

Activity of the Contractile Mechanism

STIMULATION VIA MOTOR NERVE

The activity of muscle is controlled by the central nervous system through the motor innervation of the myofibers Each motor nerve fiber splits up into a number of branches that make contact with the surface of the individual muscle fibers with several bulb-shaped endings These endings are arranged in a group, and with a specialized structure of the surface of the muscle fiber they form a motor end-plate

The stimulus conducted along the nerve fiber affects the nerve ending to release acetylcholine, which diffuses across the minute gap separating the nerve ending from the muscle fiber plasma membrane At the motor end-plate, this membrane shows a complex series of invaginations forming minute crypts At this area of the muscle fiber surface, there is a high concentration of acetylcholine esterase which splits (hydrolyzes) the acetylcholine set free during stimulation of the nerve ending

At rest, the electrical potential difference across the muscle cell membrane (i e , the *resting potential*) amounts to approximately −90 mv The release of acetylcholine affects the ionic permeability of the plasma membrane of the muscle fiber at the neuromuscular junction (postjunctional membrane) Due to the difference in concentration of Na^+ ions (high outside) and K^+ ions (high inside), the increased ion permeability gives rise to a sudden influx of Na^+ ions and an efflux of K^+ ions through the plasma membrane This short-circuits the adjacent parts of the plasma membrane and causes a drop in the membrane potential to the level where the membrane becomes electrically excited (i e , the membrane potential rises to the critical firing level, approximately −50 mv) and a wave of depolarization spreads along the muscle fiber (in the same manner as the nerve impulse is propagated along an axon) The electrical response developed as a consequence of the acetylcholine effect on membrane permeability can be recorded as an action potential of approximately 130 mv with the inside of the membrane briefly becoming positive The resting potential of about −90 mv is, therefore, not only abolished but, as in the nerve cell, the distribution of positive and negative charges is reversed The conduction of one impulse involves only a minute amount of Na^+ ions (about 4×10^{-12} moles/cm ^{2}) entering the muscle fiber and an equivalent leakage of K^+ ions to the extracellular space Through a recovery mechanism, involving active transport processes, the ion concentration differences between the muscle cell interior and the extracellular space is re-established by Na^+ extrusion and K^+ uptake

The activity of acetylcholinesterase rapidly abolishes the effect of acetylcholine The electrical response of the plasma membrane of the muscle fiber is therefore efficiently controlled by the nerve impulses reaching the motor end-plate Even without any such impulses there are minute spike potentials developed at the motor end-plate region of the muscle plasma membrane (*end-plate potentials* or *epp*) which have been ascribed to a spontaneous setting-free of minute "packages" of acetylcholine The concentration of acetylcholine that results from this "leakage" is, however, not high enough to produce a sufficient permeability change in the plasma membrane of the muscle fiber to raise the membrane potential to −50 mv , which as noted above, is the threshold for the development of a propagated electric response The minute spike potentials therefore remain localized to the end-plate region

PROPAGATION OF EXCITATION ACROSS AND WITHIN A MUSCLE FIBER

The impulse conducted along the muscle fiber from the end-plate region accounts for a spreading of a state of excitation *along* the fiber The activation of the contractile elements which are distributed over the whole cross-section of the fiber depends on spreading of the excitatory state from the plasma membrane transversally *across* the muscle fiber

The action potential is associated with currents flowing through the interior of the fiber These currents, however, are not directly responsible for activating the contractile mechanism It is, furthermore, not possible for any substance liberated at the surface of the muscle fiber in connection with the electric impulse propagation along the plasma membrane to activate the contractile elements by diffusion of the substance through the fiber, because such a mechanism would be too slow The activation is, furthermore, highly temperature-dependent, which also militates against a mechanism involving simple diffusion of an activating substance

There is good evidence that the transverse tubules (T tubules) of the sarcomere are involved in the propagation of impulses inward from the plasma membrane These tubules measure about 300 Å in diameter and run in a transverse direction through the muscle fiber They are called the T system to distinguish them from those tubules of the sarcoplasmic reticulum which are mainly longitudinal in orientation and, therefore, sometimes referred to as the L system The latter tubules form irregular networks along the myofibrils between the levels at which the tubules of the T system extend across the muscle fiber The tubules of the T system are arranged in a regular fashion extending from the plasma membrane toward the center of the muscle fiber at the Z line and/or at each A-I band boundry, there is substantial evidence that these tubules are in continuity with the plasma membrane and, therefore, that the narrow channel bounded by the tubule wall is continuous with the extracellular space It has already been noted that when a muscle fiber is stimulated locally by means of a microelectrode in contact with its surface, the threshold for a local response is minimal at the level of the I-A-band boundary in muscles where the T system is located at that level and at the Z line in muscles where the T system is confined to the Z line level In the latter case a localized contraction of the two half-sarcomeres on either side of the Z line can be elicited by applying a minimal stimulus

The nature of the impulse propagation along the T system is unknown Structurally, the conditions are fulfilled for an electrotonic spreading along the tubules of the T system of the electrical potential changes associated with the sarcolemmal membrane action potential

The activation of the contractile machinery ultimately depends on the effect of an activating factor capable of releasing the reactions that generate the active state It now appears that Ca^{++} ion is the final mediator of the process linking excitation of the plasma membrane to the initiation of contraction (excitation-contraction coupling), the action of Ca^{++} resulting from its binding to troponin (vide infra) The sarcoplasmic reticulum (S R) has been shown in vitro to be able to concentrate calcium The parts of the S R that are located closest to the A-I-band overlap are characterized by a high ATPase activity which may be related to a "calcium pump," the ATP splitting furnishing the energy to drive the pump In addition Ca may be reversibly bound to the S R It therefore appears likely that an impulse transmitted by the T system to the S R brings about a release of Ca that has been pumped into and or bound by the S R This release of Ca then initiates the activation of the contractile machinery

ELECTRICAL STIMULATION VIA THE SARCOLEMMA

Although the normal path of the activity is via the neuromuscular junction, it is possible to stimulate the sarcolemma directly If the intensity of the stimulus is subliminal a brief local depolarization can be induced which will reverse upon the removal of the stimulus However, if the stimulus depolarizes the membrane to the critical firing potential (threshold) an action potential will be observed Whereas the subliminal response is decremental and does not propagate far from the site of stimulation the action potential is self-regenerative and will be conducted in both directions away from the site of stimulation

Action potentials recorded from fast skeletal muscles depolarize the membrane rapidly, overshoot, and then repolarize rapidly to a level of approximately 70 mv (in the frog sartorius) At this level of membrane potential the repolarization process develops a relatively long time constant The membrane voltage during this latter period of slower repolarization is referred to as a negative after potential, as in the case of nerve The period of negative after potential in turn is followed by a period of hyperpolarization (the positive after potential) and then by a gradual return towards the normal resting potential, also similar to the response of nerve fibers The contribution of various sites on the sarcolemma (surface membrane, transverse tubules) to the ionic fluxes which determine the shape of the action potential has been investigated extensively, and it has been shown that depolarization of the muscle cell membrane is largely due to Na^{+} ion influx in most species although, in the crab, Ca^{++} ions are responsible for carrying most of the depolarizing charge into the cell

When the sarcolemma is depolarized or hyperpolarized by passing cathodal or anodal currents through it, it responds (like the neurilemma) as if it has both resistive and capacita-

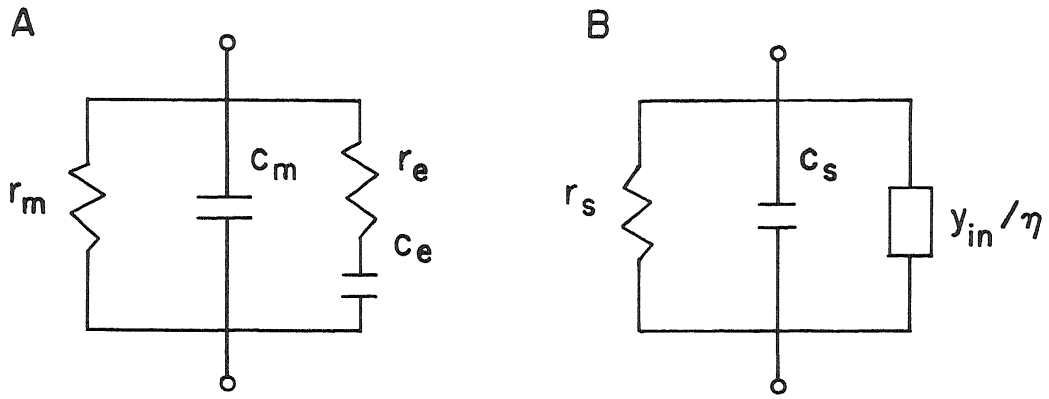

Fig 1 82 Two circuits considered for the element of inside-outside impedance in frog muscle fibers All parameters in both circuits refer to a unit length of fiber *A* four lumped parameter circuit r_m and c_m represent properties of the surface membrane and r_e and c_e properties of the path via the T system *B* distributed parameter circuit r_3 and c_3 represent properties of the surface membrane y_{in} is the input admittance of a lattice model for the T system and η is the sarcomere length (From Schneider 1970)

tive elements in parallel as well as in series Following a square wave stimulus, the membrane potential depolarizes exponentially with a time constant indicating the presence of capacitative elements which are accumulating charge The voltage drop across the membrane indicates resistance in the circuit The site and magnitude of these components have been investigated more thoroughly in nerve fibers, however, recent studies of frog sartorius have revealed additional components in muscle contributing to the electrical properties of the membrane in ways which have yet to be explained definitively

Various models have been proposed to explain the electrical properties of the muscle cell membrane For example, it has been suggested that the input impedance of frog muscle fibers may be compared to that of a cable having inside-outside impedance elements consisting of separate resistance and capacitance paths which are in parallel with a resistance and capacitance in series (Fig 1 82, model *A*) However, such models do not account for a radial potential gradient, inasmuch as the circuits are composed exclusively of lumped resistances and capacitances It has been suggested that radial gradients are possible only with circuits in which some of the resistance or capacitance elements are distributed throughout the fiber cross-section (Fig 1 82, model *B*) Thus, assuming that the contractile system is uniform across the fiber, only a system with spatially oriented resistance-capacitance elements can account for the observations that deep myofibrils are activated later than, and require greater surface membrane depolarization for activation than myofibrils located near the fiber surface

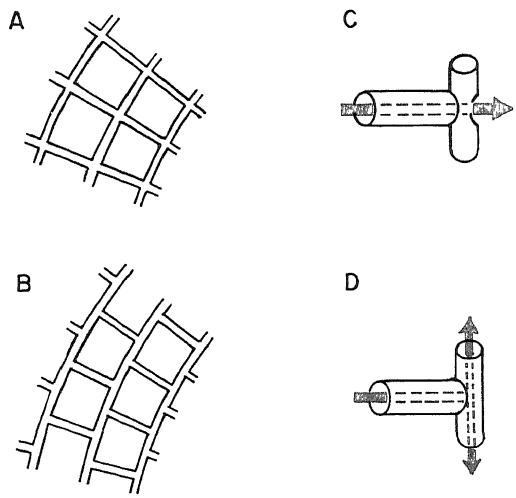

Fig 1 83 Geometries considered for the T system lattice *A* and *B* portion of the in register (*A*) or out of register (*B*) lattice *C* and *D* elements combined to give a single equivalent radial element Arrows indicate principal path of internal current for in register (*C*) or out of register (*D*) cases of the model (From Schneider 1970)

The possibility that there is a lattice system in the transverse tubules which might be represented by the model shown in Figure 1 83 was tested by stimulating muscle with AC current of varying frequency and then analyzing the (phase angle frequency) response of the fiber in terms of both of the models shown in Figures

1 82 and 1 83 It was found that the observed time constants and capacitance values were similar for both models (i e, C_e/C_m was 1 73 for model *B* and 1 74 to 1 8 for model *A*)

The calculated time constant r_m (C_e + C_m) was 17 8 msec using model *B* and 14 3 msec using model *A*

The fiber input impedance data exhibited a smoother transition in the intermediate frequency range when model *B* (which represents the T tubule lattice system) was compared to model *A* It is also noteworthy that the lattice structure accounts for the linear decrement of the applied current

Although the transverse tubules appear to be an extension of the sarcolemma, the membranes may have different conductance properties, as suggested by the analysis of the action potential recorded after the tubular system has been destroyed with hypertonic Ringer's-glycerol solution and the analysis of membrane currents after voltage clamping

The usual rapid repolarization that follows a spike generated by the muscle membrane is due to a delayed rectification of the membrane Inactivation of the conductance of Na^+ ions and increase in the conductance of K^+ ions are responsible for the quick phase of repolarization, following which there is an early and late negative after potential with the membrane remaining slightly depolarized for about 0 25 sec Then the membrane potential drops below the resting potential (hyperpolarization) and again returns to the resting level with a relatively long time constant

The origin of the fast phase of repolarization (delayed rectification) seems to be on the surface membrane, whereas, the after potential seems to originate mostly in the transverse tubules It has been shown that if the transverse tubules are destroyed by exposure to hypertonic solutions, muscle will no longer contract in response to stimulation (excitation-contraction uncoupling), in addition, the total membrane capacitance is reduced from 6 5 to 2 6 μF per cm ^{2} and the after potentials will disappear, although the earlier features of the action potential (spike and the rapid phase of repolarization) persist

The after potentials are believed to be due to K^+ ion accumulation in the tubules Using rubidium in place of potassium, it has been observed that the after potentials can be suppressed.

The contribution of Cl ions to the ionic currents of the muscle cell membrane have long been controversial It is now known that chloride conductance (G_{Cl}) is pH sensitive At values of pH of about 5 6 G_{Cl} is inhibited Under such conditions it has been shown that G_K in the tubules changes in direction during the after potential, this anomalous rectification seems to be a property of the surface membrane, whereas, the slow rectification (which accounts for the return from maximal hyperpolarization to the resting potential at the end of the action potential cycle) seems to take place within the tubules (which occupy a total of 0 002 to 0 003% of the fiber volume)

Many of the observations noted above have been verified by the recent observations of Adrian, Chandler, and Hodgkin (1970) to the effect that the potassium current can be divided into three separate components *1*) A current in a delayed rectifier channel of the muscle cell membrane which reaches a maximum in about 100 msec at a membrane potential of − 30 mv and then declines with a time constant of about 4 msec until the fiber is repolarized to − 100 mv This current inactivates completely *2*) A channel in which repolarization is associated with an increase in G_K, which is one or two orders of magnitude slower than the K current in the delayed rectifier channel *3*) A very slow inward K current which has a time constant of 0 25 sec at − 150 mv In addition a path for active uptake of K^+ ion is also postulated The data on current flow obtained with the voltage clamping technique also suggests that *1*) the delayed rectifier channel must be in the surface membrane, whereas, the two other channels must be in the T tubules, *2*) that G_K rather than tubular K concentration changes during the positive and negative after potentials, and *3*) that the after potentials can be explained if one supposes that potassium ions do not carry all the current or that some variable other than membrane potential is the factor which controls potassium permeability

RECAPITULATION OF THE ROLE OF MONO- AND DIVALENT IONS

1) K^+ ion, the major component of the intracellular fluid, functions chiefly to maintain the resting potential which approximates the K^+ equilibrium potential If the concentration of K in the extracellular fluid is increased, resting

membrane potential will decline according to the Nernst equation $E = RT/F \ln [K_I]/[K_E]$, where K_I is the intracellular K^+ concentration and K_E is the extracellular K^+ concentration

2) Na^+ ion, the major component of the extracellular fluid, functions to maintain the osmotic pressure (osmolality) of the extracellular compartment The permeability of the muscle cell membrane to Na^+ is very low at rest but increases markedly following stimulation Thus, Na^+ ions "rush" into the cell and these positive charges depolarize the membrane Because Na^+ permeability is voltage dependent, more Na^+ ions "rush" into the cell as depolarization progresses in what amounts to an autocatalytic, positive feedback process which is propagated along the muscle membrane This self-regenerative process is qualitatively identical to the action potential of nerve For a brief instant the inside is positive with respect to the outside At this point (the peak of the overshoot) the membrane potential approaches the Na^+ equilibrium potential However, the increased Na^+ permeability quickly reverses, permeability to K^+ increases and the repolarization process is initiated

The monovalent ion, Li^+, can replace Na^+ as a carrier of positive charge into the muscle fiber, however, Li^+ ions tend to accumulate inside the fiber because there is no active transport mechanism to remove Li^+ from the intracellular space

3) The role of Ca^{++} ions in muscle physiology will be discussed below in connection with the relaxation of muscle and under the heading of "Excitation-Contraction Coupling"

4) Mg^{++} ions are important for the ATPase activity of myosin Most of the Mg^{++} is bound to muscle components, although the precise distribution of Mg^{++} among these components has not yet been clarified

5) Cl^-, the major anion in the extracellular fluid, passively follows the cations moving across the muscle cell membrane distributing according to the Gibbs-Donnan equilibrium

Relaxing Factor

The relaxation of the muscle fiber is associated with a removal of Ca^{++} ions via a calcium pump and/or specific binding by the sarcoplasmic reticulum

When sarcotubular vesicles are isolated from muscle homogenates by centrifugation, they can cause isolated actomyosin systems to relax, an effect which is due to their ability to accumulate ionic calcium and thereby remove it from the medium

Addition of ATP to a hydrous gel of actomyosin shrinks the gel, reducing its water content This process (superprecipitation) is believed to be an elementary contraction process The same process can be seen in glycerinated muscle fibers (i e , muscle fibers extracted with 40 to 50% glycerin) When these fibers are exposed to ATP they show all the responses of a living contracting muscle However, when ATP is removed from the glycerinated fibers, they do not relax Clearly then, in these systems, a factor is missing which in living systems promotes relaxation following contraction

The ionic strength, ATP concentration, pH, temperature, and other conditions can be altered so that the superprecipitate of the actomyosin gel as well as the contracted glycerinated fibers can be made to relax However, in the living system all of the above conditions are probably constant, furthermore, the energy expenditure needed to effect changes in the concentration of salts, Mg^{++} or ATP of sufficient degree to promote relaxation precludes such mechanisms on thermodynamic grounds

The search for a physiological factor which reverses the contractile process has aroused considerable interest during the past 20 years In the early 50's, Marsh observed that a shrunken actomyosin gel could be made to take up water by the addition of a supernatant fluid which had been recovered from the centrifugation of ATP-treated muscle homogenate This muscle extract could relax contracted glycerinated muscle fibers The unknown component responsible for these effects was called "relaxing factor" Following the demonstration that relaxing factor was precipitated by 40% saturated ammonium sulfate, it was suggested that it was a soluble enzyme which interacted directly with myosin ATPase However, soon after it was found to sediment in a moderate gravitational field, and it therefore appeared to be particulate in nature Many investigators attempted to find a small molecule which, on release from the particulate, "relaxed" the ATP-contracted actomyosin system However, several years elapsed before it became apparent that the relaxing effect could be due to the removal of an element from the contracted actomyosin system, and therefore that the re-

laxing factor could be the system involved in the removal and sequestration of this element

In the mid-50's it was observed that the addition of ethylenediaminetetraacetic acid (EDTA) in the presence of ATP mimicked the physiological action of the relaxing factor, but it was not until 1959 that Weber demonstrated that the ATP-actomyosin system depended on minute amounts of Ca^{++} for its ATPase activity

The effect of the relaxing factor was then conceived to be a chelating system which was responsible for the removal of an agent, Ca^{++}, which regulated the actomyosin interaction The relaxing factor was identified on further study as the fragmented sarcoplasmic reticulum recovered from a muscle homogenate It was shown that these vesicular fragments could indeed concentrate Ca^{++} against very high gradients

The Regulatory Role of Calcium

It is known that pure actin and pure myosin can interact when ATP is present Ca^{++} ions, although not directly involved in this reaction, are needed for the release of an in vivo repression which prevents the interaction of actin and myosin

The site of storage of calcium is the sarcoplasmic reticulum (SR) The binding capacity of the SR system for Ca^{++} ions is 150 mM of Ca^{++}/g of protein with an association constant of $7 \times 10^6 M^{-1}$ The protein content of the SR is approximately 5 mg /ml of intact undiluted homogenized muscle The concentration of the calcium-receptive sites of the contractile system is about 0 1 mM, the association constant of calcium for the contractile system is 1×10^{-6} M^{-1} The concentration of rapidly-exchangeable calcium is 0 5 mM, and of nonexchangeable calcium 0 7 to 0 9 mM Most of the nonexchangeable calcium is bound to actin The concentration of free Ca^{++} ion in resting muscle is 3×10^{-7} M That the rate of binding of Ca^{++} ion to the SR system is indeed correlated with the rate of relaxation of muscle in vivo is shown by the finding that 40 mμM of calcium was bound by 1 mg of SR protein within 30 msec at 20° C This means that the SR content of 1 g of muscle can bind 0 2 moles Ca^{++} ions within 30 msec The amount of calcium released from 1 g of muscle ranges between 0 1 to 0 2 moles—in close accord, therefore, with the results of the binding studies However, because of the relatively high Ca^{++} ion concentration in the living cell it may take as long as 0 5 sec to remove 0 2 moles of calcium whereas the relaxation time of frog muscle at 20° C is only 0 1 sec This discrepancy may be explained by the suggestion of Ebashi and Endo (1968) to the effect that in the isolated system the SR vesicles may be partially inactivated and also that in vivo, there may exist a membrane potential across the SR tubules which enhances the removal of Ca^{++} ions from the sarcoplasm

SITE OF BINDING OF Ca IONS

Ca^{++} ions are bound to the SR membrane and concentrated in the lumen of the SR tubes It has been calculated that more than 90% of the calcium in the SR system is in bound form

In the absence of ATP, Mg^{++} binds readily with the SR system, however with addition of ATP, Ca^{++} replaces Mg^{++} It is suggested that the binding sites have a higher affinity for Mg^{++} than for Ca^{++} However, ATP may cause a conformational change in the relevant SR proteins, thereby increasing their affinity for Ca^{++}

Ebashi has suggested that Ca^{++} ions first bind with specific sites in the membrane of the SR system (step 1) and that this is the crucial step in the relaxation of the muscle Most of the Ca^{++} which acts as the trigger for contraction may be derived from this bound form Part of the initially bound Ca^{++} is then transported into the lumen (step 2) of the reticulum This transport is mainly regulated by the free Ca^{++} ion concentration inside the lumen which may not exceed 1 mM It is possible that a part of transported Ca^{++} is bound to certain structures in the lumen ATP is absolutely necessary for step 1 and its breakdown may take place in association with step 2

Whatever may prove to be the detailed mechanism of Ca^{++} accumulation it is clear that during the resting state the SR system is capable of reducing the sarcoplasmic Ca^{++} content below the threshold level for the activation of the contractile process (i e , less than 10^{-7} M)

Ca^{++} is the common regulatory ion in smooth and cardiac as well as skeletal muscle, however, contractile elements from various types of muscle are also sensitive in some degree to other alkaline earth metal ions For example, cardiac contractile elements have been found to have appreciable sensitivity to Sr^{++} and Ba^{++}, whereas skeletal and visceral smooth muscle are less sensitive to the latter

ions It is of interest therefore that cardiac troponin appears to be six times more sensitive to Sr^{++} than skeletal troponin

Ca^{++} AND THE INTENSITY OF THE ACTIVE STATE

There is a direct relationship between calcium ion concentration [Ca^{++}] and the intensity of the active state [I_{as}] inasmuch as the velocity of contraction (which parallels I_{as}) is proportional to [Ca^{++}]

Increasing free Mg^{++} ion concentration from 0 05 to 8 mM decreases the Ca^{++} sensitivity of the contractile system Although the total magnesium concentration in muscle amounts to 10 to 12 mM, the concentration of free Mg^{++}, is likely to be low, because myoproteins (200 mg /ml muscle homogenate) offer many binding sites to Mg^{++}

In glycerinated rabbit muscle, as compared with intact muscle, the sensitivity of the contractile elements to Ca^{++} is higher by 0 5 pCa unit, presumably because the native tropomyosin in these systems may be partially destroyed by glycerination (pCa refers to the negative logarithm of the Ca^{++} concentration)

THE SITE OF ACTION OF CALCIUM

If Ca^{++} ions are introduced by microiontophoresis at consecutive points along the surface of the sarcomere of glycerinated crab muscle [soaked in relaxing medium containing Mg-ATP and ethyleneglycoltetra-acetic acid (EGTA)], it is found that the site which requires the lowest iontophoretic current for the initiation of contraction is at the level of the A-I junction

As the micropipette containing the Ca^{++} solution is moved away from A-I junction, progressively stronger currents are needed to induce contraction Thus, it was concluded that Ca^{++} ions had to reach the zone of A-I overlap in order to contract the sarcomere in this species Essentially the same phenomenon has been demonstrated autoradiographically in frog muscle which was exposed to Ca^{45} and quickly frozen immediately after stimulation Using this technique it was demonstrated that the density of Ca^{45} is highest at the A-I junction directly after the initiation of contraction One to two seconds thereafter, most of the Ca^{45} was no longer observed at the A-I junction but rather was seen to be stored in the SR system or the extracellular compartment Thus, these experiments provide strong evidence indicating that the site of action of calcium is at the area of overlap of the thick and thin filaments

Excitation-Contraction Coupling

From the foregoing it is clear that the stimulation of the muscle, either through its nerve or directly, sets up a process which starts on the sarcolemma and ends in the contractile machinery

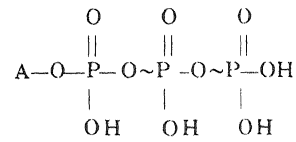
The pathway from the surface to the core of the fiber has been observed only recently It should be recalled that minute electrical currents at the level of the Z band in frog skeletal muscle induce local contractions and also that, in the frog, the transverse tubular system is located at the level of the Z lines—whereas, in the crab muscle, local stimulation is effective only at the A-I junction area and the transverse tubules are also found in this area It should also be recalled that when the T tubules are destroyed by exposure of muscle fibers to glycerin, electrical stimuli no longer elicit a contractile response Thus, it seems clear that the depolarization process initiated at the myoneural junction in the postjunctional membrane must then travel to the core of the myofibril through the T-tubule system

Electron micrographs have shown that the closed end of the T tubules are in close proximity (50 Å) to the terminal cisternae Thus, it is conceivable that the wave of depolarization traveling down the T tubule may trigger a new event involving the sarcoplasmic reticulum and leading to the contractile response

On the basis of extensive observations it has become clear during the last few years that the passage of the wave of electrical activity via the T tubules into the core of the myofibril induces a release of calcium ions which had been bound to the membranes of the sarcoplasmic reticulum or stored within it After release the calcium ions diffuse to and bind at calcium sensitive sites (troponin A) It has been suggested that the binding of calcium to troponin A allosterically removes an inhibiting effect of troponin B on the interaction of actin and myosin and, thus, calcium is the link which couples excitation (stimulation) to contraction (response)

The entire process can be abbreviated as follows Stimulus → Depolarization of the sarco-

lemma → Action potential initiated and propagated along the T tubules → calcium released from the SR system → Calcium ions diffuse and attach to the active site on troponin A → the inhibitory effect of troponin B on the interaction of actin and myosin is removed → actin filaments slide along myosin filaments shortening the sarcomere This series of events is fully reversible under normal conditions Following repolarization there is an increase in the uptake of calcium ions by the sarcoplasmic reticulum As this sequestration proceeds, more Ca^{++} ions dissociate from their binding sites on troponin A resulting in a restoration of actomyosin-inhibiting property of troponin B and, accordingly, in a return of the thick and thin filaments to the resting state (relaxation) Indeed Podolsky and Teichholz (1970) have evidence that the rate of muscle relaxation is proportional to the removal of calcium from the contractile protein



The Energy-Generating Systems

The energy for muscle contraction is derived from chemical reactions in the muscle fiber The main energy source is glycogen, which is present at a concentration of 0 5 to 1% of the wet weight of the tissue The energy associated with muscle contraction is made available without any oxygen being consumed, even when oxygen is present The oxidative (aerobic) chemical reactions are therefore not directly associated with muscle contraction but with the recovery processes which operate to provide energy in a form that is readily available to the contractile machinery, thereby securing a quick response to a stimulus.

The compound that appears to be ultimately involved in providing energy to the contractile machinery is adenosine triphosphate (ATP) In this process, energy is utilized in a reaction coupled with the hydrolytic splitting of the terminal phosphate group from ATP,

$$ATP \rightarrow ADP + P_i \text{ (inorganic phosphate)}$$

This reaction involves a liberation of about 7600 to 7800 calories/mole It has become customary to refer to the bond between the terminal phosphate group and the neighboring phosphate group as a "high energy" or "energy rich" bond and to designate it by the symbol ~ The adenosine triphosphate structure, therefore, can be written as follows.

or

where A = adenosine adenine + D-ribose This formula shows two energy-rich phosphate bonds in the ATP molecule Only the one associated with the terminal group is directly utilized during muscle contraction

The ATPase activity of myosin permits the hydrolysis of ATP to take place at the contractile machinery itself where the conditions are topochemically favorable for energy transfer from ATP to the myosin-actin system

The restoration involves a phosphorylation of ADP to ATP In muscle, creatine phosphate (phosphocreatine) represents a second high-energy compound, in which phosphate is bonded to creatine by means of a high-energy bond Prompt resynthesis of ATP is achieved by phosphate group transfer from creatine phosphate to ADP, catalyzed by creatine kinase (Fig 1 84) Creatine P, depleted in this process, is regenerated by the transfer of a P from ATP to creatine During the recovery period ATP is formed by oxidative phosphorylation of ADP In this way a second form of storage of high-energy phosphate as creatine phosphate is built up in the muscle during recovery The ATP content of resting muscle is about 5×10^{-6} moles/gram muscle tissue which is four to six times less than the content of creatine phosphate The ATP and the creatine phosphate represent energy stored in a form that can be utilized rapidly Recharging of ATP through oxidative phosphorylation is a much slower process Since the high-energy phosphate storage in the muscle is sufficient to allow the muscle to contract only 50 to 100 times, the energy reservoirs are rapidly depleted For maintenance of muscle contractility, a steady supply of energy is required to recharge ADP

Since the reactions associated with the contraction, dephosphorylation of ATP, as well as the phosphate transfer from creatine phosphate to ADP, are nonoxidative processes, it becomes obvious that no oxygen is consumed during contraction provided that no recovery metabolism is maintained in parallel Oxygen is con-

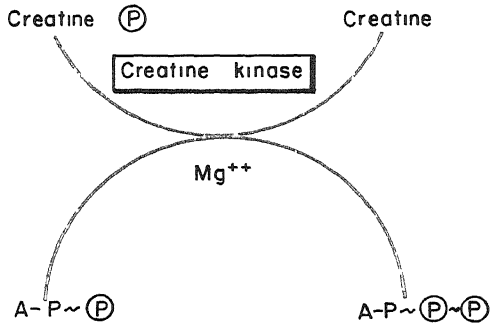


Fig 1 84 Resynthesis of ATP with phosphate from phosphocreatine

sumed during the recovery phase in connection with oxidative phosphorylation of ADP

The energy required for the high-energy phosphate bonds of ATP and creatine phosphate is supplied by glycolysis and by the oxidation of acetyl CoA (derived from pyruvic acid) in the citric acid cycle with the associated oxidative phosphorylation by the respiratory chain

In addition to glycogen, fatty acids and amino acids can furnish fuel for the muscle, and in resting muscle, glycogen breakdown is not required to maintain metabolism Muscle metabolism can be maintained by the uptake of carbohydrates and other compounds from the blood In resting muscle, carbohydrates are responsible for about 60% of the energy requirements of the tissue

When 1 mole of glucose is phosphorylated to glucose-6-phosphate and then enters the glycolytic pathway to be converted to lactic acid there is a net gain of 2 moles of ATP However, when glycogen per se is broken down to lactic acid, there is a net gain of 3 moles of ATP per glucose residue of glycogen so converted It is obvious that a limited recharging of ADP and creatine can occur in muscle without access to oxygen Breakdown of lactic acid, however, depends on the presence of oxygen, and under anaerobic conditions, the lactic acid concentration will increase in the muscle and then be transported by the blood to the liver

Glycolysis can be inhibited by iodoacetate poisoning and under those conditions the muscle will contract until the ATP and the creatine phosphate stores have been depleted

Under aerobic conditions, the end product of glycolysis is pyruvic acid instead of lactic acid Pyruvic acid is oxidatively decarboxylated to a derivative of acetic acid, acetyl coenzyme A (acetyl CoA), and enters the aerobic citric acid cycle of Krebs, which results in its complete oxidation to CO_2 and H_2O During the degradation, 15 ADP molecules are phosphorylated per molecule of pyruvic acid, which means that 30 ADP molecules are phosphorylated during oxidation of the two pyruvic acid molecules derived from each glucose molecule Since, as noted above, 3 ADP molecules are phosphorylated during glycolytic conversion to lactic acid of each glucose residue derived from glycogen and 6 ATP molecules derived from the oxidation of the 2 DPNH molecules generated during glycolysis, a total of 39 moles of ATP are formed from glycogen per mole of glucose residue degraded

Total oxidation of glucose to CO_2 and H_2O yields 686,000 cal /mole, but only 56,000 cal /mole is produced when the glucose degradation does not proceed further than to lactic acid The efficiency of glycolysis, that is, of the energy-generating reactions under anaerobic conditions, can be calculated by assuming that the phosphorylation of three ADP molecules represents about 24,000 cal This is $24,000/56,000 \times 100$, or about 43% of the potentially available energy during glycolysis following glycogenolysis In comparison with the energy released during complete oxidation of glucose—686,000 cal /mole—the energy stored in 3 molecules of ATP will represent $24,000/686,000 \times 100$, or about 3% of the total energy available as chemical energy in glucose This shows the low energy yields of anaerobic energy metabolism. In comparison, 36 + 3 ADP molecules are phosphorylated in the aerobic degradation of a glucose equivalent derived from glycogenolysis representing a free energy storage of about 312,000 calories The efficiency of the oxidative degradation of glucose is therefore $312,000/686,000 \times 100$, or about 45%, which is in good agreement with the efficiency estimated from measurements of the recovery heat

GLYCOGEN METABOLISM

The first step in the synthesis of glycogen in muscle involves phosphorylation of glucose to glucose 6-phosphate, a reaction catalyzed by *glucokinase* and associated with utilization of energy-rich phosphate in the form of ATP

Glucose + ATP → glucose 6-phosphate + ADP

The product, glucose 6-phosphate, is a relatively energy-poor compound and this reaction therefore means that the equilibrium state of this reaction favors the formation of glucose-6-phosphate (G-6-P). G-6-P is converted to glucose 1-phosphate, a reaction catalyzed by the enzyme *phosphoglucomutase* (Fig. 1-85). Glucose 1-phosphate is then activated by reacting with uridine triphosphate (UTP) to form uridine diphosphate glucose (UDPG). This reaction is catalyzed by *UDPG pyrophosphorylase*. The glucose moiety of UDPG is then transferred to a pre-existing glycogen molecule (primer) to which it is attached in an α 1, 4-linkage. This reaction is catalyzed by the enzyme *glycogen synthetase* (UDPG-glycogen-transglucosylase). The formation of such bonds gives rise to linear changes of glucose residues. At intervals chains of 8 to 12 glucose residues are picked up and transferred to make a branch which is attached to the main chain of glucose residues by means of an α 1,6 linkage. This reaction is catalyzed by the "*branching enzyme*" (amylo-1,4-1,6 transglucosylase). In this way, a branch point is established, and the glycogen molecule grows to a large, highly branched structure (Fig. 1-86) with a molecular weight that ranges from 240,000 to 10^7.

During glycogenolysis (Fig. 1-87), glycogen is first partially degraded to α-D-glucose-1-phosphate, this degradation is catalyzed by *glycogen phosphorylase*, an enzyme whose activity is confined to the 1,4 links. All of the residues on the branches, except for the proximal residue, are transferred to the main chain by the *debranching enzyme*. The 1,6 linkage involving the proximal residue is then split by *amylo-(1,6)-glucosidase*, releasing this branch point residue as free glucose. Thereafter the remaining molecule can be degraded completely by glycogen phosphorylase.

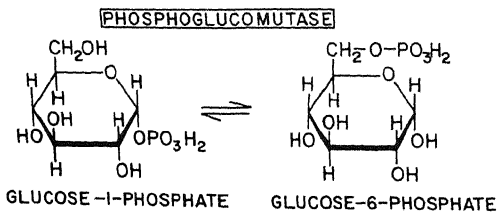

Fig. 1-85 Interconversion of glucose phosphates by the enzyme phosphoglucomutase.

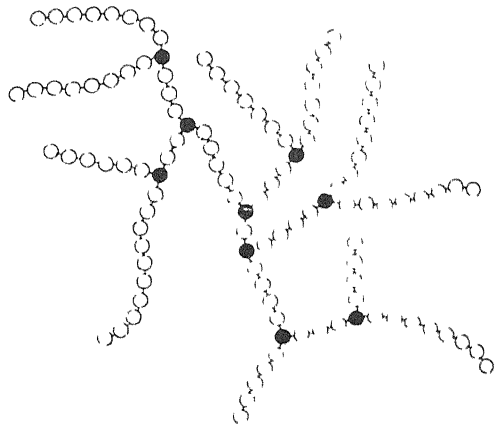

Fig. 1-86 Part of a branched glycogen molecule with each circle representing one glucose residue.

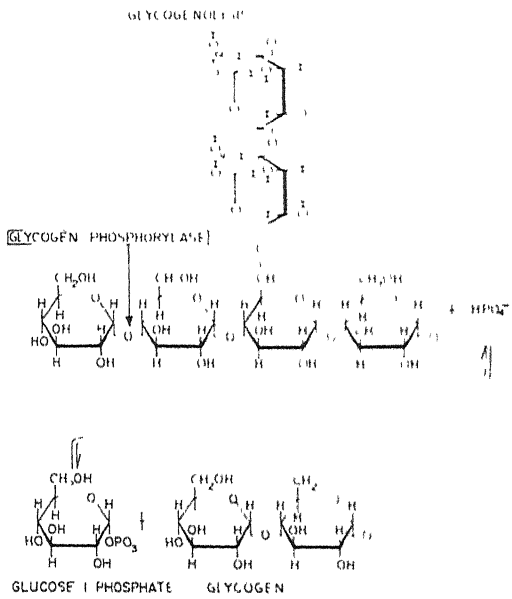

Fig. 1-87 Glycogenolysis.

Glycogen phosphorylase, with a molecular weight of 370,000, consists of four polypeptide chains. The molecule is acted on by a muscle enzyme, *phosphorylase phosphatase* to remove phosphate groups from serine residues present in each polypeptide chain. This results in a rearrangement of these chains to a dimeric form of the enzyme which is virtually inactive in the absence of adenosine-5'-monophosphate (AMP). The tetramer, which does not require AMP, is referred to as phosphorylase *a* and the less active dimer as phosphorylase *b*. The enzyme contains pyridoxal phosphate bound to a

lysyl residue through an azomethine linkage (Schiff base) Phosphorylase *b* is found in resting muscle Active enzyme, i e , phosphorylase *a*, is generated by the action of phosphorylase *b* kinase in the reaction

2 phosphorylase *b* + 4 ATP → phosphorylase *a* + 4 ADP

Phosphorylase *b* kinase (PBK) also appears in an active (phosphorylated) and an *inactive*[1] (*dephosphorylated*) form, the inactive form is converted to the active enzyme by an ATP coupled enzyme system, known as phosphorylase *b* kinase kinase (PBKK) PBKK, like many other protein kinases, requires adenosine 3′-5′-phosphate (cyclic AMP) for its activation

The breakdown of muscle glycogen is largely determined by the extent of conversion of phosphorylase *b* to phosphorylase *a* in a process which is under control of the nervous and endocrine systems via neurohumoral-hormonal entities such as epinephrine and by intracellular mediators ("second messengers") such as cyclic AMP Recently it has been found that the kinase kinase also catalyzes the conversion of glycogen synthetase to the inactive phosphorylated synthetase (glycogen synthetase D) and may be related to or identical with glycogen synthetase kinase, therefore, when the phosphorylase system is activated by phosphorylation, the synthetase is inactivated by the very same process This biochemical switch permits glycogen breakdown to occur without the concurrent competition of synthesis Such a coupling makes eminent physiological sense because futile competition between glycogen synthesis and breakdown with a consequent wasteful dissipation of energy is thus prevented

Glucose 1-phosphate is converted to glucose 6-phosphate in a reaction catalyzed by the enzyme *phosphoglucomutase*

Glucose 1-phosphate⇌glucose 6-phosphate

This reaction requires glucose-1,6-diphosphate and Mg^{++} as cofactors The enzyme is reversibly phosphorylated during this reaction by a transfer of one of the phosphate groups from glucose-1,6-diphosphate to a serine residue The phosphate group of the esterified enzyme then presumably is transferred to the 6-carbon in glucose 1-phosphate to regenerate glucose 1,6-diphosphate The glucose-1,6-diphosphate necessary for this reaction is formed by transfer of a phosphate group from ATP to glucose 1-phosphate in a reaction catalyzed by *phosphoglucokinase* These reactions can be summarized as follows

(1) glucose-1,6-diP + enzyme ⇌ glucose-6-P + enzyme-P

(2) enzyme-P + glucose-1-P ⇌ glucose-1,6-diP + enzyme

The resultant of these reactions is the conversion of glucose-1-phosphate to glucose-6-phosphate

Since glucose 1,6-diphosphate is regenerated in the above reactions the energy expenditure associated with them is small in relation to the net energy transferred to ATP during oxidation of glucose

The glucose 6-phosphate enters the main pathway of glycolysis followed by complete oxidation via the citric acid cycle and its associated oxidative phosphorylation system The scheme in Figure 1 88 summarizes the pathways of glycogenesis and glycogenolysis

GLYCOLYSIS

Glycolysis involves the degradation of glucose to pyruvic or lactic acid This breakdown of glucose can occur without access to oxygen, in which case the end product is lactic acid Two molecules of ADP are phosphorylated to ATP during glycolysis

Glucose + 2ADP + 2 P⇌2 lactic acid + 2 ATP

The conversion of free glucose to glucose-6-phosphate is bypassed when glycolysis follows glycogenolysis because glucose-6-phosphate is then formed directly from glucose 1-phosphate in a reaction not involving utilization of phos-

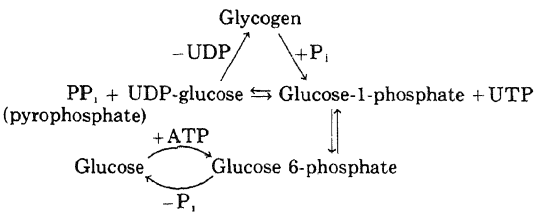

Fig 1 88 Summary of pathways of glycogenesis and glycogenolysis

[1] The dephospho form of PBK can be activated by Ca^{++} ions, a phenomenon which suggests that the enzyme may be rendered active in conjunction with the Ca^{++}-dependent triggering of the contractile process

phate-bond energy The net gain of glycolysis will therefore, in this case, be 3 moles of ATP per mole of glucose residue in glycogen

Glucose 6-phosphate is converted to fructose 6-phosphate in a reaction catalyzed by *phosphohexose isomerase* A second phosphate group is introduced at the 1-carbon of fructose 6-phosphate to yield fructose 1,6-diphosphate The phosphate group is transferred from ATP and the transfer is catalyzed by the enzyme *phosphofructokinase* Since 1 mole of ATP is dephosphorylated per mole fructose 1,6-diphosphate formed, this reaction involves expenditure of energy

In the next step the 6-carbon compound fructose 1,6-diphosphate is split between C-3 and C-4 to yield two three-carbon compounds, dihydroxyacetone phosphate and D-glyceraldehyde 3-phosphate The enzyme *aldolase* catalyzes this cleavage

The two triose-phosphates formed are interconvertible by isomerization, and dihydroxyacetone phosphate is converted to D-glyceraldehyde 3-phosphate in a reaction catalyzed by *triose phosphate isomerase*

D-glyceraldehyde 3-phosphate is then oxidized to 1,3-diphosphoglyceric acid by *phosphoglyceraldehyde dehydrogenase* (triose phosphate dehydrogenase) in the presence of inorganic phosphate, and DPN^+ bound to each subunit of the enzyme Sulfhydryl groups in the molecule are of decisive importance for the activity of this enzyme The inhibition of glycolysis by iodoacetate is attributed to the fact that this compound reacts with these sulfhydryl groups

The energy of oxidation involved in the oxidation of 3-phosphoglyceraldehyde to a carboxylic acid is retained within the molecule in the form of the bond energy of the intermediate, 1,3-diphosphoglyceric acid

The bond energy is sufficient for a transfer of a phosphate group from the 1 position of 1,3-diphosphoglyceric acid to ADP The enzyme *3-phosphoglyceric acid kinase* catalyzes this reaction

$$\text{1,3-diphosphoglyceric acid} + \text{ADP} \rightleftharpoons \text{3-phosphoglyceric acid} + \text{ATP}$$

The sum of this reaction and that involving oxidation of glyceraldehyde 3-phosphate is the following

$$\begin{array}{c}\text{Glyceraldehyde 3-phosphate} + P_i + DPN^+ + \text{ADP} \\ \Downarrow \\ \text{3-phosphoglyceric acid} + \text{DPNH} + \text{ATP} + H^+\end{array}$$

One molecule of ATP is thus formed for each molecule of 1,3-diphosphoglyceric acid dephosphorylated The energy now stored in the ATP molecule has been derived from the energy of the exergonic oxidation of D-glyceraldehyde 3-phosphate This is an example of the coupling of an energy-releasing oxidation with phosphorylation of ADP in order to retain energy in a chemically available form thus preventing it from being dissipated as heat Oxidation of diphosphopyridine nucleotide (DPNH) is also coupled to ADP phosphorylation and yields 3 moles of ATP per mole DPNH (see below)

An exchange reaction between cytoplasmic and intramitochondrial DPNH is required because the permeability of the mitochondrial membrane for DPNH is low Several mechanisms for such an exchange have been proposed, but the actual reactions that predominate in vivo are not known

The 3-phosphoglyceric acid is transformed into 2-phosphoglyceric acid in an intermediate step in which 2,3-diphosphoglyceric acid is utilized as a cofactor The overall reaction is catalyzed by *phosphoglyceromutase* and is similar in mechanism to that involving G-1,6-diP (see above)

2-Phosphoglyceric acid is converted by dehydration to phosphoenol-pyruvic acid in the presence of *enolase* The phosphate group of phosphoenol pyruvic acid is linked to the molecule by a high-energy bond. A transfer to ADP of the phosphate group yields 1 molecule of ATP and pyruvic acid This reaction is catalyzed by *pyruvate kinase* in the presence of Mg^{++}

This is the last reaction during glycolysis that can furnish energy for synthesis of ATP Under anaerobic conditions, DPNH formed as a result of conversion of 3 phosphoglyceraldehyde to 3-phosphoglyceric acid can be oxidized to DPN^+ in a reaction where pyruvic acid is reduced to lactic acid The coupling of these two reactions is essential under anaerobic conditions, because DPNH cannot be oxidized by the mitochondrial electron transport system which requires oxygen The coupling occurs, however, also in the contracting muscle with normal blood supply when the requirements regarding the speed of DPNH oxidation are too high to be satisfied by the mitochondrial system. Lactic acid is therefore formed also under aerobic conditions when the muscle activity exceeds a certain intensity

The coupling of the reactions leading to res-

toration of DPN$^+$ can be summarized as shown in Figure 1 89 No oxygen, however, is consumed during glycolysis and the presence of oxygen is not required

The reactions in the glycolytic breakdown of glucose are summarized in Figure 1 90

Glycolysis occurs in the sarcoplasm, and the enzymes involved are part of the easily extracted "soluble proteins" from muscle tissue which constitute about 30% of the total muscle protein

The *citric acid cycle* (tricarboxylic cycle or Krebs cycle) represents a cyclic sequence of chemical reactions, by which acetic acid bound to coenzyme A (CoA) as acetyl coenzyme A (Acetyl CoA) is oxidized to CO_2 and H_2O (Figs 1 91 and 1 92) Pyruvic acid derived from glycolysis furnishes one source of acetyl CoA Pyruvic acid is oxidized in a series of reactions involving several enzymes, and four cofactors which form a complex constituting *pyruvic acid dehydrogenase* The following overall scheme illustrates the net effect of the reactions of Figure 1 93

The acetyl CoA is an energy-rich compound and can also be formed from fatty acids and certain amino acids The citric-acid cycle, therefore represents a common pathway in the oxidative degradation of carbohydrates, fats, and proteins Glucose and fatty-acid metabolism represent, however, the main sources of acetyl CoA

In the citric-acid cycle, acetyl CoA reacts with the 4-carbon oxaloacetic acid to form the 6-carbon citric acid, a reaction catalyzed by citrate synthase, formerly referred to as the "*condensing enzyme*" Citric acid is converted to its isomer, isocitric acid Oxidative decarboxylation of isocitric acid results in the formation of α-ketoglutarate In a series of reactions analogous to the pyruvate dehydrogenase reactions (see above), succinyl CoA is formed from α-ketoglutarate and CoA The energy of the thioester bond of succinyl CoA is used to form GTP from GDP in a reaction producing free succinate and free CoA Succinate is oxidized to form fumarate and reduced FAD Hydration of fumarate to malate and finally oxidation of malate to form oxaloacetate completes the cycle One molecule of the 2 carbon acetyl fragment is oxidized during the cycle, with 2 molecules of CO_2 and 4 hydrogen atoms

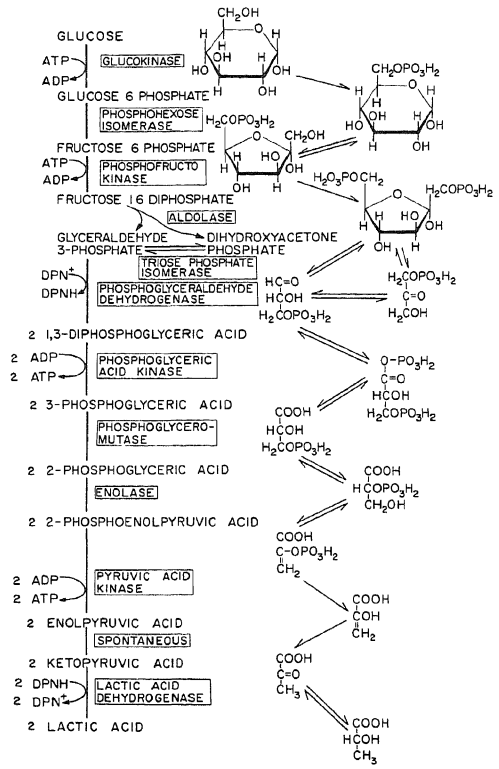

Fig 1 90 Glycolysis

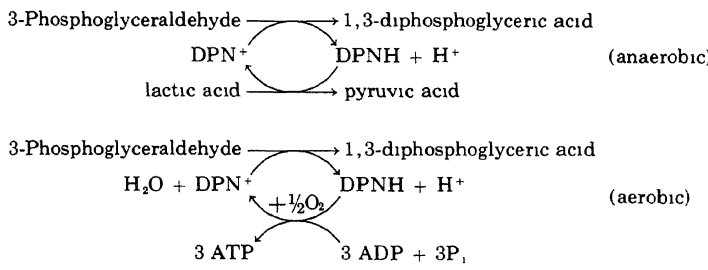

Fig 1 89 Anaerobic and aerobic restoration of DPN$^+$

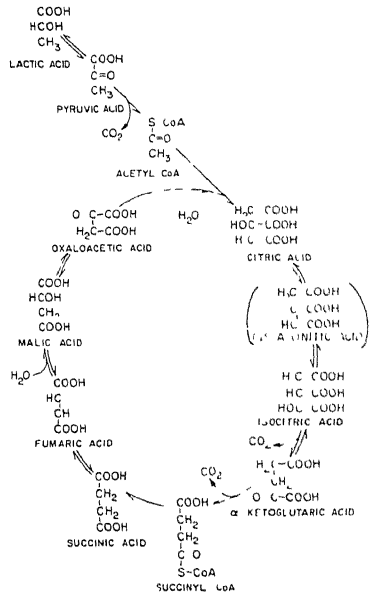

Fig 1 91 The citric acid cycle

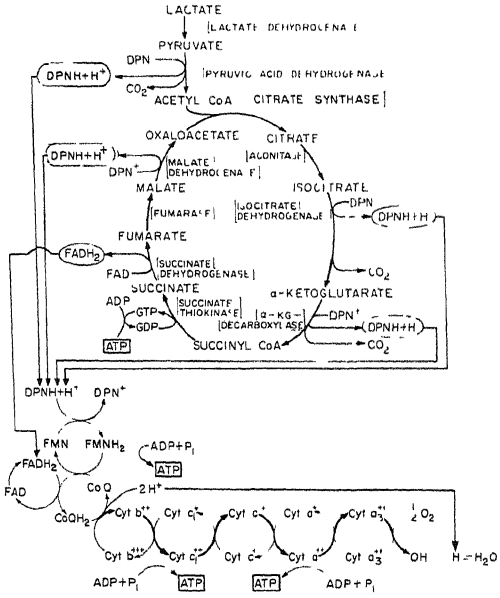

Fig 1 92 The citric acid cycle and the electron transport chain

removed The net exchange during one cycle is shown in the following scheme

$$CH_3COOH + 2O_2 \rightarrow 2CO_2 + 2H_2O + \text{energy}$$

The five energy yielding reactions involve 3 steps in which DPNH is produced, one step in which FADH is produced and one substrate level phosphorylation as follows

(1) Isocitrate + DPN → α ketoglutarate + CO_2 + DPNH + H
(2) α ketoglutarate + DPN + CoA → succinyl CoA + CO_2 + DPNH + H
(3) Succinyl CoA + GDP + P_i → succinate + CoA + GTP
(4) Succinate + FAD → fumarate + FADH
(5) Malate + DPN → oxaloacetate + DPNH + H

OXIDATIVE PHOSPHORYLATION (FIG 1 92)

The reactions in the citric acid cycle are coupled to the respiratory chain consisting of a sequence of hydrogen and electron carriers

The electron carriers are iron containing hemoproteins or cytochromes which transfer electrons by alternating between reduced and oxidized states, the iron switching between ferrous and ferric forms An intermediate step involving the removal of hydrogen from DPNH by DPNH dehydrogenase (which is a flavoprotein), precedes the passage of electrons along the series of cytochromes in the carrier chain The flavoprotein is oxidized by ubiquinone (coenzyme Q, CoQ), a lipid-soluble quinone acting as a coenzyme The exact position of ubiquinone in the respiratory chain is not known, but it is frequently considered to be positioned between FAD and cytochrome *b*, where it then would act as a hydrogen acceptor In the next step, involving oxidation of ubiquinone, the electron from hydrogen is transferred from ubiquinone to the first cytochrome in the cytochrome series, cytochrome *b* (Cyt *b*), and the proton is added to the medium This, therefore, is the step at which hydrogen transfer changes to electron transfer in the respiratory chain Electrons are now passed along the chain of cytochromes, involving in addition to cytochrome *b*, cytochrome c_1 (Cyt c_1), cytochrome c (Cyt c), cytochrome *a* (Cyt *a*) and cytochrome oxidase or cytochrome a_3 (Cyt a_3) Only the last member or the last two members of the group, cytochrome a_3 and *a*, can react directly with oxygen When oxygen is reduced by cytochrome oxidase, hydroxyl ions are formed that combine with the protons generated at the oxidation of ubiquinone to form water The net effects of the electron transport along the respiratory chain are illustrated in Figure 1 92

During the electron transfer along the respiratory chain, starting with DPNH, 3 ADP mol-

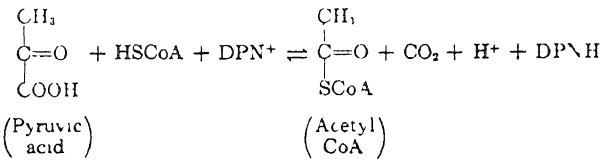

Fig 1 93 Summary of reactions in which acetyl CoA is produced as pyruvic acid is oxidized

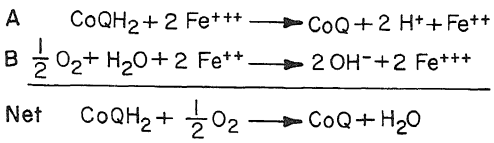

Fig 1 94 Summary of reactions in which ubiquinone ($CoQH_2$) oxygen and cytochrome oxidase interact to form water

ecules are phosphorylated to yield 3 ATP molecules per atom of oxygen This is expressed as a P/O ratio of oxidative phosphorylation of 3 The energy for the formation of the high-energy bonds is derived at three points along the respiratory chain, these three points are considered to be in the segment between DPNH and cytochrome b, between cytochromes b and c, and at the oxidation of cytochrome *c* by cytochrome oxidase The minimum difference in oxidation-reduction potential which is required to provide about 8000 cal for phosphorylation of ADP is 0 18 v A difference in potential that is sufficiently large to satisfy this requirement exists at the first point of phosphorylation, and this reaction can therefore proceed in connection with the transfer of a single electron The potential differences at the two other points are, however, too small to make energy available for ATP synthesis in connection with the passage of a single electron Two electrons would be required It is not understood how the energy associated with two consecutive single electron passages can converge to generate 1 molecule of ATP

At the fourth energy-yielding reaction in the citric-acid cycle described above, succinate is oxidized to fumarate by succinate dehydrogenase Since the oxidation of DPNH is bypassed, the P/O ratio is 2 instead of 3

The mechanism by which the phosphorylation of ADP is coupled to the electron transport along the respiratory chain is unknown It has been assumed that the energy is transferred to ATP through two intermediate compounds via energy-rich bonds If this coupling mechanism is inhibited by drugs, respiration can, under experimental conditions, proceed without the generation of ATP, indicating that the electron transport system can remain intact when the phosphorylation is uncoupled

Under physiological conditions, however, respiration and phosphorylation are tightly coupled and the rate-limiting factors in these processes are the concentrations of ADP and inorganic phosphate The ADP concentration, on the other hand, is determined by the rate at which ATP is utilized This represents a self-regulatory mechanism by which the rate of energy generation is adjusted to the requirements of the cell

Table 1 6 summarizes the energy-yielding and energy-requiring reactions during glucose degradation In reactions 4, 5, and 9, ATP is formed from ADP participating in the reaction In the other reactions except for reaction 10, ATP generation is a consequence of DPNH oxidation in the respiratory system of mitochondria with phosphorylation of ADP coupled to the reaction

$$DPNH + H^+ + {}^1\!/_2O_2 = DPN^+ + H_2O$$

DPN is bypassed in reaction 10 and hydrogen is transferred to FAD, and ATP is formed in connection with a coupling of $FADH_2$ oxidation and ADP phosphorylation according to the following net reaction

$$FADH_2 + {}^1\!/_2O_2 \rightleftharpoons FAD + H_2O$$

In reactions 6, 7, and 8 1 mole of CO_2 is formed for each mole of DPNH formed In glycolytic degradation of glucose equivalents derived from glycogenolysis reaction 1 is not involved and the total number of moles of ATP formed per mole glucose equivalents is, therefore, 39

The enzymes of the citric-acid cycle and the components of the respiratory chain are located in the mitochondria of the muscle cells While the former enzymes can be extracted fairly easily from mitochondria, the components of the respiratory chain are tightly bound to the mitochondrial structure

Table 1 6
Energy yield in glucose degradation

Reaction	ATP yield
(1) Glucose + ATP → glucose 6-phosphate + ADP	1
(2) Fructose 6-phosphate + ATP → fructose 1 6-diphosphate + ADP	1
(3) 2 D-glyceraldehyde 3-phosphate + 2 DPN$^+$ + 2 P_i ⇌ 2 1, 3 diphosphoglyceric acid 2 DPNH + 2 H$^+$	6
(4) 2 1,3-diphosphoglyceric acid + 2 ADP ⇌ 2 3-phosphoglyceric acid + 2 ATP	2
(5) 2 Phosphoenolpyruvic acid + 2 ADP → 2 pyruvic acid + 2 ATP	2
(6) 2 Pyruvic acid + 2 CoA + 2 DPN$^+$ → 2 acetyl CoA + 2 CO_2 + 2 DPNH + 2 H	6
(7) 2 Isocitric acid + 2 DPN$^+$ ⇌ 2 α ketoglutaric acid + 2 CO_2 + 2 DPNH + 2 H$^+$	6
(8) 2 α-ketoglutaric acid + 2 CoA + DPN$^+$ → 2 succinyl CoA + 2DPNH + 2 H$^+$ + 2 CO_2	6
(9) 2 Succinyl CoA + 2 GDP + 2 P_i → 2 succinic acid + 2 CoA + 2 GTP 2 GTP + 2 ADP ⇌ 2 GDP + 2 ATP	2
(10) 2 Succinic acid + 2 FAD ⇌ 2 fumaric acid + 2 $FADH_2$	4
(11) 2 Malic acid + 2 DPN$^+$ ⇌ 2 oxalacetic acid + 2 DPNH + 2 H	6
Total	38

As noted in Chapter 1, the mitochondrion is characterized by a double surface membrane which forms a boundary separating the interior of the mitochondrion from the surrounding cytoplasm In the interior, a system of inner membranes forms plates that are arranged more or less in parallel, and extend perpendicular to the long axis of the mitochondrion, almost across its whole diameter Sometimes these inner membranes are arranged diagonally or longitudinally In the muscle mitochondria, the inner membranes are closely arranged and separated by layers of mitochondria matrix that are only a few hundred Ångstrom units in thickness (Fig 1 95)

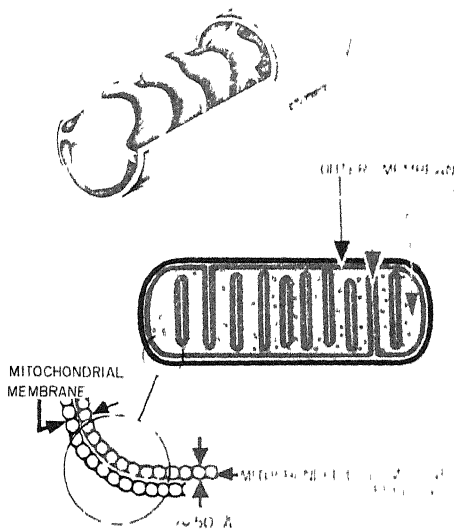

Fig 1 95 The structure of mitochondria

The mitochondrial membranes consist of two presumably identical elements that are in close apposition to form a complex membrane structure The two membrane elements can easily be separated by uptake of water and they then appear to bound vesicular structures The whole mitochondrion also can increase its volume considerably by uptake of water, and the maintenance of a normal volume depends on retaining the metabolism of the mitochondrion The mitochondria contain 30 to 40% of lipid by weight, mainly located in the membrane structures

It is generally accepted that the components of the respiratory chain are arranged in the proper sequence in the membrane elements of the mitochondria and prevented from random motion due to this association Another type of constraint which may be imposed upon the mitochondrial membrane is the orientation of the binding sites of the carriers; e.g , the binding sites for DPHN dehydrogenase and succinic acid dehydrogenase are assumed to face the matrix at the surface of the membrane elements It has been speculated that the electron transfer might be facilitated by the close arrangement of the components of the respiratory chain, which would allow transfer with small changes in orientation of the individual electron carriers

Electromyography

The structural basis of electromyography is the motor unit In normal skeletal muscles,

fibers probably never contract as isolated individuals Instead, several of them contract at almost the same moment, all being supplied by branches of the axon of one spinal motor neuron

FUNCTION OF A MOTOR UNIT

The muscle fibers of a motor unit normally contract sharply upon the arrival of impulses at frequencies ranging up to 50/sec This frequency seems to be the upper physiological limit for axonal propagation of motor neurons in most mammals including man However, motor units may be deliberately fired at much slower frequencies, even to as low as single isolated contractions at will Normal human beings can learn easily to provide various frequencies of impulses usually below 16/sec — from their spinal motor neurons

The number of striated muscle fibers that are served by one axon, i e , the number in a motor unit, varies widely Generally, muscles controlling fine movements and adjustments (such as those attached to the ossicles of the ear and of the eyeball, larynx, and pharynx) have the smallest number of muscle fibers per motor unit The muscles that move the eye have less than 10 fibers per unit, the muscles of the middle ear, 10 to 125, the laryngeal muscles 2 to 3, and the pharyngeal muscles have 2 to 6 These are all rather small and delicate muscles and they control fine or delicate movements On the other hand, large, coarse-acting muscles have motor units with many muscle fibers, e g , the human gastrocnemius has 2000 or more

Even the largest bundles of muscle fibers are quite small, and so a strong contraction of a skeletal muscle requires the participation of many motor units Further, there is a complete asynchrony of the motor unit contractions imposed by asynchronous volleys of impulses coming down the many axons Thus, with motor units contracting and relaxing at differing rates, a smooth pull results (In certain disturbances the contractions become synchronized, resulting in a visible tremor)

The fibers in a motor unit of the rabbit's sartorius may be scattered and intermingled with fibers of other units Thus, the individual muscle bundles seen in routine histology do not correspond to individual motor units as such In rat muscle, the fibers of a motor unit are widely scattered In man, a similar condition is probable, the spike potentials of each motor unit in the biceps brachii are localized to an approximately circular region of 5-mm diameter in which the fibers of the unit are confined However, the potentials can be traced in their spread to over 20-mm distance, thus the area of 5-mm diameter includes many overlapping motor units

Motor Unit Potential. During the normal twitch of a muscle fiber, a minute electrical potential is generated, which is dissipated into the surrounding tissue The duration of the action potential associated with this twitch is about 1 to 2 msec , or even 4 msec Since all the muscle fibers of a motor unit do not contract at exactly the same time—some being delayed for several milliseconds—the electrical potential developed by the single twitch of all the fibers in the motor unit is prolonged The electrical result of the motor-unit twitch, then, is an electrical discharge lasting about 5 to 8 msec (and often as long as 12 msec) The majority of these motor-unit potentials have an amplitude of around 0 5 mv When displayed on a cathode-ray oscilloscope, the result is a sharp spike that is most often biphasic (Fig 1 96), but it may also have a more complex form, depending on physical and other factors

Generally, the larger the motor-unit potential registered, the larger is the motor unit producing it However, complicating factors, such as distance of the unit from the electrodes and the types of electrodes and equipment used, determine the final size and pattern of the individual motor-unit potential that is recorded For further details, the reader should consult

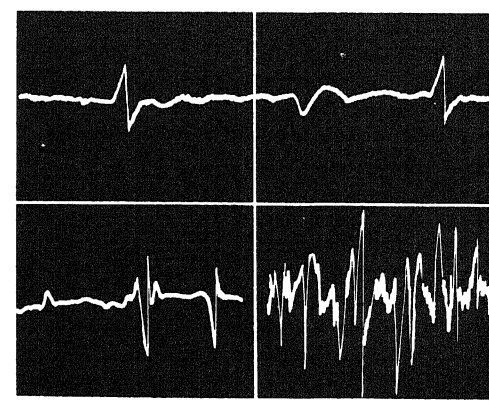

Fig 1 96 Normal electromyograms The single potential in the upper left corner has a measured amplitude of 0 8 mv and a duration of 7 msec

the papers of Basmajian (1967), Buchthal et al (1957), and Hakansson (1957)

Petersen and Kugelberg (1949) have shown that the electrode type affects the recorded duration and amplitude of the action potentials They demonstrated characteristic variations, e g , the smallness of potentials in facial muscles as compared with those in muscles of the extremity Furthermore, they (and others) have found a slight prolongation with advancing age

Under normal conditions, the smaller potentials appear first with a slight contraction As the force is increased, larger and larger potentials are recruited, this being the normal pattern of recruitment This normal pattern is absent in cases of partial paralysis due to injuries or lesions of the lower motor neuron, i e , the small potentials never appear, apparently because only the larger motor units have survived

Electromyographic Technique. The types and construction of electrodes used in electromyography vary widely The two main types of electrodes used for the study of muscle dynamics are surface (or "skin") electrodes and inserted (usually wire or needle) electrodes (described in detail by Basmajian, 1967)

Basically, an electromyograph is a high-gain amplifier with selectivity for frequencies in the range of 10 to several 1000 cycles per second (c p s) It has been suggested that the sharply-peaked spectra of motor-unit potentials derived with surface electrodes render the use of amplifiers with limited frequency-response quite practical, and it has been found that 20 to 200 c p s is the most desirable frequency range for the elimination of amplifier "noise," general nonmuscular "tissue noise" and movement artifact without significant loss of motor unit potentials

Function of Whole Skeletal Muscle

GROSS ORGANIZATION

Approximately 434 skeletal muscles, composed of some 250 million muscle fibers, account for 40 to 45% of the human body weight The muscle fibers are enmeshed in collagenous and reticular connective tissue At the ends of the elongated muscle fibers the connective tissue forms a common bundle of fibers, the tendon The connective tissue surrounding individual muscle fibers is called the endomysium Groups of muscle fibers, collected into bundles or fascicles are bound together by a more dense layer of collagenous and elastic fibers called the perimysium Finally the collagenous tissue which binds the fascicles into definitive muscle is called the epimysium The connective tissues of all these three layers are actually in continuity with each other

The arrangement of the muscle fibers in a muscle is variable (see Fig 1 97) and has been classified as follows

1) Muscle fibers parallel to the long axis of the muscle (e g , the strap like sartorius the pectineus, and the fusiform biceps brachii and flexor carpi radialis)

2) Muscle fibers oblique to the long axis of the muscle Muscles whose fibers are arranged so that they insert obliquely into a tendon in-

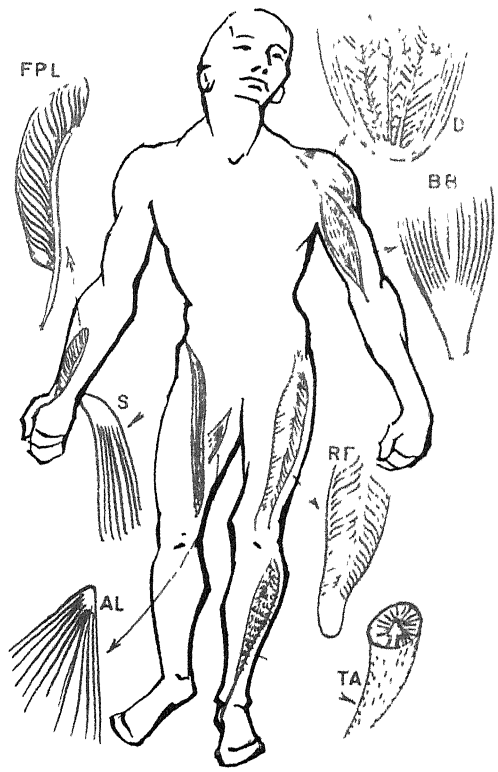

Fig 1 97 The form and distribution of several varieties of striated skeletal muscle The pennate, flexor pollicis longus (*FPL*), multipennate, deltoid (*D*), fusiform, biceps brachii (*BB*), bipennate, rectus femoris (*RF*) circumpennate tibialis anterior (*TA*) radial, adductor longus (*AL*) and strap-like sartorius (*S*) (The male figure redrawn from the First Muscle Tabula in *Fabrica* by Vesalius)

clude several varieties Because of their resemblance to feathers, with *a*) barbs unipennate (e g , flexor pollicis longus), *b*) bipennate (e g , rectus femoris), *c*) circumpennate (e g , tibialis anterior), and *d*) multipennate (e g , deltoid)

3) Muscle fibers arranged in a radial or triangular shape (e g , adductor longus, pectoralis minor)

Muscles whose component fibers are in parallel array are able to shorten over greater distances than muscles whose fibers are organized in the pennate manner The penniform arrangement of muscle fibers is associated with those muscles which exert great force rapidly over a short distance

In order for muscles to perform their function they are attached, for the most part, from one bone across a joint or joints to another bone by *tendons* or flattened sheets of connective tissue called *aponeuroses* The tendons and aponeuroses are formed of collagen, which is flexible but practically inextensible

The points of muscular attachment are called the origin and the insertion The origin of a muscle is usually the fixed or proximal attachment, while the insertion is the distal attachment to the bone which is moved There are exceptions and in many cases the designation of the origin and insertion of a muscle has become a matter of anatomical convention The force developed by an uncontrolled maximal contraction of a whole muscle is of little practical use in the movements of man and animal Therefore, the force and movement generated in a given circumstance by a given muscle depends upon the time-integrated individual activities of its component motor units For fine control of movement one or more motor units are employed As more force is required the number of stimuli carried by each motor unit nerve is increased, along with the recruitment of additional motor units The grading of muscular activity is the result, therefore, of asynchronous firing of the motor units of a whole muscle

In considering the function of muscles in man, it should be noted that no muscle acts alone even in the simplest movement, i e , a variety of muscles which are described as synergists and antagonists are involved in each action The synergists are muscles which act together to produce a movement which no muscle could produce alone An example of synergistic function can be seen in the adduction of the hand at the wrist The flexor carpi ulnaris will both flex and adduct the hand To produce adduction alone, the extensor carpi ulnaris must be brought into action to offset flexion and yet permit adduction of the hand by the flexor carpi ulnaris Antagonists, on the other hand, are muscles with opposed function For example, the biceps brachii and triceps brachii are mutually antagonistic with respect to movement at the elbow joint The muscle which produces the movement is termed the agonist while the muscle which opposes the movement is termed the antagonist The antagonist is usually reflexly inhibited when the agonist is brought into action, e g , if one holds a weight on the palm of the hand with the elbow flexed perpendicular to the body, the biceps brachii (in this case the agonist) develops tension while the triceps brachii (the antagonist) is flaccid This action is reversed—the triceps being contracted and the biceps relaxed—when the hand presses down onto a table with the arms flexed When however, the arm is extended and the elbow joint is fixed, both the biceps and the triceps are contracted

Not all striated muscles are associated with the movement of skeletal parts at joints or with the fixation or maintenance of joint stability as related to posture Muscles serve as sphincters when they encircle an orifice (e g , eyelid, lips, and anus) Striated muscle is found in the upper two-thirds of the esophagus in a tubular arrangement which aids in the swallowing mechanism The diaphragm is a thin muscular sheet which upon contraction serves to enlarge the thorax and compress the abdomen, effects which are associated with inspiration This action is reversed during expiration when the muscle relaxes In addition, there are certain cutaneous muscles which have at least one of their attachments to the skin, e g , the mimetic facial muscles and the panniculus carnosus of the trunk

TRANSMISSION TO THE SKELETON OF MUSCLE FORCE

The force generated by a muscle is transmitted to the skeleton by means of its tendons The submicroscopic collagen filaments of tendons extend along the surface of the individual muscle fibers at the tapering ends of the muscle fibers The surface area of the muscle fibers is fairly large here due to longitudinal folds of the

plasma membrane There is close contact between collagen filaments and the muscle fiber surface

The shape of a tendon varies with the shape of the muscle to which it is attached, but the muscle fibers are always oriented at an angle to the main direction of the tendon Muscles, in which the angle is relatively large, are called pennate muscles This angle, which never exceeds 10 to 20°, serves to prevent fraying of the tendon when the diameter of the fibers increases in connection with contraction and shortening

A tendon may form one or several flat sheets at the region of contact with the muscle, and the muscle fibers can impinge on one or both sides of such a sheet The length of the fibers extending between tendons is usually considerably shorter than the overall length of the muscle The distance bridged by the muscle fibers is related to the range of shortening under physiological conditions and to the fact that under these conditions the maximal shortening of individual muscle fibers is kept within a certain limit, viz , about 30% of the maximal length of the muscle in the body This is presumably an adjustment to the relationship between the maximal tension developed by a muscle as a function of its length

In places where a large force is required but where the range of shortening is limited, muscles are characterized by multipennate structure with the tendons forming several septa arranged in two planes In this case the effective cross-section of the muscle is considerably larger than the anatomical cross-section The septa of the tendons in the human deltoid muscle were found to develop gradually during embryologic growth and to be reduced in "old age " It is therefore likely that the gross structure of a muscle is dynamically adjusted to its functional requirements as is its cross-sectional area.

The cross-sectional area of a muscle increases when the muscle is forced repeatedly to develop maximal or close-to-maximal tension, as in regular exercise or work that requires forceful muscle action This increase is due to an increase of the cross-sectional area of the individual muscle fibers (hypertrophy) but not to a formation of new fibers (hyperplasia) Hypertrophy will persist and increase only if the work load is continuously increased during a training period If the load is kept constant the growth of the muscle stops when its strength has been adjusted to the load

Muscles exposed to sustained rhythmic activity over fairly long periods of time at a load below maximum show an increase in the density of the network of blood capillaries extending between the muscle fibers This appears as an adjustment to the requirements for increased oxygenation associated with this form of activity In animals experiments have shown the effect to be more pronounced in the young than in adults

The subdivision of the muscle tissue into individual muscles is, as was pointed out above, determined by mechanical factors, the muscle tissue being split up into individual muscles at places where large relative movements between parts of the muscle mass occur during movement of the body Such translational movements are most extensive between muscles that exhibit antagonistic effects, such as flexors and extensors Such muscles are also frequently separated by extensive connective tissue septa The individual muscles can therefore be classified with respect to their mechanical effects on the skeleton

The participation of a muscle in a particular movement depends on the pattern of impulses transmitted to it from the central nervous system Surprisingly these patterns can at times involve the activation of mechanically antagonistic muscles (or parts of muscles) and the failure to activate mechanically synergistic muscles It was found, for instance, by electromyographic recording, that the ventral and dorsal portions of the human deltoid muscle participate in the abduction of the arm during the whole range of the movement in spite of the fact that these components of the deltoid are mechanically antagonistic during part of this movement On the other hand, these components are not necessarily activated in adduction —even when the arm is so positioned as to render them mechanically synergistic.

Therefore, one cannot always deduce the patterns of muscle activity associated with a particular movement A direct recording of the muscle activity is required to give precise information regarding the patterns of activation of the various muscles participating in any particular type of movement. This consideration applies particularly to movement in ball joints

CORRELATED STRUCTURE AND FUNCTION OF SKELETAL MUSCLE FIBERS

It has been recognized for many years that muscles vary in color, not only from species to species but also within the same animal Striking examples of this are the crimson red pectoralis of the pigeon as contrasted with the stark white chicken pectoralis and the red soleus lying near the white gastrocnemius in the lower limb of animals and man In birds (falcon, goose, and chicken) it has been shown that the amount of red pigmentation in the pectoralis muscle can be correlated directly with the capacity for sustained flight Furthermore, it was shown experimentally that it takes fewer stimuli per second to produce a smooth, sustained, maximal contraction (tetanus) in the red muscles than in the white muscles A generalization derived from many investigations indicates that all slow-contracting muscles have red pigmentation, but not all red muscles are slow-contracting (e g , the soleus is a red, slow-contracting muscle, while the masseter is also a red muscle but it contracts more rapidly)

In more quantitative terms, whole muscles provide a spectrum of speeds of contraction and relaxation as shown in Figure 1 98 It can be seen that the contraction time of an extraocular muscle (7 5 msec at 37° C) is 5 times faster than that of the gastrocnemius muscle (40 msec) and 12 times faster than that of the soleus muscle (90 msec) The extraocular muscles and the soleus represent the fast and slow extremes in most mammals It is important to remember that whole muscles are not normally

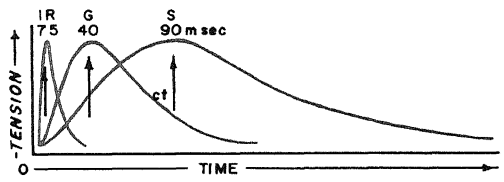

Fig 1 98 Illustration of the isometric contraction-relaxation (twitch) curves for three mammalian skeletal muscles The lateral rectus (*L R*) gastrocnemius (*G*) and soleus (*S*) represent the extremes (fast and slow) and midrange in a spectrum of contraction-relaxation times for mammalian muscles The arrows indicate peak tension development which corresponds to the contraction time for each muscle (lateral rectus 7 5 msec gastrocnemius 40 msec , and soleus 90 msec)

activated synchronously to yield the maximal twitch response of the kind recorded in Figure 1 98 Furthermore, the twitch response of isolated whole muscles does not reveal the heterogeneous nature of the tissue either in functional or structural terms

Microscopic examination of histological sections of muscle reveals variability in cross-sectional diameter, internal structure, and certain histochemical reactions of the muscle fibers An examination of the structural-functional components of the gastrocnemius also illustrates the heterogeneity of muscle The white gastrocnemius muscle of the cat is in the midrange of muscle speed (contraction time is about 40 msec and contraction-relaxation time about 160 msec) The contraction time of the motor units which comprise the gastrocnemius vary from 17 8 to 129 msec with a distribution peak between 30 and 40 msec The peak distribution corresponds to the contraction time for the twitch of the isolated whole muscle In addition, not all motor units produce a twitch response, however, the slow-responding motor units do develop tension when given multiple (tetanic) stimulation

In general, large motor units have a higher threshold, contract more rapidly, and develop a greater degree of tension than the smaller motor units

Histochemical and electron microscopic studies reveal that the gastrocnemius is composed of three distinct types of muscle fibers About 50 to 55% of the muscle fibers and 70% of the cross-sectional area are composed of fibers which are large and contain few mitochondria, as demonstrated by histochemical localization of succinic dehydrogenase and adenosine triphosphatase activity About 30% of the muscle is composed of smaller dark cells with a greater density of mitochondria The remaining 14 to 20% is composed of the smallest dark fibers with densely packed mitochondria The large fibers are the classical white, fast twitch fibers, while the smaller dark fibers represent two types of red, slow contracting fibers The soleus muscle of the cat (but not those of the rabbit and rat) is composed entirely of the same intermediate dark fibers found to comprise 30% of the gastrocnemius Therefore, these fibers can be classified as *slow twitch* muscle fibers The smallest dark fibers in the gastrocnemius are probably *slow* muscle fibers,

judging from the physiological characteristics of some of the motor units in the gastrocnemius

Although the cat soleus muscle appears to be structurally homogeneous its motor unit contraction time varies from 50 to 193 msec The peak distribution of motor units has a contraction time of 80 to 90 msec , which corresponds to the contraction of the twitch of an isolated whole muscle Approximately 90% of the soleus motor units develop 70% of their maximal tension at low frequency stimulation i e 20/sec Some units develop a large fraction of their contractile power at 5 to 10 stimuli/sec The soleus can maintain tone or tension as required by slow, low frequency firing of its various motor units Experimental evidence also indicates that there is an overlap in contraction times (from 50 to 129 msec) between the slower motor units of the gastrocnemius and the faster motor units of the soleus muscle

Even the fast contracting extraocular muscles from the cat are composed of three morphologically distinct muscle fibers The isolated muscle produces both a twitch-type contraction after single shocks and a slow, graded nontwitch contraction which is elicited only after multiple stimulation The variety of structural and physiological properties of these muscles are, therefore, basically similar to those of the slower gastrocnemius

THE INNERVATION AND SUBMICROSCOPIC ORGANIZATION OF TWITCH AND SLOW MUSCLE FIBERS

The twitch muscle fibers can be characterized physiologically by their ability to produce (on nerve stimulation) a propagated action potential and to respond with fast shortening or tension development Within this group many differences exist in color, contractile behavior, rates of conduction and contraction time The slow fibers, however, differ fundamentally from the twitch fibers because they have lower levels of resting potential (50 to 70 mv as compared to 80 to 90 mv for fast fibers), they do not produce propagated action potentials, they exhibit a longer latency of response (6 to 8 msec as compared to 2 to 4 msec for fast fibers)—and they do not respond to stimulation by rapid shortening or rapid tension development Only repeated stimulation results in a significant rise in tension by these slow muscle fibers In addition the slow muscle fibers are innervated by numerous nerve endings (the en grappe type), distributed widely over the whole fiber length, whereas the twitch fibers are innervated by a single discrete localized nerve ending (the en plaque type) with a distinct neuromuscular junction The numerous areas of nerve contact which locally activate the contractile apparatus of the fiber compensate for the inability of a slow fiber to produce propagated muscle impulses

Although the slow muscle fiber system is widely found it has been studied in greatest detail in the frog In this animal tension development by slow fibers following reflex activation is similar to tension development after direct nerve stimulation (provided that the direct stimulation is of sufficient intensity to activate most of the small nerve fibers serving the muscle) The motor units of the slow fiber system may be normally activated, therefore, by a synchronous high frequency discharge from the spinal cord In the frog the nerve fibers to the slow muscle fibers are small and slow conducting (2 to 8 m /sec) while the nerve fibers to the twitch fibers are large and fast conducting (8 to 40 m /sec) No overlap of innervation between the two muscle groups has been found The slow muscle fibers are reflexly activated even during periods when the twitch fibers are at rest The slow fibers can also be activated during twitch fiber activity and can maintain large tensions originally produced by the twitch fibers over very long periods by virtue of low frequency stimulation A functionally useful synergism has been demonstrated by the twitch and slow fibers in the frog tibialis muscle First, small nerve stimulation at 30/sec results in a smooth rise in tension If a burst of twitch activity is added, via the large nerve system, the final tension developed exceeds that which would have been developed without the twitch activity Secondly, when stimulation ceases there is a very gradual relaxation of the generated tension If a burst of twitch activity is initiated during the slow relaxation phase, the residual tension in the slow fibers collapses rapidly

Slow fibers and twitch fibers have similarities and differences in their fine structure In both, the myofilaments of the myofibrils are of the same length even though sarcomere lengths may differ However, the slow fibers have no discrete M lines, the H zones are poorly de-

fined and the Z lines are thick Although the myofibrils tend to be large and vaguely defined in cross-section, this cannot be considered as a sole criterion for slow fibers

A striking difference between twitch and slow fibers is the absence or poor development of the transverse tubular or T system in the slow fiber In the twitch fiber the T tubule is in continuity with the sarcolemma, but, in those slow fibers in which a T system can be recognized, the small delicate tubules have no specific localization with respect to the sarcolemma or the contractile apparatus Thus, local contractions are not confined to specific areas of the myofibril The smallest contractile unit of many twitch fibers is that specific area of the myofibril between two adjacent M lines, the T-system being located at the Z line In other twitch fibers, the smallest contractile unit is the half sarcomere and, in this case, the T system is found at the level of the junction of the A and I bands (see Fig 1 99)

The motor nerve endings on slow muscle fibers, as revealed by electron microscopic studies, are readily distinguishable from those of twitch muscle fibers The specific region of nerve-muscle contact is small compared with that on twitch fibers In addition, there are no junctional folds in the muscle membrane or sarcolemma in the region of the nerve ending Such junctional folds are a constant feature of the motor end-plate in twitch fibers

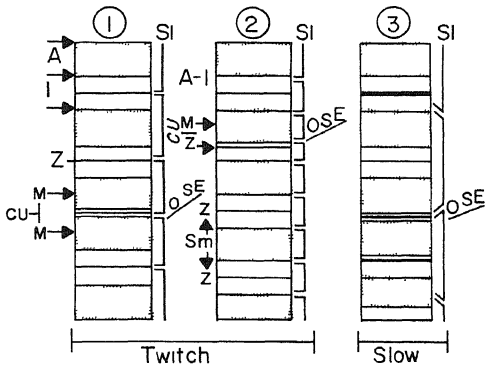

Fig 1 99 Local excitation of twitch and slow muscle fibers The response to local subthreshold stimulation (*SE*) delivered to the sarcolemma (*SI*) is specific and discrete in twitch fibers In twitch fiber 1 a localized contraction can be elicited in the region of the Z line This is the precise localization of the transverse tubules or T system in this fiber The smallest *contractile unit* (*CU*) therefore is that area of the myofibril between two adjacent M lines (M) *A* A band *I* I band *Z* Z line

In fiber 2 the local response is found at the level of the A band-I band junction (*A I*) The T system in this fiber is at the A band-I band junction The *contractile unit* (*CU*) is thus a half sarcomere or that area of the myofibril between adjacent Z and M lines The sarcomere (*SM*) includes one A band and two half I bands Fiber 3 represents a slow muscle fiber Stimulation of this fiber results in a variable or diffuse response No portion of the fiber is selectively excitable The T system when found in slow fibers has a meandering course

Among the various factors that may account for the difference in the slow and fast fibers, the nerve endings appear to have the most influence For several years, cross innervations have been made between slow and fast mammalian muscles The procedure is to cut the motor nerve to these fibers and cross them so that slow muscle fibers are innervated by fast firing nerves and fast muscle fibers are innervated by slow firing nerve endings It has been shown that after recovery from the cross innervation procedure, the slow fibers have a modified behavior They contract more rapidly and they undergo morphological and biochemical alterations, e g , methyl histidine appears in myosin and there is an enhancement of the activities of several enzymes inducing the ATPase associated with myosin The main effect of cross innervation of fast muscle with slow nerve fibers is a slowing of the twitch

It has been suggested that changes in the rate of firing of nerve fibers innervating skeletal muscle fibers may be a factor in the differentiation of slow and fast fibers There are some indications that if a fast muscle is cross-innervated with slow nerve fibers, but electrically stimulated at a rate of 30 to 60/min (normal fast fiber rate), a change from fast muscle properties to slow muscle properties is prevented Although we have very limited information concerning the exact role of motor nerves as a trophic influence, it is well-established that the integrity of the nerve supply is of utmost importance for the preservation of normal muscle structure and function, e g , sectioning a motor nerve is always followed by atrophy as well as paralysis of the muscle to which it is connected It is highly probable therefore that a trophic factor is synthesized in, or at least conveyed to, the muscle through its nerve

DIFFERENTIATION OF FAST AND SLOW TWITCH MUSCLES

The growth and development of mammalian muscles with different contraction times has

been given much attention In general, all muscles in newborn animals are equally slow It takes about 6 weeks (in cats) for the fast twitch fibers to attain their adult speed The more slowly contracting muscles, such as the soleus and crureus, pass through a short period during which their contraction times quicken, but this is followed by a progressive slowing until the adult condition appears in about 20 weeks It can be shown that the differentiation of the slow contraction time can be abolished if the cord is transected or if the lumbosacral spinal cord is isolated from incoming stimuli In this case, the muscles do not become slow, but after a few weeks the soleus and crureus become almost as fast as normal fast muscles (e g , gastrocnemius) In adult rabbits, a similar transformation in the soleus will occur if the tendinous insertion of the muscle is cut (tenotomy) Electromyographic studies show that the soleus is normally continuously activated Upon tenotomy, the continuous activity ceases even with intact motor innervation It can be concluded that motor impulse activity plays a fundamental role in determining the speed of contraction in mammalian skeletal muscle, although the exact mechanism is not known

Following tenotomy, the red, slow contracting soleus is transformed into a white, fast contracting muscle Not only have the mechanical properties of the soleus been changed, but the red color has disappeared The red color of muscle is due to myoglobin which is related to the hemoglobin of red blood cells Myoglobin from skeletal muscles has a molecular weight of 16,700 and contains 1 heme (iron-porphyrin complex) per molecule The hemoglobin of the blood is composed of 4 hemes/molecule and differs also in the protein globin Myoglobin has a greater affinity for oxygen than does hemoglobin, and it serves as an oxygen reservoir within the muscle fiber In addition to its high affinity for oxygen, myoglobin loads and unloads its oxygen with great speed Myoglobin is probably synthesized within the muscle fiber much as hemoglobin is synthesized within the red blood cell

A direct relationship has been found between the myoglobin content of muscle and the rate of blood flowing through a given muscle mass, usually referred to as the fractional blood flow and expressed as the per cent of cardiac output perfusing 100 g of muscle

The density of the capillary network (as measured by the alkaline phosphatase reaction) is highest in the red fibers lowest in white fibers, and intermediate in "intermediate" fibers Myocardial fibers and the external oculomotor fibers have a denser capillary network than other muscles Twitch time is proportional to the fractional flow (thus, red muscles twitch more slowly than white muscles)

The myosin ATPase activity is greatest in fast muscle fibers least in slow fibers, and intermediate in "intermediate" fibers The pH optimum is in the alkaline range for the ATPase of white (fast) fibers and in the acid range for the ATPase activity of slow fibers, the "intermediate" fibers have maximal ATPase activity in an intermediate pH range In addition to ATPase, the properties of aldolase and other enzymes have also been found to differ when red and white fibers were compared The high myosin ATPase, which probably is related to the ability to shorten rapidly, serves to provide the speed and acceleration needed in the functions that the white muscles serve

Metabolism of the red fibers is mostly aerobic while white muscles can also function anaerobically as illustrated by the increase in the lactic acid content in the veins draining an exercising muscle Such anaerobic metabolism leads to "oxygen debt," from which the muscle must ultimately recover by oxidative replenishment of its energy stores During fetal development while white fibers are differentiating, the histidine and lysine moieties of the muscle proteins are methylated It is estimated that white fibers contain 1 mole of 3-methyl-histidine per mole of myosin, whereas fetal, red, and cardiac muscle fibers do not contain any 3-methyl histidine The ATPase activity of the fibers increase three fold with the appearance of 3-methyl histidine. Actin fibers also contain 3-methyl histidine, however, the methylation in actin is unrelated to that in myosin

Red slow muscle fibers undergo sustained rhythmic activity They respond to stimuli with prolonged contractures. They constantly adjust to postural change They operate during periods of prolonged anoxic stress as demonstrated by diving mammals Accordingly, those animals whose activity is sustained generally have red muscles The lower myosin ATPase in red muscle permits muscular contraction to proceed with slower utilization of ATP This

facilitates the appropriate balance between chemical energy supply and mechanical energy utilization that must occur in a muscle that contracts steadily and without rest for long periods of time.

White fast muscles undergo only short bursts of activity and possess little myoglobin. It should be recalled, however, that most muscles are a mixture of both red and white fibers. Nature has devised a mechanism, whereby the neuromuscular system utilizes both tonic and phasic contractions in order to provide an exquisite range of functional activity about which there is still much to learn.

5 / AMINO ACIDS AND PROTEINS

The Molecular Framework and Machinery of Living Systems

Proteins are the realization of the information contained in deoxyribonucleic acid (DNA) Through them this information is transformed into physiological work They are the primary constituents of cellular machinery and form an integral part of the regulatory systems that determine how the machinery operates

The ubiquitous distribution of the various classes of proteins reflects the roles they serve in the body

1) As *structural elements* they are found in the membranes of cells and organelles They are a major component of the various fibers of connective tissue—collagenous, reticular and elastic—as well as the ground substance

2) Their function as *enzymes* is legion As such they are responsible for the ordered sequential reactions which result in chemical and biological work This makes the thermodynamically unfavorable process called "life" possible Special classes of enzyme proteins fulfill a mechanochemical role Actin, myosin, and the related muscle proteins are involved in the conversion of chemical energy [adenosine triphosphate (ATP)] into mechanical work

3) *Intramembrane carrier proteins* act as shuttles, mediating the transport of various molecules and ions across the cell membrane When energy is required for the passage of substances across the cell membrane (active transport) it is the carriers and their allied cofactors that generate a vectorial quality for the net movement of solutes into or out of the cell

4) Proteins also serve a *carrier function in plasma* by binding small molecules and ions and transporting them throughout the body Thus, thyroxin-binding globulin transports thyroxine to cells where it is released and rendered active Transferrin, an iron-binding globulin, delivers Fe^{++} to hemoglobin-synthesizing loci The activity of ions such as Ca^{++} can be controlled by the ratio of the free to the bound species When H^+ ion is bound, the protein acts as a buffer to minimize changes in pH Since cells are impermeable to proteins, they also participate in determining the ionic distribution and, hence the electrical potential difference across cell membranes (Gibbs-Donnan equilibrium) By virtue of its osmotic activity albumin mediates the distribution of body fluid between the plasma and extracellular compartments

5) The *antibody proteins* (immunoglobulins) contribute to the body's defense against infection

6) Acting as *hormonal messengers*, peptides and proteins (e g , insulin, growth hormone, vasopressin, etc) carry information that regulates cell permeability and cell metabolism

7) They provide a *source of fixed nitrogen* for the synthesis of essential nonprotein nitrogenous compounds such as heme, creatinine, etc

8) After hydrolysis, the constituent amino acids can be deaminated and metabolized to CO_2 and H_2O, and thus serve as *sources of energy*

One of the most important properties of living systems, that of specificity, is expressed through proteins This property is determined by the primary protein structure as dictated by the nucleic acid sequence in DNA and, in turn, by the conformational consequence of this primary structure Each animal species and each tissue within an organism can be characterized by its component proteins Indeed, it is the variation of protein content among tissues which results in functional specialization and tissue specificity (differentiation) This arises from the fact that each tissue selects amino acids in a particular ratio from the total body pool of amino acids and polymerizes them into proteins characteristic for that tissue The varieties of proteins so produced (Table 1 7) were classified at the turn of the 20th century chiefly on the basis of solubility properties, and there seems to be little prospect of a better classification scheme in the near future

What is common to all proteins is the fact

Table 1 7

Class of Protein	Characteristics	Examples
	A Simple proteins	
1) *Albumins*	Soluble in water and coagulable by heat Present in both animal and plant tissues	*Serum albumin, egg albumin, lactalbumin*, and various vegetable albumins such as *leucosin* (in wheat, rye, and barley), *legumelin* in lentils, soy beans, beans and peas, and *phaselin* in kidney beans
2) *Globulins*	Soluble in dilute saline solutions, insoluble in water Animal globulins are coagulated by heat Vegetable globulins imperfectly or not coagulated by heat	*Serum globulin, fibrinogen* (and *fibrin*) *vitellin* of egg yolk, and vegetable globulins such as *excelsin* (Brazil nuts), *edestin* (hemp), *phaseolin* (kidney beans), *legumin* (peas and lentils), and *tuberin* (potatoes) A number of other vegetable globulins have been isolated and named
3) *Glutelins*	Found only in plants Insoluble in water, saline, or alcohol, but soluble in very dilute alkali	*Glutenin* of wheat, *oryzenin* of rice, and *glutelin* of maize
4) *Prolamines or gliadins*	Found in cereals (except rice) Soluble in 70 to 90% alcohol, insoluble in water They contain a large proportion of proline and compounds giving rise to ammonia-nitrogen	*Gliadin* of wheat, *hordein* of barley, and *zein* of maize
5) *Albuminoids or scleroproteins*	Especially resistant to the usual reagents They enter into the construction of protective and connective tissues, e g , skin, tendons, ligments, and bones	*Keratin* of hair, skin, bone, feathers, tortoise shell and eggshell, *elastin, collagen, ossein* and *gelatin* of tendons, ligaments, bone, etc
6) *Histones*	Soluble in water and precipitated by ammonia solution and by alkaloids They contain a large percentage of basic (diamino) acids (Table 1 8)	*Globin* of hemoglobin, *thymus histone, scombron* and *gadus histone* in spermatozoa of mackerel and codfish, respectively
7) *Protamines*	Found in combination with nucleic acid in heads of fish spermatozoa Constructed predominantly of basic amino acids	*Salmine* and *sturine* in spermatozoa of salmon and sturgeon, respectively
	B Conjugated proteins Proteins whose molecule is combined with another nonprotein group	
1) *Nucleoproteins*	Nucleic acid in combination with a protein belonging usually to the class of histones or protamines	Present in cell nuclei
2) *Chromoproteins*	Protein in combination with a pigment (e g , hematin) containing iron, copper, or other metal	Hemoglobin, hemocyanin, etc
3) *Glycoproteins*	Proteins other than nucleoproteins in combination with a carbohydrate group	*Mucin* in salivary gastric and intestinal secretions, *ovomucoid* of egg white and *chondromucoid* of cartilage
4) *Lipoproteins*	Proteins in combination with lipid	Present in plasma, milk, cell nuclei
5) *Phosphoproteins*	Proteins other than nucleoproteins and lecithoproteins in combination with a phosphorus-containing group	*Caseinogen* (and casein), *vitellin* of egg yolk

C *Derivatives of proteins—derived proteins* These are produced by the action of acids, alkalis or proteolytic enzymes upon certain of the proteins listed above		
a) *Primary derivatives*		
1) *Proteans*	Insoluble products formed in the early stage of the action upon proteins of water, dilute acids, and enzymes	
2) *Metaproteins*	Formed in a later stage of the action of acid or alkali	*Acid* metaprotein, *alkali* metaprotein
3) *Coagulated proteins*	Formed by the action of heat or of alcohol upon solutions of proteins	
b) *Secondary derivatives*		
1) *Proteoses*	Formed by the action of pepsin or trypsin upon proteins. They are soluble in water from which they are precipitated by saturation with ammonium sulfate. They are incoagulable by heat	*Albumose* from albumen, *globulose* from globulin, *caseose* from casein
2) *Peptones*	These represent a further stage in action of proteolytic enzymes. They are soluble in water but are not precipitated from an aqueous solution by ammonium sulfate. They are not coagulated by heat	
3) *Peptides, dipeptides, tripeptides* and *polypeptides*	Products formed in the final stages of proteolytic digestion	Glycyl-alanine, leucyl glutamic acid, etc

that they are made up of amino acids (Table 1-8). What is specific about proteins is the ratio of the component amino acids and the order (primary sequence) in which they are polymerized. Therefore, a consideration of the amino acids is the logical starting point for a survey of the physiology of proteins.

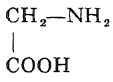
Physicochemical Properties of Amino Acids

Amino acids are the monomeric building blocks which, as noted above, are joined together in a specific sequence to form proteins. The type and configuration of amino acids within the plant and animal kingdoms are not in all cases identical. For instance, within the plant kingdom, amino acids can be found that occur in the *D* as well as the *L* configuration (as in bacterial cell walls) or have various modifications in the side chain (e.g., hydrogen replaced by a halogen, etc.). There are 24 naturally occurring amino acids found in protein hydrolysates from animal tissues (Table 1-7). Other amino acids are not polymerized into proteins but found as monomers in tissue, e.g., γ amino butyric acid (GABA). The general structure for an amino acid is as shown in Figure 1-100. The penultimate carbon atom, designated α, is covalently bonded to an amine or imine function, a carboxylic acid function and an R group which differentiates one amino acid from another.

Thus, fundamentally, it is the sequence of R groups of a chain of amino acids which accounts for the characteristic structural and functional properties of proteins.

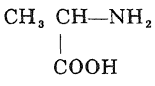
The R group is simply H in the case of glycine but it may be an aliphatic, aromatic or heterocyclic group in other amino acids. Within these larger categories the R group is further delineated by a variety of specific substituents (Table 1-8).

ACID-BASE PROPERTIES OF AMINO ACIDS



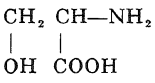
In aqueous solution amino acids and proteins behave as weak acids or weak bases depending

Table 1 8
Classification of the amino acids[a]

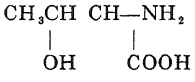


I Aliphatic Amino Acids

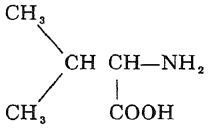
A Monoamino-monocarboxylic acids



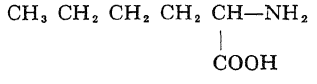
1) Glycine (or glycocoll) $C_2H_5NO_2$, or amino-acetic acid



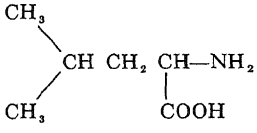
2) Alanine, $C_3H_7NO_2$, or α-amino-propionic acid



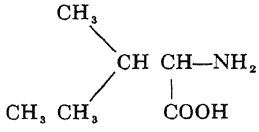
3) Serine, $C_3H_7NO_3$, or α-amino-β-hydroxy propionic acid



4) Threonine, $C_4H_9NO_3$, or α-amino-β-hydroxy-*n*-butyric acid

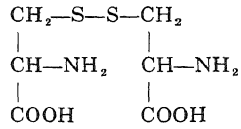


5) Valine, $C_5H_{11}NO_2$, or α-amino-isovaleric acid

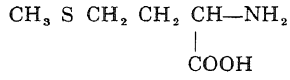


6) Norleucine, $C_6H_{13}NO_2$, or α-amino-*n*-caproic acid

7) Leucine, $C_6H_{13}No_2$, or α-amino-isocaproic acid

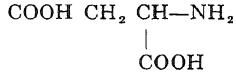


8) Isoleucine, $C_6H_{13}NO_2$, or α-amino-β-ethyl-β-methyl-propionic acid

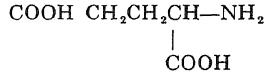


Sulfur-containing monoamino-monocarboxylic acids

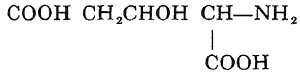
9) Cystine, $C_6H_{12}N_2S_2O_4$, (or dicysteine) or di-(β-thio-α-amino-propionic) acid



10) Methionine, $C_5H_{11}SNO_2$, or α-amino-γ-methyl-thiol-*n*-butyric acid

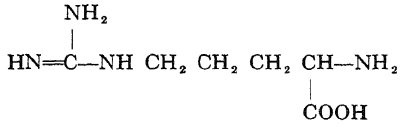


B Monoamino-dicarboxylic acids

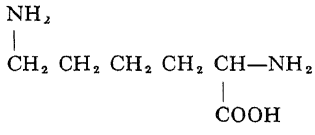


11) Aspartic acid, $C_4H_7NO_4$, or α-amino-succinic acid

12) Glutamic acid, $C_5H_9NO_4$, or α-amino-glutaric acid

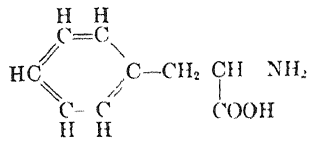


13) Hydroxyglutamic acid, $C_5H_9NO_5$, or α-amino-β hydroxy-glutaric acid

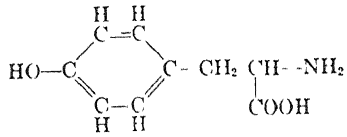


C Diamino-monocarboxylic acids

14) Arginine, $C_6H_{14}N_4O_2$, or α-amino-δ-guanidine-*n* valeric acid

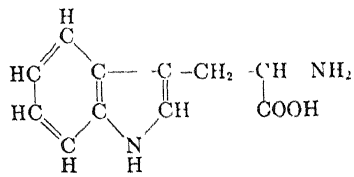


15) Lysine, $C_6H_{14}N_2O_2$, or α-ϵ-*diamino-caproic acid*

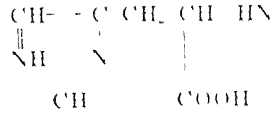


II AROMATIC AMINO ACIDS

16) Phenylalanine $C_9H_{11}NO_2$ or α-amino β-phenyl propionic acid

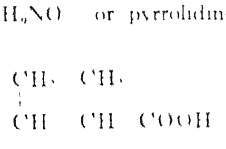


17) Tyrosine, $C_9H_{11}NO_3$, or α-amino-β-parahydroxy phenyl propionic acid



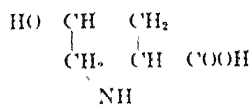
III HETEROCYCLIC AMINO ACIDS

18) Tryptophane $C_{11}H_{12}N_2O_2$, or α-amino-β-indole propionic acid



Indole nucleus

19) Histidine $C_6H_9N_3O_2$ or α-amino β-imidazol propionic acid



Imidazole ring

20) Proline $C_5H_9NO_2$ or pyrrolidine α-carboxylic acid

Pyrrole nucleus

21) Hydroxyproline (oxyproline) $C_5H_9NO_3$, or γ-hydroxy pyrrolidine α-carboxylic acid

[a] *Hydroxylysine, thyroxine, 3-5-duodotyrosine* or iodogorgoic acid, *citrulline (α-amino δ-carbamido n-valeric acid)* and *ornithine(α,δ-diamino-valeric acid)*, and several others would have to be added to complete the list of naturally occurring amino acids

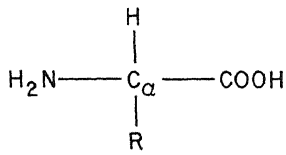


Fig 1-100 General structure of an amino acid

on the number and nature of acidic and basic R group substituents Thus, proteins and amino acids serve as physiological buffers in the extracellular and intracellular fluids Weak electrolytes (acids and bases) do not ionize readily Consequently, addition of a proton (H^+) or hydroxyl ion (OH^-) to such a system removes the ion from solution so that the pH tends to remain constant, as shown in Figures 1-101 and 1-102

Amino acids and proteins, thus behave as Bronsted acids and bases (proton donors and proton acceptors, respectively) As such, information concerning their pH behavior can be obtained by titration pH is defined as log $[H^+]$ where $[H^+]$ represents the molar concentration of hydrogen ions The acid dissociation constant, Ka, for the reaction, HA $H^+ + A^-$, is

$$[H^+][A^-]/[HA] \text{ at equilibrium}$$

Therefore

$$[H^+] = ([HA]/[A^-])\ Ka$$

Taking the negative logarithm of both sides of this equation yields

$$-\log [H^+] = -\log ([HA]/[A^-]) + (-\log Ka) \text{ or}$$
$$pH = pKa + \log [A^-]/[HA]$$

This is the Henderson-Hasselbach equation which relates the pH of a system to the degree of ionization of the species under consideration

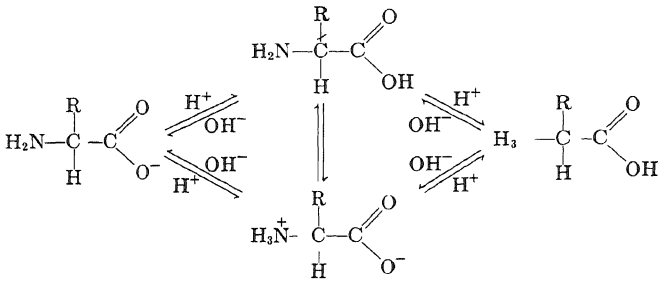

Fig 1 101 Titration of an amino acid

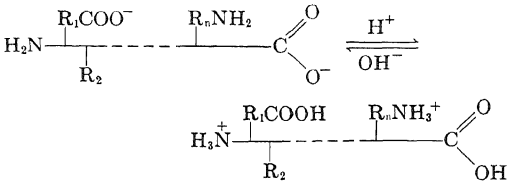

Fig 1 102 Titration of a protein

At 50% ionization the ratio $[A^-]/[HA]$ being 1 and log 1 being 0,

$$pH = pKa$$

Operationally the pKa of the ionizable groups of an amino acid or protein can be determined as the points of inflection observed by plotting the results of a titration of the amino acid or protein in terms of pH vs the amount of added base or acid Figure 1 103 illustrates the titration of the aromatic amino acid tyrosine starting with its fully protonated form (acidic solution) Since there are three groups involved in proton donation (NH_3^+, phenolic hydroxyl, carboxyl) there will be three stages in the titration, each requiring 1 Eq of base (NaOH) to reach the end point Each stage has a pKa which is characteristic of the group being titrated Since it requires a total of 3 Eq of NaOH to neutralize the three groups, tyrosine is an example of a polybasic acid All amino acids exhibit this amphoteric behavior Figure 1 104 illustrates the dissociation stages of glycine, a neutral amino acid, glutamic acid, an acidic amino acid, and lysine, a basic amino acid Examination of the various stages of dissociation of these and other amino acids reveals an H^+ ion concentration, characteristic for each amino acid, at which it has a net charge of zero, i e , the sum of its positive charges equals the sum of its negative charges This H^+ ion

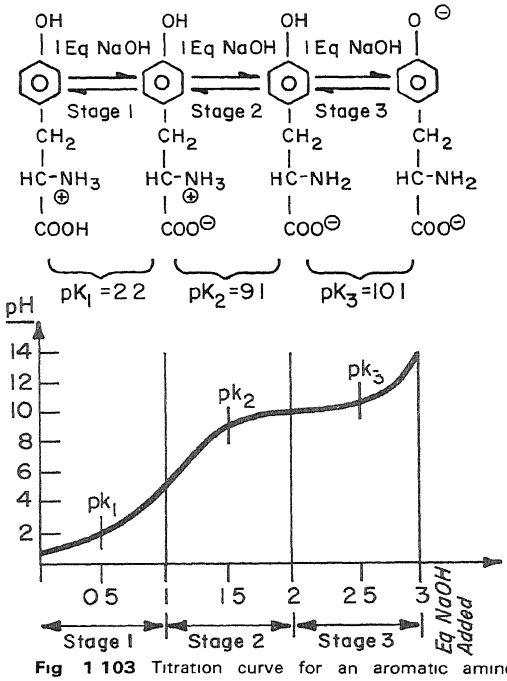

Fig 1 103 Titration curve for an aromatic amino acid tyrosine showing three stages of titration

concentration is the *isoelectric point* of the amino acid, the corresponding pH is designated by the symbol pI At its isoelectric point an amino acid behaves as an ampholyte (zwitterion), in other words, at its pI, an amino acid is electrically neutral and it can behave as an acid or a base For acidic amino acids pI < 7, for basic amino acids pI > 7 Most amino acids are zwitterions in the physiological pH range

Zwitterions are dipoles Schematically they may be represented as shown in Figure 1 105

There are several consequences of this dipolar structure which affect the physical properties of amino acids in solution and in the crystalline form and, indeed, the physical proper-

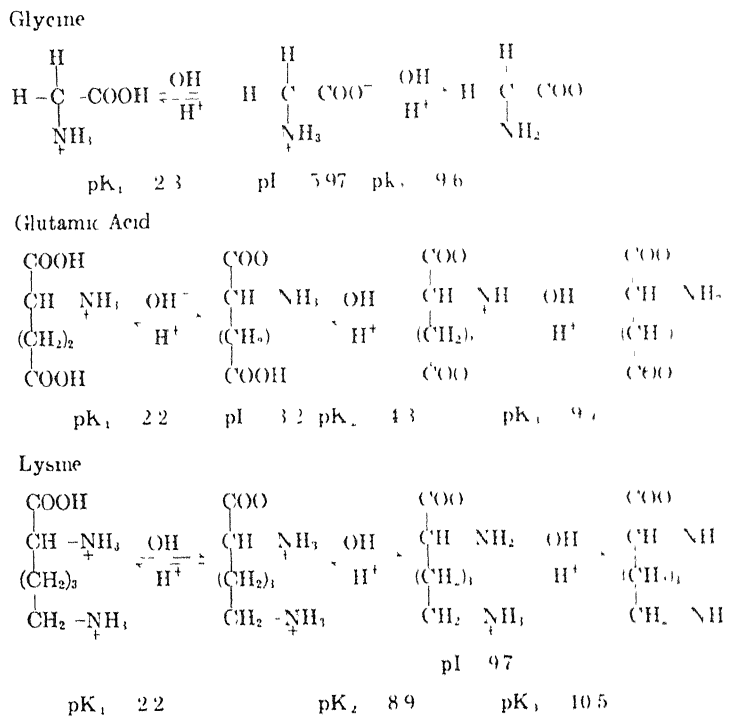

Fig 1 104 Dissociation stages of glycine (a neutral amino acid) glutamic acid (an acidic amino acid) and lysine (a basic amino acid)

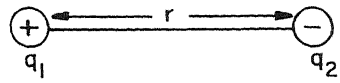

Fig 1 105 Structure of a zwitterion

ties of an amino acid confirm that it exists in the form of a zwitterion rather than in the form of a neutral or an uncharged molecule

A dipole consists of charges (q_1, q_2), opposite in signs but equal in magnitude, separated by a fixed distance (r) When a dipole is placed in a uniform, external electric field, it will spin about the center of the fixed distance in order that net force on it will be zero (Fig 1 106) The product of the charge, q, and the distance, r, is the dipole moment, and amino acids are found to have appreciable dipole moments as would be expected for zwitterions Inspection of the final state diagram indicates that since the charges are equal and opposite, the resultant force is zero. Consequently, the dipole experiences no net force and is stationary in an electric field, i e , it does not migrate to the cathode or anode Accordingly, at its pI, an amino acid does not migrate in an electric field

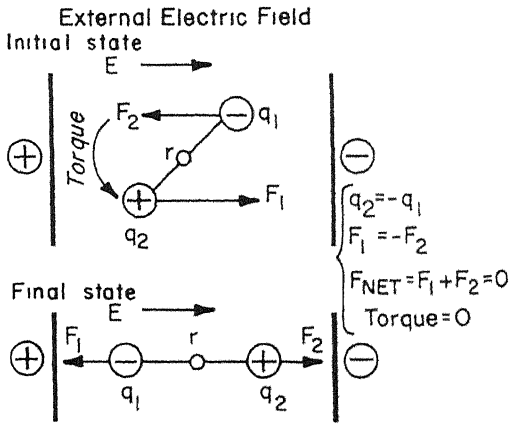

Fig 1 106 Diagram illustrating rotation of a dipole in presence of uniform external electric field

When two or more dipoles come together they orient themselves in a specific way such that they interact electrostatically as sketched in Figure 1 107 Thus, amino acid crystals melt with decomposition because additional energy must be supplied to break the intermolecular electrostatic bonds This extra energy is in excess of that required to reach the melting point and the crystal undergoes decomposition in-

stead of a simple transformation to the liquid state Amino acids are more soluble in polar solvents (e g , water) than in nonpolar organic solvents, and they raise the dielectric constant of any solution in which they are dissolved Spectrographic analysis also indicates that amino acids exist as dipoles When amino acids are joined to form proteins, the dipoles arrange themselves so that they cancel themselves out and leave the overall protein structure as a net dipole

Physicochemical Properties of Proteins

PEPTIDE BONDS

In the synthesis of the protein molecule chains of amino acids are formed by the linkage of the carboxyl group of one amino acid to the α amino group of another amino acid with the concomitant liberation of a molecule of water (*peptide bond* formation) This joining of two amino acids through a secondary amide linkage (peptide bond), viz , —C—N—, leads

to the formation of a dipeptide (Fig 1 108) The similar addition of another amino acid will yield a tripeptide In this manner polypeptides are built up In representing peptides and proteins the N-terminus (amino-terminus) is written on the left and the C-terminus (carboxyl-terminus) on the right

There is a large body of evidence which indicates that in peptides and proteins, the amino acids are indeed linked via peptide bonds For example, the structure of myoglobin, an iron containing protein in muscle, has been determined by Kendrew (1962) and his associates, using x-ray analysis at a resolution of 1 5 A which allows individual atoms to be distinguished The electron density analysis clearly showed that the interamino acid linkages were peptide bonds

In the chemical synthesis of peptide and protein hormones such as oxytocin, vasopressin, insulin, etc the individual amino acids are linked together by classical methods for the formation of peptide bonds and the final products exhibit the same physicochemical properties and biological activities as their naturally occurring counterparts The peptide bond gives a characteristic infrared and far-ultraviolet absorption spectrum, natural and synthetic peptides and proteins give analogous spectra

The fact that proteins give an intensely positive biuret reaction provides a useful if less direct evidence for the peptide bond hypothesis Biuret, a compound with the following structure,

reacts with an alkaline solution of copper sulfate to form a purple colored complex, the intensity of which is related to the amount of biuret present

When an intact soluble protein is titrated over a broad pH range, it is found that relatively few amino and carboxyl groups are titratable These titratable groups are the terminal free amino and carboxyl functions of the protein and the acidic and basic groups of the side chains (R groups) of amino acids such as arginine, lysine, asparagine, glutamine, serine, tyrosine, histidine, etc If the protein is hydrolyzed, the number of titratable amino and carboxylic groups increase in a 1 1 ratio and at equal rates

The characteristics of the peptide bond have been analyzed by x-ray diffraction There are

Fig 1 107 Electrostatic interaction of two dipoles

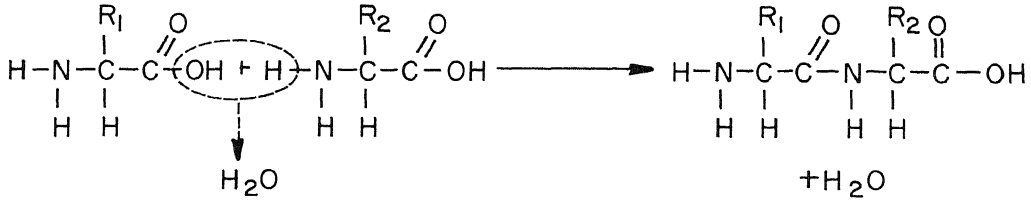

Fig 1 108 Formation of peptide bond linking two amino acids to yield a dipeptide

six atoms involved in this bond and generally it is coplanar (Fig 1 109) From the length of the C-N bond, it was determined that it is of 50% double bond character Thus, rotation about this bond is restricted and consequently the α carbons are trans to each other

Peptide linkages form the backbones of proteins Therefore, a generalized protein may be represented as in Figure 1 110

It will be seen that projecting off the backbone of this prototype protein are the various amino acid residues The primary structure of a protein is defined as the linear sequence of the peptide-bonded amino acids The projecting side chains (R groups) of the constituent amino acids are important in determining the superstructure of proteins

From the primary structure analysis of hemoglobin, myoglobin, carboxypeptidase A, lysozyme, ribonuclease (RNase) and others, it is clear that most amino acids occurring in proteins (from animal sources) are of the L-configuration and that the ordering of amino acids in the protein is random although genetically determined Given one amino acid out of the 20, there is an equal probability for any one of the other 20 amino acids to occur next to it, i e , any dipeptide sequence is as likely as any other

Considering a generalized protein (such as in Fig 1 100, where the nature of the R groups are left unspecified) there is sufficient flexibility in the covalently bonded peptide backbone to allow this polymer to assume a large number of conformations The conformation of the backbone is termed the secondary structure of the protein Before discussing the theoretically predicted and experimentally confirmed secondary structure of proteins it is important to understand the "weak" or secondary interactions (bonds) which determine the conformation assumed by a given polymer

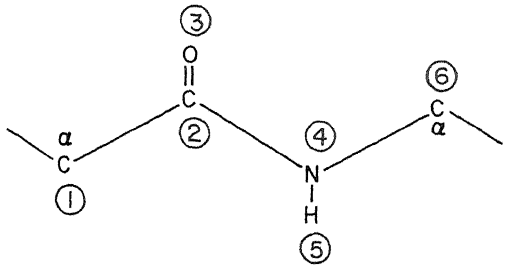

Fig 1 109 Characteristics of a peptide bond as revealed by x-ray diffraction

OTHER TYPES OF BONDS

Covalent bonds generally have energies between 50 to 110 kcal /mole Consequently they are stable at physiological temperature (37° C), they have relatively short bond lengths, and the number of bonds which can be formed between atoms is determined by the valence Furthermore bond formation proceeds under the aegis of enzymes In contrast, secondary (noncovalent) bonds have energies between 1 to 7 kcal /mole, therefore, a single secondary bond exists only for a very short period of time at 37° C Finally, secondary bonds can be formed and disrupted without the intervention of enzymes This latter characteristic is of no small consequence for cellular economy and is of central importance in the process of self-assembly of macromolecular complexes from subunits

Weak bonds are essentially interactions involving the electron clouds around atoms or groups of atoms, these interactions fall into three classes the van der Waal's bond, the hydrogen bond, and the ionic bond (A fourth class of weak interaction, the "hydrophobic bond," is discussed below, however the hydrophobic interaction is not a true bond in the chemical sense)

The van der Waal's bond is the weakest It has an energy of approximately one kcal /mole (random thermal motion in a solution at 37° C is about 0 6 kcal /mole) This bond results from the synchronization of the motion of the electrons around two approaching atoms or groups Each electron cloud induces a complimentary dipole in the other This is a very short range

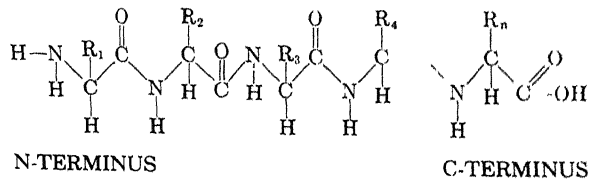

Fig 1 110 Generalized structure of a protein showing peptide bonds, N-terminus and C-terminus

force The energy falls off as the sixth power of the distance between interacting centers (i e , E ∞ $[1/r^6]$) As the interacting centers get closer, the attractive force is opposed by the repulsive force generated by the proximity of the electron clouds around the atoms This can be seen in a plot of energy vs distance (Fig 1 111) The distance r_v is the van der Waal's radius It has a characteristic value for each atom or group involved in an interaction This distance is a compromise between the proximiy necessary for the attractive force to be generated but not counteracted by the repulsive force resulting from the overall negative charges of the electron clouds

Inherent in the requirement for proximity is a steric requirement In order for the interacting groups to approach the critical distance needed for the induction of the attractive force, there must be a complimentarity of overall structure in the surfaces of the molecules to which the interacting groups or atoms are attached If this does not obtain, the bond will not form since the groups will be too far apart Lastly, since the forces are weak, the van der Waal's interaction will be more effective when several atoms or groups participate

A hydrogen bond is based on the attraction of unlike charges When a hydrogen atom is covalently bonded to a moderately strong electronegative atom (or group), it assumes a partial positive charge because the molecular orbital of the electrons is displaced in the direction of the electronegative atom, thus decreasing the neutralization of the positive charge at the site of the hydrogen nucleus This partial positive character allows the hydrogen to interact with any negative atom in another molecule to form a hydrogen bond (Fig 1 112) A-H is the donor species, B-C the acceptor species

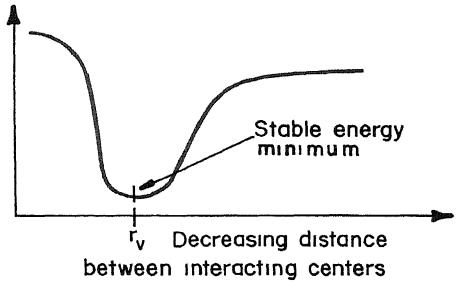

Fig 1 111 Plot of energy as a function of distance or bonds of van der Waal s type

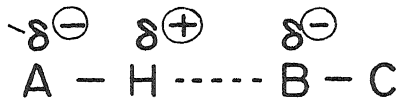

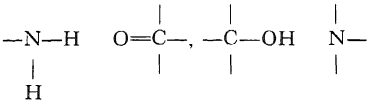

Fig 1 112 Diagram showing hydrogen bond

The following are some examples of common hydrogen bonds

Thus, any covalently bonded hydrogen with a partial positive character can interact with a covalently-bonded atom that has a net negative charge or unshared electrons The result of this interaction is the joining together of the two molecules via this hydrogen bridge This same interaction also occurs intramolecularly This results in two portions of a chainlike molecule being held in close proximity An example of the *intermolecular* hydrogen bond is that which holds two strands of DNA together An example of the *intramolecular* hydrogen bond is that which participates in the maintenance of the coiled superstructure of proteins (Fig 1 113)

The polar nature of water molecules leads to the formation of intermolecular hydrogen bonds and, accordingly, to a water structure often referred to as "iceberg structure " These intermolecular H bonds make and break rapidly, thus, the water structure is transient although its interaction with proteins is one of the factors that serve to determine the overall conformation of proteins

Hydrogen bonds have energies between 3 to 7 kcal /mole, thus, they are stronger than van der Waal's bonds Nonetheless, at physiological temperatures, they do not persist singly for a long time However, when present in ordered groups of molecules such as proteins or DNA, they have a longer lifetime and exhibit the characteristics of cooperative interactions This is a statistical phenomenon At physiological temperatures, weak bonds are in a state of flux, i e , they are constantly being formed and disrupted. However in the native state there are at any time a sufficient number of intact bonds that serve to maintain secondary structure If the temperature is raised more bonds are broken per unit time than are formed Further-

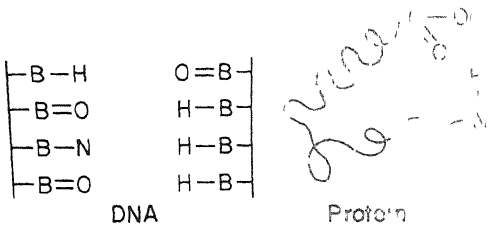

Fig 1 113 Hydrogen bonds in DNA and in a protein molecule

more, as the bonds break, it requires less energy to disrupt the remaining ones This causes an "unzipping" effect, which along with other factors, results in a "melting" of the polymer superstructure as shown in Figure 1 114 Figure 1 114 is a graphic representation of cooperativity In the temperature range T_1 to T_2 there is a rapid transition due to many bonds breaking per unit time for a small temperature increment Approaching T_1 from the left, it requires a larger temperature increment to start the process because initially there are many intact bonds Beyond T_2, most of the bonds are disrupted and further input of energy elicits a lesser response

Ionic bonds (salt bridges) occur between covalently bound atoms that are oppositely charged These bonds or bridges can be formed intramolecularly or intermolecularly, as shown in Figure 1 115, *a* and *b* respectively

Of the three classes of weak interactions discussed, the hydrogen bond is the one involved in the secondary structure of proteins

CONFORMATION OF PROTEIN MOLECULES

The most stable conformation of a polypeptide backbone requires that the carbonyl oxygens and amide nitrogens be hydrogen bonded, the peptide bond be planar, the hydrogen bonded unit be linear, and the geometrical operation in going from one residue to the next be the same along the whole chain There are two structures which meet these requirements, the α-helix and the β-pleated sheet (β-structure)

The backbone of a protein consists of a linear repetition of peptide groups In a regular linear polymer, the monomers are capable of forming sets of secondary bonds of varying strengths The energy differences between these sets of bonds will result in an unstable state for the overall polymer. However, if every monomer can be placed so that each is oriented identically within the molecule, then each monomer will form secondary bonds with identical energy contents Hence, helical symmetry is a result of the unique monomer arrangement which is the most stable of all of the possible arrangements

The α-helix (Fig 1 116) has the following characteristic parameters

1) Hydrogen bonds are parallel to the central axis of the helix
2) Hydrogen bonding occurs between the carbonyl group of the first amino acid residue and the amide group of the fourth residue between the carbonyl of the second residue and the amide of the fifth residue etc
3) The vertical distance corresponding to one turn of the helix i e the pitch of the helix is 5 4 Å
4) A complete spiral requires 3 6 residues
5) Therefore the vertical translation per residue equals 5 4/3 6 or 1 5 Å

The α-helix results from the formation of the maximum number of *intramolecular* hydrogen bonds The β-structure (pleated sheet) also satisfies the requirements for maximum conformational stability (Fig 1 117) However, in this case the hydrogen bonds occur *intermolecularly* between the carbonyl and amide groups on extended polypeptides that lie side by side Consequently the hydrogen bonds are perpendicular to the long axis of the backbone This gives rise to sheetlike structures which may involve parallel or antiparallel arrays of peptide strands

The foregoing considerations were based on the studies of crystalline amides and peptides However, secondary structure can also be demonstrated in polypeptides in solution Hydrogen bonding causes alterations of the dissociation constants of the involved groups, spectral changes and alteration in the rate at which

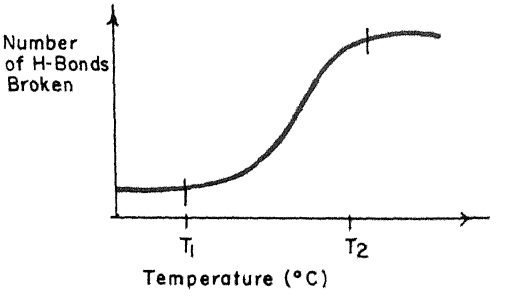

Fig 1 114 Stability of hydrogen bonds as a function of temperature

deuterium (D) will exchange for hydrogen in the protein, because an H atom involved in a hydrogen bond will exchange with D more slowly or not at all Measurement of the above parameters serves to indicate the H-bonding and the degree of secondary structure of a protein in solution

The interactions of the amino acid side chains (R groups) attached to the coiled or pleated peptide backbone—with each other and/or with the solvent environment— determine the next level of geometric complexity and give the overall molecule its final three-dimensional character (*tertiary structure*) Thus, the tertiary structure defines the steric relationship of each atom to every other atom in the molecule

There is a fourth class of weak interactions which is of major importance in determining the final three-demensional conformation of the protein molecule, the hydrophobic "bond " This is not a true bond in the chemical sense Rather, it represents the tendency of hydrophobic (nonpolar) residues to associate together, away from the aqueous (polar) environment This gives rise to apolar clusters, i e , centers in the polymer where water is excluded

This behavior can be understood by considering the components of an aqueous protein solution Such a solution is composed of polar

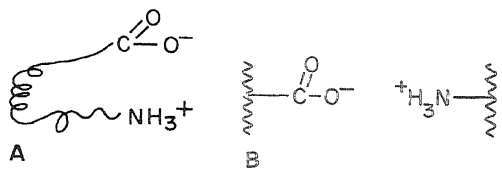

Fig 1 115 Intramolecular (*a*) or intermolecular (*b*) ionic bonding

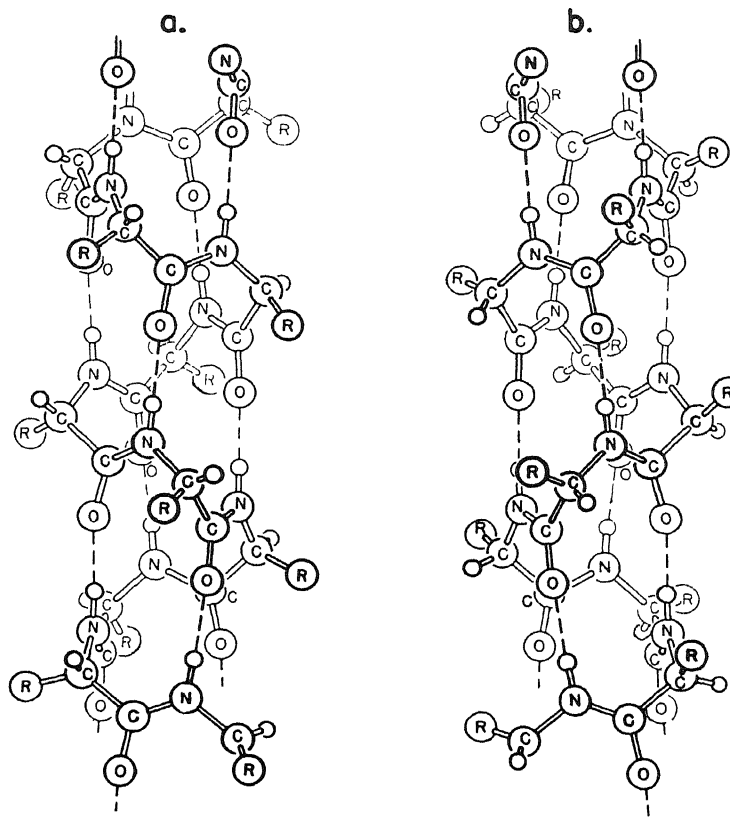

Fig 1 116 Drawings of the left-handed (*a*) and right-handed (*b*) α-helical forms of a polypeptide chain containing L-amino acids The side chains *R* and hydrogen atoms attached to the α-carbons in the main chain have positions corresponding to the known configuration of L-amino acids (From Low and Edsall 1956)

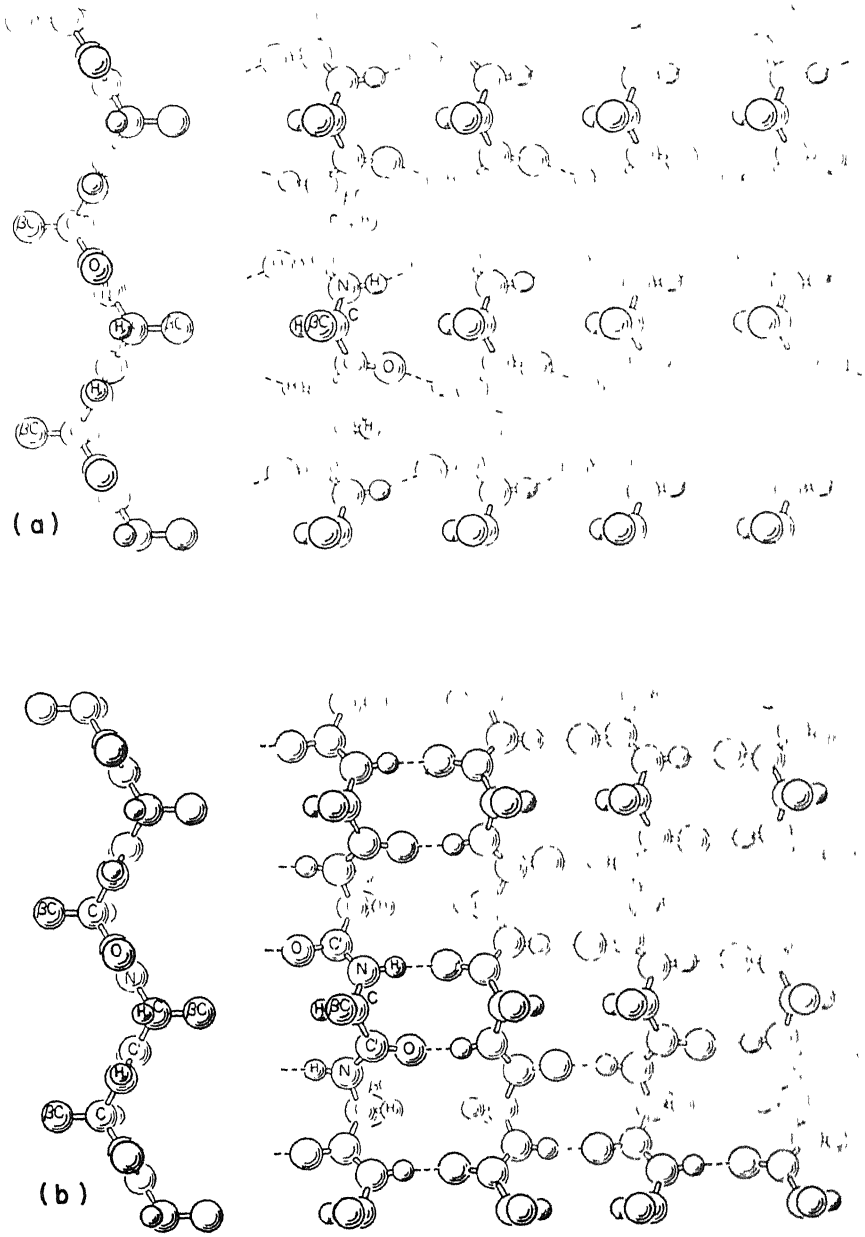

Fig 1 117 Representation of the parallel (*a*) and antiparallel (*b*) pleated sheet structures for polypeptides (From Pauling and Corey 1951)

solvent molecules (water), polar side chains (R groups) of amino acids, and apolar amino acid R groups The polar R groups can interact and form H bonds with the iceberg lattice of water Each R group becomes surrounded by a cage of water molecules but this ordering effect on the aqueous solutions decreases with the distance of the water molecules from the R group The lattice structures thus formed are transient, and the individual water molecules are free to move within the lattice On the other hand, nonpolar groups do not interact or form H bonds with the water lattice but rather serve to "lock" the water lattice structures and impede the mobility of free water molecules This constitutes a decrease in entropy which requires an

expenditure of free energy, a circumstance which is in contrast to the general tendency of systems to minimize their energy content and maximize their entropy ($\Delta G = \Delta H - T\Delta S$)

The amino acid side chains can be considered as polar and nonpolar A polymer composed of a fixed ratio of polar to nonpolar side chains in aqueous solution can theoretically exhibit several conformations each of which has a different energy content, as illustrated in Figure 1 118 The conformation with the lowest overall energy is the most stable Consequently, A (Fig 1 118) will be the longest lived, and hence, the predominant conformation However, let us introduce another polymer which contains the same total number but a *slightly* larger proportion of nonpolar side chains Now, if only the backbone is considered, the most stable conformation will be one in which its secondary bonds are maximized, i e , a helix However, if our consideration is extended to include the side chains, the most stable structure will no longer be a helix but rather a new conformation resulting from a compromise between the tendency to form a helix being offset by the tendency of the side chains to twist the backbone so that nonpolar groups can associate The compromise conformation usually favors the maximization of secondary bonds for the side chains (approximately 50% of the amino acid side chains are nonpolar)

Since peptide sequence is random, nonpolar side chains can occur in widely separated locations along the backbone However, when these side chains come into proximity, they form hydrophobic bonds These nonpolar groups usually place themselves in the interior of the protein molecule, leaving the polar side chains outside to interact with the solvent To bring these groups out of their hydrophobic pocket, where water is excluded, and to force them into a polar solvent (water) requires a large increase in free energy expenditure because of the decrease in entropy of the system

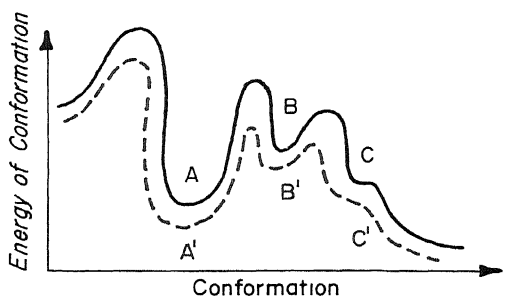

Fig 1 118 Variability of energy of conformation (ordinate) of different conformations of a polymer in aqueous solution

Thus, conformation A' (Fig 1 118) is more stable than conformation A, more energy being required to disrupt the structure and force the nonpolar side chains into the aqueous environment in which they cannot interact with each other or with the water This would produce a large decrease in entropy (hence, the necessity for a large energy expenditure) However, conformation A contains fewer apolar residues, consequently the magnitude of the decrease in entropy associated with disruption of A would be less than that associated with disruption of A'

Therefore, the tertiary structure of a protein is the thermodynamically most stable arrangement It represents the compromise result of simultaneous maximization of polar, hydrophobic, and hydrogen-bonding interactions

The hydrogen bonding of the peptide backbone involves interactions between one part of the protein molecule and another (intramolecular interactions) and between the protein molecule and the solvent (intermolecular interactions) When because of the hydrophobic interaction of the side chains, the protein molecule is so twisted that the peptide linkages are forced into the interior of the molecule with little access to solvent, the intramolecular reactions will be maximized and the α helical conformation is generated Conversely those regions of peptide backbone which are not interiorized, and therefore can form hydrogen bonds with the solvent will assume the conformation of a random coil

The thermodynamically most stable state of a protein, its tertiary structure, is its native conformation This is the conformation that exhibits biological activity This concept has been verified in the case of the enzyme, ribonuclease

Loss of tertiary structure in a protein is brought about by any factor or combination of factors which disrupt its weak interactions (secondary bonds) and is termed *denaturation* Denaturation can be accomplished by manipulations which change a highly ordered structure into a random one, such as heating, drastic pH changes, shaking, organic solvents, detergents and irradiation A denaturated protein lacks

biological activity, denaturation can be reversible (as is the case following treatment with urea) or irreversible (as is the case following heat treatment of proteins) The denaturation process can be followed in solutions of proteins by observing spectral changes (optical rotation ultraviolet absorption at 280 mμ) and changes in solubility (precipitation)

When the enzyme ribonuclease is denatured by reductive cleavage of its disulfide[1] bridges and by treatment with urea, it loses its biological activity However, if the urea is removed from the denatured preparation and then its cysteine moieties are reoxidized to reform disulfide bridges, biological activity is restored Furthermore, analysis of the resulting structure indicates that the disulfide bridges assume their original positions Thus, prior to reformation of the disulfide bridges, the random (denatured) structure must convert to the native conformation upon removal of the urea The basis for this conclusion rests upon the fact that there are four disulfide bridges (eight half-cystine residues) in the native conformation at specific loci in the molecule If the native state were not obtained prior to reoxidation of the eight cysteine residues the disulfide bridges would be reformed at random In this experiment there was no agent present in the solution to direct the conversion of the denatured enzyme to its native conformation The basis for this renaturation would appear to be solely the characteristic property of proteins to assume the thermodynamically most stable state Thus, the information present in the primary structure of ribonuclease will dictate the most stable conformation of the molecule, i e , the sequence of the amino acids in the molecule will determine the type, number, and location of the secondary bonds This is an extremely important consideration inasmuch as it explains how primary amino sequence in conjunction with a very limited number of secondary interactions—viz , hydrophobic bonding, hydrogen bonding, ionic bonding—serves to establish the many protein conformations associated with living systems All proteins existing in the same environment, with the same amino acid sequence must have the same conformation Changing the amino acid sequence establishes a different conformation by establishing a different state of maximal thermodynamic stability This new conformation may be associated with complete or partial loss of biological activity or rarely, with the same or enhanced biological activity The ramifications of these considerations will be further explored in the discussion of the genetic code and protein synthesis

In summary, the peptide backbone of a protein is sufficiently flexible to allow the molecule to assume a large number of different conformations (conformers) However secondary interactions, particularly involving the amino acid side chains restricts the ultimately realized conformation to one that is unique for the primary sequence of the protein and its environment These secondary interactions may lead to different ultimate conformations for different protein molecules or for different regions within a single protein molecule, e g , helices, random coils or compact configurations established by bending and folding of the peptide backbone Such bending and folding, which characterize the globular proteins, bring into contact amino acid residues that may be widely separated in the primary structure[2]

In addition, nonpolar groups located in the interior of protein molecules give rise to hydrophobic pockets which can be important determinants of the molecular complementary that underlies specificity in hormone-receptor, enzyme-substrate and antigen-antibody interactions and also can play a role in the electronic aspects of enzymatic reactions, e g., by amplifying the effects of charged groups in their vicinity (by excluding the dielectric effect of water)

QUATERNARY STRUCTURE

Proteins (such as hemoglobin, the immunoglobulins, the allosteric enzymes, etc.), consisting of more than one chain per molecule are said to have a *quaternary structure* The forces involved in holding the multiple polypeptide chains (subunits) together in a single molecule are the same as those which establish the sec-

[1] Disulfide bridges are low energy covalent sulfur-sulfur bonds formed between 2 cysteine residues, i e ,

$$2\ \text{CYS-SH} \underset{\text{reduce}}{\overset{\text{oxidize}}{\rightleftharpoons}} \text{CYS-S-S-CYS}$$

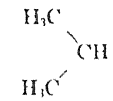
The disulfide bridge is an important component of the tertiary structure of many proteins, adding strength and support to the three-dimensional architecture (conformation) of the molecules

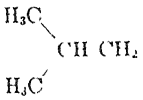
[2] This phenomenon may be of importance in the combination of antigen and antibody molecules where antigen-induced "additional" folding of the antibody polypeptide chains may be required for the formation of the antigen-antibody complex

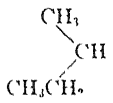
ondary and tertiary structure They operate under the same set of thermodynamic restrictions Thus, each subunit of the functional protein possesses its own conformation and is capable of interacting with another subunit The subunits can be identical or different What is required for the secondary interactions to operate is a complimentarity of surface configurations so that reactive sites on subunits can approach each other closely enough for the formation of ionic bonds, hydrogen bonds, hydrophobic interactions, and interchain S-S bonds The overall active conformation of the protein aggregate is specified by the conformations of the individual subunits Once the subunits exist in their thermodynamically most stable configuration, they then associate *spontaneously*, giving rise to the active aggregate protein This process is referred to as self-assembly It is not mediated by enzymes and does not require an external energy supply It can account for the elaboration of giant macromolecular complexes For example, lactic acid dehydrogenase and aspartyl transcarbamylase are such macromolecular enzyme complexes Virus coat proteins also follow this mode of assembly, i e , once the subunits are synthesized, they spontaneously aggregate around the genetic material

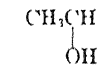
From the viewpoint of cellular economy this is an important consideration It means that no enzymes are required to direct assembly Furthermore, if a subunit is defective it will not interact properly and, accordingly, it will be excluded from the superstructure On the other hand, if a defect develops in a macromolecular superstructure which is synthesized as a single polypeptide chain, a complete breakdown and resynthesis would be necessary for repair of the defect This process can be viewed as a molecular assembly line The subunits are synthesized and then joined to yield the finished functional product

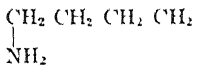
Since the subunits are held together by weak interactions they can be dissociated reversibly by mild procedures such as changing pH or ionic strength In the dissociated state the protein is biologically inactive, aggregation leads to a recovery of biological activity

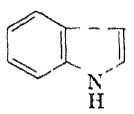












The subunit construction of a giant enzyme complex facilitates the allosteric regulation of its function, e g , a given subunit may form a complex with a small molecule, the allosteric effector or repressor, thereby inducing a conformational change in the entire aggregate which leads to activation or inhibition, respectively, of enzymatic activity

SOURCES OF AMINO ACIDS IN THE METABOLIC POOL

Protein ingestion provides an *exogenous* source of amino acids Before discussing the metabolism of amino acids it is important to enumerate some of their nutritional parameters Protein nutrition must be considered from the standpoint of the amino acids which constitute the ingested protein There is a qualitative as well as quantitative requirement In a classical study Osborn and Mendel kept groups of rats on various diets of purified proteins and measured the ability of these proteins to support growth (Mendel, 1923) Rats maintained on gliadin or zein (wheat and corn protein, respectively) exhibited poor growth, whereas, rats maintained on ovovitellin (from egg yolk) or lactalbumin (from milk) exhibited excellent growth The latter groups of animals grew well because the ingested protein contained all *essential amino acids*, viz , amino acids which are required for vital anabolic reactions, but which cannot be synthesized endogenously from readily available precursors at a rate sufficient to meet the metabolic needs of the animals Essential amino acids (Table 1 9) must be included in the diet or they will be commandeered from the animals' own tissue protein Thus, an inadequate intake of essential amino acids results in deficient protein synthesis, net tissue catabolism and ultimately death of the animal—regardless of the absolute quantity of protein ingested Diets containing proteins which are deficient in one or more essential amino acids can be supplemented with either the deficient amino acids or, more feasibly, with other proteins that do not lack these amino acids This is the reason that the diet should contain a wide range of foods and that those people who choose to or are forced to restrict their diets to food of a single type (such as rice or corn) are likely to develop protein deficiency syndromes

Another determinant of the qualitative and quantitative protein requirements is the physiological state of the organism These requirements vary with age, sex, disease, nutritional state, etc Thus, histidine is an essential amino

Table 1 9
Amino acids essential for normal human nutrition

Amino Acid	R Group (Side Chain)
Valine (Val)	
Leucine (Leu)	
Isoleucine (Ile)	
Threonine (Thr)	
Lysine (Lys)	
Methionine (Met)	
Phenylalanine (Phe)	
Tryptophane (Try)	

[a] Histidine (His) is essential only for infants and young children Tyrosine (Tyr) can be synthesized only from phenylalanine (Phe), therefore a deficiency of Phe renders Tyr essential and, conversely, an ample supply of Tyr reduces the requirement for Phe because synthesis of Tyr is not necessary The relationship between cystine (Cys) and methionine (Met) is similar, for cystine can be synthesized from methionine which, as noted above, is essential

acid for infants and small children but not for adults (the reason for this difference is unknown) Menstruation, lactation, and pregnancy are associated with an increased quantitative requirement for all amino acids, essential and nonessential

For amino acid utilization to be optimal, the diet must include a sufficient caloric intake to circumvent the need to catabolize amino acids for energy, thus, allowing these compounds to be used in synthesis Fat and carbohydrate fulfill this function and, therefore, are referred to as *protein sparers* Thus, it can be seen that particular amino acids along with an adequate caloric intake are essential for normal protein metabolism Over and above this, the protein must be made available for utilization by the tissues i e there must be adequate hydrolysis by the proteolytic enzymes of the digestive tract because absorption of intact protein does not occur under normal conditions In some situations small quantities of protein do gain access to the circulation a circumstance which can lead to sensitization and in turn to the development of hypersensitivity (allergy) to the particular food from which the sensitizing protein derives (e g strawberries) In other situations, blood proteins are lost by abnormal leakage through the intestinal epithelium

After ingested protein is hydrolyzed the amino acids must then be absorbed efficiently into the portal circulation The separate functions of digestion and absorption become manifest in certain pathological states For example in a condition characterized by deficiency of the pancreatic proenzyme, trypsinogen, malnutrition ensues because of failure of digestion (maldigestive malnutrition) This condition can be remediated either by trypsinogen replacement, which corrects the digestive failure, or through supplementation of the diet with protein hydrolysates, thus bypassing the initial enzymatic deficiency

The absorptive cells of the small intestine accumulate free amino acids from the gut lumen (concentrative uptake) and then deliver them to the portal circulation These transport mechanisms are active and possess specific physical and chemical characteristics which are under genetic control In vivo as well as in vitro studies indicate that a single amino acid utilizes more than one mode of transport for absorption

The cooperation of several transport systems is required for the absorption of an amino acid mixture and it is through these several systems that specificity is obtained Each system can handle several amino acids; consequently the various individual amino acids handled by a given system will compete with each other for transport from the gut lumen to the plasma Thus, the absorption of an amino acid can be affected by back transport of a related amino acid from the plasma to the gut lumen. Further characteristics of transport systems will be discussed subsequently when pathological conditions are considered

The *endogenous* input of amino acids into the plasma derives from the breakdown of tissue proteins (effected by proteolytic enzymes called cathepsins) and from the synthesis of nonessential amino acids primarily by liver

cells Free amino acids from all sources enter the plasma, however the plasma concentration remains relatively constant This constancy of plasma amino acid concentration is due to the regulation of and interrelationships between the complex transport and metabolic systems For example, amino acids introduced into the portal circulation as a consequence of protein ingestion can increase the concentration of amino acids in the portal vein by 10-fold This increase is not reflected in the systemic circulation because there is an active uptake of amino acids by the tissues leading to an intracellular free amino acid concentration 10 times greater than the plasma concentration

Amino acid transport processes regulate absorption, metabolic equilibrium, and renal conservation The transport mechanisms, in turn, are regulated by hormones and nuclear cytoplasmic interactions Since the intracellular concentration of amino acids is greater than the extracellular concentration, cellular metabolism has access to a greater pool of metabolites than is available from the immediate extracellular source Metabolic changes in the internal pool can trigger compensatory changes by modifying the transport systems In this way, amino acids are either taken up or discharged from the cell The interrelations among the various pools is summarized in Figure 1 119

INTERMEDIARY METABOLISM OF AMINO ACIDS

Amino acid metabolism is a diverse repertoire of reactions which form a loom upon which the structure and enzymatic machinery that govern the chemical reactions of living systems are woven into their characteristic patterns Diversity stems from the variety of the carbon skeletons of the various amino acid side chains and the fact that amino acids supply the major source of fixed nitrogen for the body To handle this class of metabolites requires a large number of enzymes and an elaborate system of controls The various carbon skeletons are metabolized by sets of their own specific enzymes Handling of the nitrogen moiety requires other enzymatic apparatus which determines whether the nitrogen is transferred to amino acid precursors, fixed in nonprotein nitrogenous compounds, fixed in proteins, or eliminated from the body

All amino acids contain C, H, O, and N, some contain S The catabolism of amino acids results in CO_2, H_2O, nitrogenous end products (principally urea) and sulfates and, in addition, is coupled to the generation of adenosine triphosphate (ATP) However, the primary importance of the amino acids is not as metabolic fuel, but in the synthesis of proteins and of

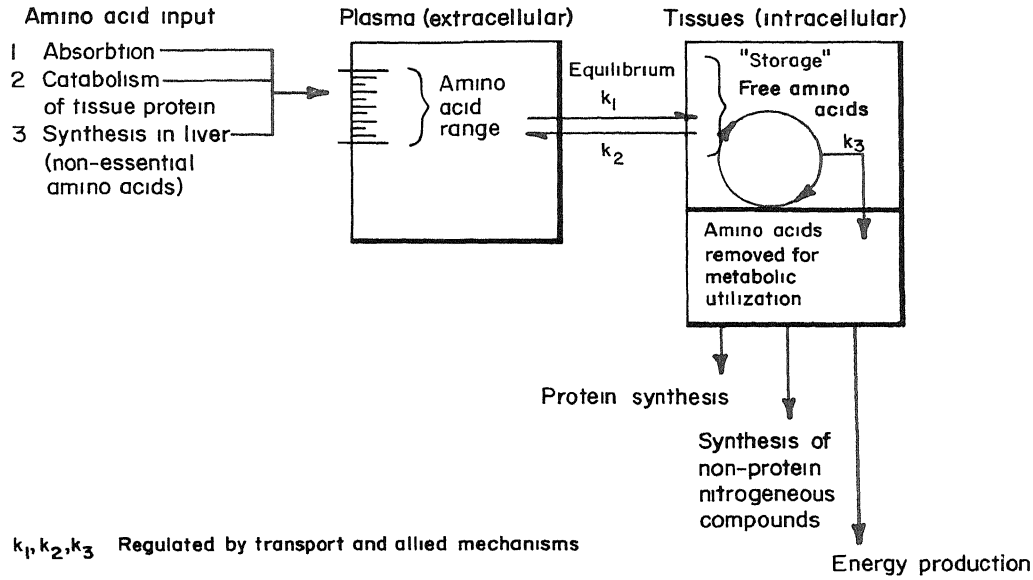


Fig 1 119 Interrelations among the several pools of amino acids within the body

other nitrogen containing compounds. (See Fig. 1.120 and Table 1.10).

The catabolism of amino acids can be considered in terms of the fates of the carbon and nitrogen moieties. The first stage of catabolism involves the removal of the amino group (deamination). The resulting carbon skeleton is then metabolized as an intermediate of either the Krebs cycle or of fatty acid oxidation cycles. Amino acids that yield intermediates of the former cycle are called glycogenic, those that yield intermediates of the latter cycle are referred to as ketogenic (see Table 1.11). Glucogenic amino acids provide carbon skeletons for the synthesis of glucose (gluconeogenesis) in the liver and kidney. This process is under hormonal control (glucocorticoids) and helps energy production keep pace with utilization.

Another aspect of amino acid catabolism is the poorly understood phenomenon termed the *specific dynamic action* or *calorigenic effect* of food. This refers to an extra increment of heat production over and above the caloric content of the food ingested. Fats, carbohydrates, and proteins all evoke this action. However, proteins produce a larger increment, viz., up to 30% more heat can be generated than can be accounted for by the quantity of protein ingested. Fats and carbohydrates by comparison yield an increment of only a few per cent.

Decarboxylation of amino acids yields the corresponding amines. Some of these compounds are important physiological entities with hormonal, neurotransmitter, and other functions (e.g., epinephrine, serotonin, etc.; see Table 1.8); others are toxins (e.g., the action of bacteria on incompletely digested *amino acids* yields toxic amines referred to as ptomaines). Decarboxylation reactions are mediated by specific amino acid decarboxylases. These reactions require pyridoxal phosphate (codecarboxylase) as a cofactor. The general reaction is represented in Figure 1.121.

The nitrogen moiety of amino acids has essentially two fates in the body. It can be removed from the amino acid (deamination) and eliminated from the body, principally as urea. Alternatively, it may be transferred from an amino acid to an α-keto acid, thus forming a different amino acid and leaving behind a different α-keto acid. These reactions, which are referred to as *transamination*, are carried out primarily in the liver.

There are two systems which are involved in the oxidative deamination of amino acids. The flavin adenine dinucleotide-(FAD) dependent L-amino acid oxidase system has a low activity and is not widely distributed in the body. Also, it does not metabolize dicarboxylic, diamino or

Table 1.10
Some physiologically significant nitrogen-containing compounds and the amino acids from which these compounds are derived

Amino Acid(s)	Nitrogenous Compound
Tyr	Epinephrine, norepinephrine, thyroxin, melanin, dihydroxyphenylalanine
Glu	Pyrroles, porphyrins, heme
Gly, Glu, Asp	Purines, pyrimidines
Gly, Arg, Met	Creatine, creatinine
Cys	Ethanolamine
Try	Taurine, nicotinic acid, 5-OH-tryptamine, serotonin

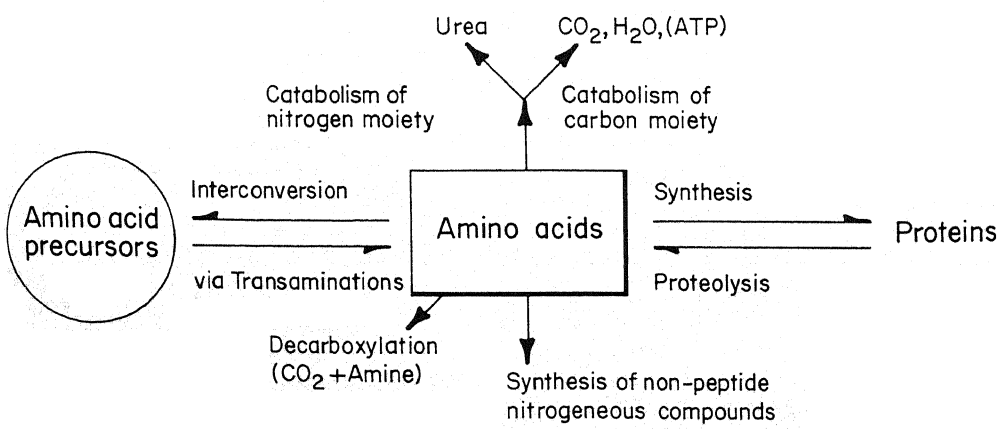

Fig. 1.120. Metabolic pool of amino acids as a source of proteins and other nitrogen-containing compounds.

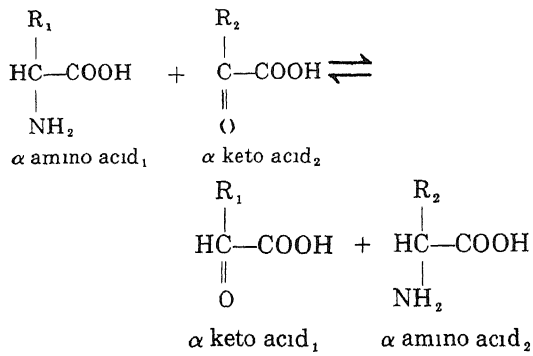
β-hydroxy amino acids and glycine The enzymes of this system catalyze the general type of reaction shown in Figure 1 122 D-amino acid oxidases are also present in liver and kidney, however, their physiological role is obscure



The second, more important system for oxidative deamination has a wide distribution and high activity This is the L-glutamic acid dehydrogenase system It is the major pathway for deamination and is central to amino acid interconversions This is an nicotinamide adenine dinucleotide-(NAD) dependent system and catalyzes the general reaction shown in Figure 1 123 The reversibility of this system is its essential feature as will become apparent in the discussion of transamination reactions (see below)

The amino acid, glycine, is deaminated to glyoxylic acid and NH_3 by a special system involving glycine oxidase

Special systems also exist for the deamination of the hydroxy-amino acids, serine, threonine, and homoserine These are nonoxidative deaminations The enzymes catalyze primary dehydrations which lead to spontaneous deaminations, pyridoxal phosphate is required as a cofactor

A second type of nonoxidative deamination involves the sulfur containing amino acids cysteine and homocysteine The primary reaction is loss of H_2S (desulfhydration) resulting in an amino acid which spontaneously hydrolyzes to pyruvic acid and ammonia Again this system requires pyridoxyl phosphate as a cofactor

All amino acids with the exception of threonine and lysine, have been shown to undergo transamination reactions Since these are intermolecular transfers of the nitrogen moiety, NH_3 is not generated Transaminase systems require pyridoxal phosphate as a cofactor The general reaction can be summarized as follows

Glutamic acid is a common intermediate in the various transamination systems The forward

Table 1 11
Glycogenic and ketogenic amino acids

Glycogenic	Ketogenic	Either Glycogenic or Ketogenic
Alanine	Leucine	Isoleucine
Arginine		Lysine
Aspartic acid		Norleucine
Cysteine		Phenylalanine
Glutamic acid		Tyrosine
Glycine		
Histidine

Valine		

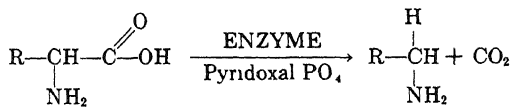

Fig 1 121 Decarboxylation of amino acid to yield an amine

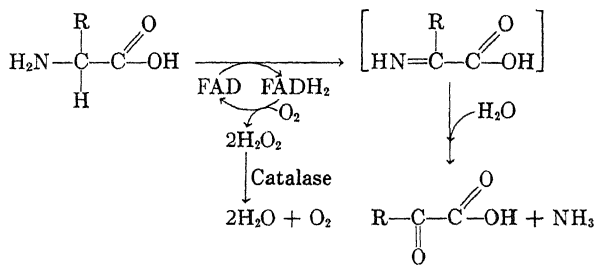

Fig 1 122 Reactions of the L-amino acid oxidase system

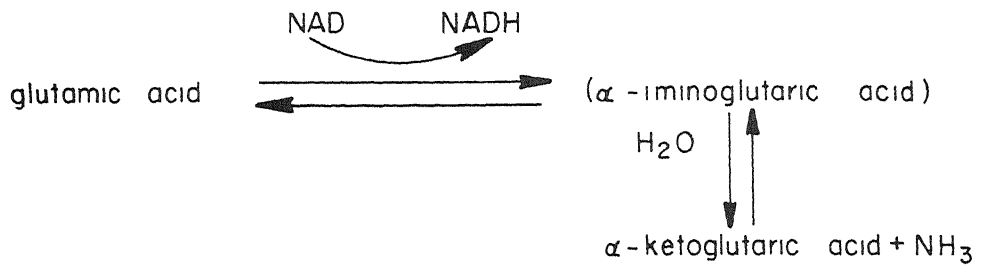

Fig 1 123 Reactions of L glutamic acid dehydrogenase system for deamination of amino acids

reaction removes amino groups from other amino acids (R_1) forming glutamic acid (R_2) via transamination Glutamic acid (R_2) can then act as a NH_2 donor to transaminate keto acid precursors to form other amino acids Thus, the reversible deamination of glutamic acid to α ketoglutaric acid and NH_3 is a central reaction for amino acid synthesis as well as catabolism In addition this reaction links carbohydrate and protein metabolism through the Krebs cycle (α-ketoglutarate)

Glutamate, aspartate, or alanine seems to be common to every reaction This means that the NH_2 group from any other amino acid can appear in any of these three amino acids NH_2 entering glutamate can be removed via the glutamic dehydrogenase system This provides a pathway for deamination of a wide range of amino acids This "transdeamination" pathway results in formation of α-ketoglutarate and NH_3

The following reactions represent the above transamination systems

alanine + α-ketoglutarate $\longleftrightarrow$ pyruvic acid + glutamic acid

glutamic acid + oxaloacetic acid $\longleftrightarrow$ α-ketoglutarate + aspartic acid

alanine + oxaloacetic acid $\longleftrightarrow$ pyruvic acid + aspartic acid

In certain diseases (myocardial infarction, liver diseases), damaged cells release transaminase systems into the blood stream Consequently, the levels of activity in the serum of glutamic-oxaloacetic transaminase (SGOT) and other transaminase systems are increased This increase is proportional to the extent of damage and, therefore, assays of the level of activity of SGOT and/or other transaminases are of clinical significance

Free NH_3 results from deamination of amino acids, pyrimidines and purines, from the deamidation of glutamine, asparagine (and their α keto analogues) and to some extent from the action of urease-containing intestinal bacteria on urea (urea $\xrightarrow{\text{urease}}$ CO_2 + NH_3) Free NH_3 in high concentrations is incompatible with life Ammonia must therefore be either bound in the organism or excreted It has already been shown that NH_3 may be bound by the "amination" of α-keto acids Amidation of glutamate and aspartate to form glutamine and asparagine, respectively, are other reactions that bind free NH_3 for transport in the plasma ATP is required for the glutamine synthetase reaction In the kidney, glutamine is converted by glutaminase to glutamate and ammonia, the latter diffusing into the tubular urine where it combines with H^+ to form NH_4 The renal tubular cells also contain glutamate dehydrogenase and transaminase systems as well as amino acid oxidases, therefore, the kidney can also generate NH_3 from other amino acids

Some ammonia is excreted as uric acid, however, the major portion of NH_3 is excreted by conversion to urea The enzymes of this detoxication system are present in the liver and constitute the Krebs-Henseleit cycle (Fig 1 124)

Amino nitrogen can enter this cycle either through fixation with CO_2 to form carbamyl phosphate (I), or glutamate can transaminate oxaloacetic acid to yield aspartate (II) Each revolution of this cycle converts 2 molecules of NH_3 and 1 molecule of CO_2 to urea

Amino acid metabolism is summarized in Figure 1 125

Overall protein metabolism is reflected by the nitrogen balance of the organism The nitrogen content of the ingested food is measured and compared with the nitrogen excreted in the feces and urine over a given period of time *Positive nitrogen balance* is obtained when the total nitrogen intake is greater than the total nitrogen output, as is the case when anabolic reactions (principally protein synthesis) predomi-

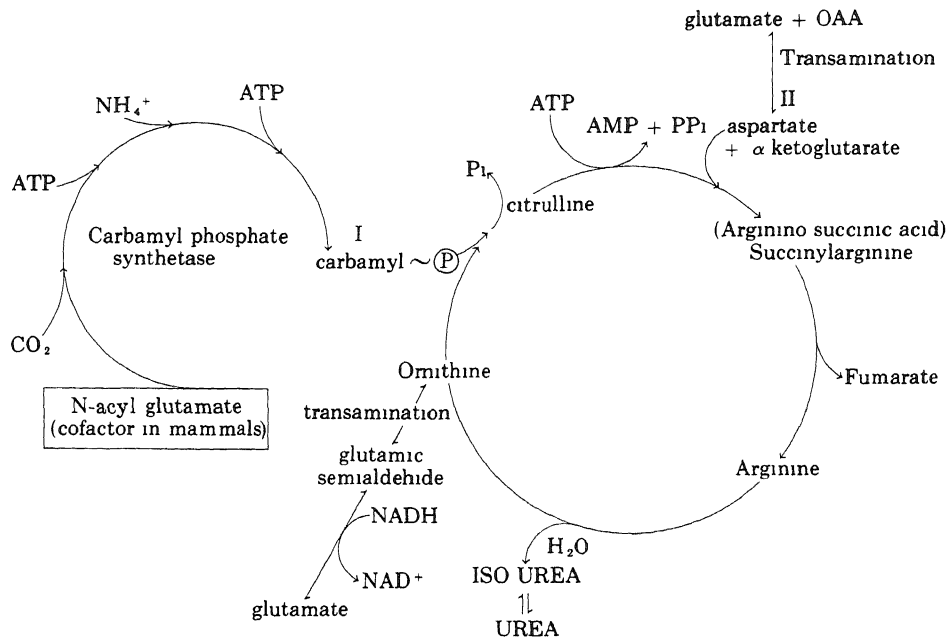

Fig 1 124 Krebs-Henseleit cycle

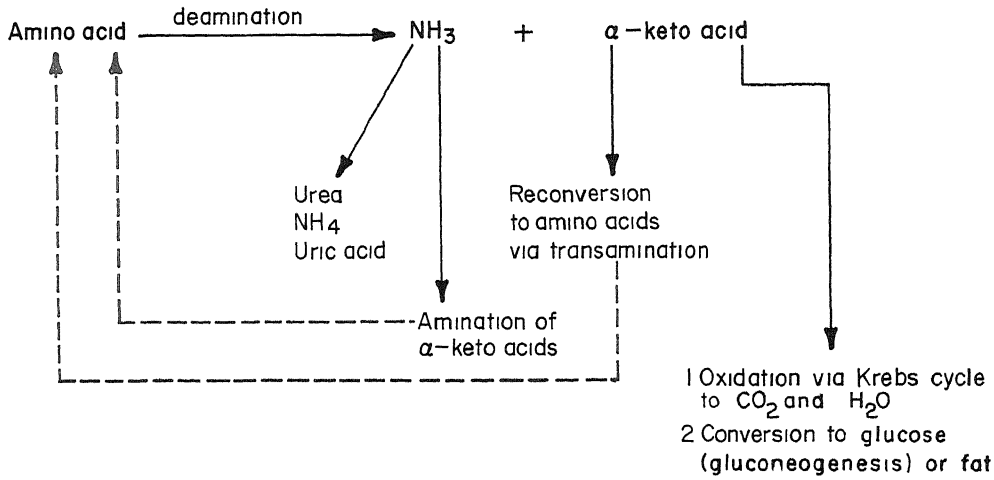

Fig 1 125 Summary of chemical reactions through which amino acids are metabolized

nate over catabolic reactions, e g , during growth or during periods of tissue repair after trauma, surgery, or illness If catabolic reactions exceed anabolic reactions, nitrogen excretion exceeds intake and the organism is in *negative nitrogen balance* This occurs in wasting diseases and starvation, when tissues are being broken down to meet metabolic demands, and when the diet is deficient in essential amino acids If input equals output, catabolism equals anabolism and the organism is in *nitrogen balance* This is the condition for the normal adult

Aminoacidopathies and Proteinopathies

To date, there are over 50 disorders of amino acid metabolism which have been described It would not be appropriate here to detail these disorders with regard to specific biochemical lesion, metabolic consequence, clinical manifestation, and treatment Rather, a generalized

discussion of aminoacidopathies from the standpoint of genetics and metabolism will be developed

GENETIC BASIS OF MOLECULAR DISEASE

Inborn errors of metabolism or the more recent appellation—molecular diseases—are genetically determined defects in protein structure or function Thus in considering these diseases attention must be focused on the genotype as well as on its *expression*, i e , the phenotype On the molecular level, there is little difficulty conceptualizing a correspondence between DNA and polypeptides The cistron and its polypeptide are colinear and commensurate (3 bases per 1 amino acid) One cistron determines one polypeptide

The polypeptide can be a functional unit in itself such as the hormone adrenocorticotropic hormone (ACTH), or it may be a subunit which must combine with one or more other subunits to be active as in the case of hemoglobin However, cistrons which code for the subunits which comprise a functional biological entity (e g , enzyme complex, hormone, antibody, etc) need not be spatially contiguous Thus, the "gene" for such a functional biological entity can be composed of cistrons which are separated from each other along the length of the chromosome

The normally functioning organism is a result of the coordinated sequential expression of the information contained in its DNA Simultaneous expression of all genes would lead to cellular "anarchy " To circumvent this, there exists within the cell elaborate control mechanisms of nuclear-cytoplasmic interactions The resulting limitations on the number of gene products (polypeptides) found within any given cell results in specialization The organization of similar cells (i.e , cells with similar repertoires of reactions) into functional clusters yields tissues For orderly reactions to occur between tissues information must be exchanged among them This can be realized either by direct entry of one tissue product into the cells comprising a target tissue (e g , steroid hormones), or the tissue product may interact at the cell membranes of the target tissues resulting in the generation of a train of intracellular events, as exemplified by the action of a number of peptide hormones.

Interactions between systems are complex because all the systems are performing their own specialized functions simultaneously Thus, the history of a system constitutes one group of variables, among many, which determines the character of its response to a given stimulus (signal) Signals, therefore, may be amplified or ignored depending on the state of the system In addition, signals may be synergistic or antagonistic in evoking a response As the number of component systems increase, the complexity of the possible reactions increase This is ultimately reflected in the number and range of which the organism is capable It is the elaboration of many interacting control systems which integrate the activities of the organism to yield a response which is appropriate and graded to the intensity of the stimulus Indeed, it is the sum of these molecular control systems which characterize the organism biochemically and physiologically In viewing the organism macroscopically the molecular basis for its behavior is not always obvious since the stimulus-response relationship has been altered through the interaction of these multiple control systems

These control systems, in turn, are expressions of the genotype of the organism, which in its turn must be controlled Spatial and temporal regulation of the genotype is responsible for the character of the aforementioned systems and their behavior The expression of the full genotype in any one cell or tissue is never realized Only that portion of the DNA is expressed which results in products and activities that characterize particular cells or tissues

It will be recalled that the visible expression of the information in DNA is the phenotype, and also that particular traits, such as blood group, eye color, etc , are controlled by genes which exist in pairs (*alleles*), located on the same loci of the homologous chromosomes The alleles may be identical (*homozygous*) or they may be different (*heterozygous*) Usually, if they are heterozygous, one allele is dominant in the phenotype, the other is recessive (i e , the recessive allele is present in the genotype but not usually expressed in the phenotype) A well-known example is the dominance of brown eyes over blue eyes, which dictates that a child receiving a gene for brown eyes from one parent and its "blue" allele from the other parent will have brown eyes Thus, the child is heterozygous for eye color The expression of the recessive phenotype requires that the child be homozygous, i e , that he receive the reces-

sive "blue" allele from each of his parents Where there are more than two alleles capable of occupying the two homologous chromosomal loci that determine a given trait, this phenomenon is called *multiple allelism* Thus, eye color has many expressions, e g , brown, black, blue, green, hazel, etc , and is an example of the "continuous" variation that can result from multiple allelism and/or from partial expression of each of two different alleles This latter phenomenon has been termed *incomplete dominance* or *penetrance*

The foregoing treatment of the mode of expression of the phenotype of an organism is a simplification, but it provides a useful framework for the consideration of the transmission of traits through generations The "gene" is actually comprised of many cistrons which specify many enzymes which, in turn, govern the production of the ensemble of pigments that determine eye color These enzymes may be single polypeptides, subunit assemblies, or more probably mixtures of both—the full array of cistrons responsible for the trait constitutes the single inheritable entity which we recognize as the "eye color gene "

Another example of continuous phenotypic variation is height This trait, however, is the result of the interactions of many genes at different loci plus environmental influences such as nutrition Thus, the potential for greater height, although included in the genotype, may not be phenotypically expressed if environmental conditions militate against it, e g , inadequate dietary input

When differences in phenotype are not continuous but exhibit a quantal nature (i e , when there are two or more distinct forms of expression with no intermediate forms) then the phenomenon is referred to as polymorphism and exemplified by the ABO blood groups This is a case of multiple allelism in which there are three alleles, A, B, or O Various allelic combinations result in the four phenotypes—A, B, AB, or O—each of which is distinct from the other

The expression of any particular gene depends in part on the nature of its neighboring genes, thus, position on the chromosome per se can alter the functioning of a particular gene Events such as crossing over in meiosis can influence the immediate environment of a gene, and thereby alter or eliminate the gene's phenotypic expression, even though it remains in the genotype and its structure is unaltered For example, a gene located on a segment of a chromosome in the euchromatin condition of coiling, (i e , "normally" coiled and therefore translatable into a polypeptide) can after synapsis end up in a region of tightly coiled, nontranslatable heterochromatin, and thus have its expression in the phenotype suppressed Furthermore, the same gene may be expressed differently in different tissues, e g , the "transport system" for dibasic amino acids is found in the gut, kidney, and leukocytes but it functions differently and independently in each tissue—in the disease known as cystinuria the leukocyte system is normal, but the gut and kidney systems are abnormal

In humans the sex chromosomes have different morphologies—the X chromosome is larger than the Y chromosome XX is the female genotype, XY is the male genotype Some loci on the X chromosome are not represented on the Y chromosome and vice versa However, since the sex chromosomes are homologous they have some loci in common Since the female has two X chromosomes and the male only one, it would be expected that an enzyme determined by a gene located on the X chromosome would be present in twice the amount in the female as compared with the male But this is not the case For example, glucose-6-phosphate dehydrogenase is an enzyme determined by a gene located on the X chromosome It is conveniently assayed in red blood cells where it has been found to exhibit the same level of activity in both males and females This finding may be explained by a suppression of the action of one of the alleles in the female through coiling and clumping of the chromatin This concept, termed *dosage compensation*, is supported by cytological evidence in that diploid autosomal cells, neutrophils, exhibit a clump of chromatin known as the *Barr body* Since it is not found in the cells of the male, this is thought to be repressed sex chromatin

It is possible for more than one genotype to give rise to a single phenotype (*genetic heterogeneity*) Hemoglobins with structural differences can be grouped into classes with common characteristics, e g , altered electrophoretic mobility, altered ultraviolet spectrum and thermal instability The hemoglobins which comprise any one of the above "phenotypic" classes may have different amino acids substituted in different places on different chains

Thus, the same phenotype may result from changes at several different loci in the molecule or from multiple changes at a single locus, i e , a particular trait (e g , a given electrophoretic mobility) can result from an amino substitution located at several different positions in the α chain of hemoglobin, and the same trait can result from the same or different substitutions at several positions in the β chain, likewise the same trait can result from the substitution of different amino acids at a single position in one of the chains The latter phenomenon is referred to as *homoallelic mutation*, the former as *heteroallelic mutation*

In a broader sense, the study of hemoglobinopathies and other mutations provides excellent examples of how the confluence of genetics (both molecular and classical) and cellular processes at the molecular level becomes apparent in higher organisms Five genes determine the hemoglobin chains (α, β, γ, δ, and ϵ) The primary sequence of all but the ϵ chain has been determined, thus, the evolution of proteins can be discerned by noting homologous regions on the various chains This provides insights into meiotic processes which result in gene duplications, unequal crossing over, deletions, linkages, etc Moreover, since the amino acid sequences of the products are known, the relationship between structural alteration (amino acid replacement) and changes in function are revealed

The regulation of genetic processes can be studied by, for example, following the change from fetal hemoglobin (which possesses 2 α chains and 2 γ chains) to adult hemoglobin (which possesses 2 α chains and 2 β chains), this conversion is a result of the suppression of the γ gene and the activation of the β gene In sickle cell anemia, an abnormal hemoglobin is produced which causes red blood cells to assume a sickled or crescent shape This sickling trait is manifest at normal levels of blood oxygen tension in homozygotes, in whom it gives rise to a characteristic syndrome which proves fatal, in the heterozygote, this sickling trait is manifest only at low levels of blood oxygen tension The abnormality in the hemoglobin molecule that is responsible for sickle cell disease involves a change in only one amino acid (glutamic acid to valine) within each of the two beta chains of the globin tetramer It is noteworthy that this single amino acid substitution —which produces the aberrant hemoglobin— gives rise to a striking constellation of clinical signs, i e , splenomegaly jaundice, swelling of joints, cardiac enlargement bone deformities (kyphosis, tower shaped skull sabre shins), etc These clinical signs are all a consequence of the body's attempt to compensate for the malfunction of the erythrocytes due to the abnormal hemoglobin

A proteinopathy such as sickle cell anemia is an example of a qualitative genetic effect By contrast, in the group of disorders known as the thalassemias, the genetic effect is quantitative, i e , it arises from the fact that gene mutations mandate certain amino acid substitutions which reduce the rate of protein (hemoglobin) synthesis

This type of clinical molecular physiological analysis is, of course, not restricted to the hemoglobins As we establish the primary structure of other biologically important proteins, such as the immunoglobulins, their functions also become amenable to study by this approach

ROLE OF MUTATIONS IN MOLECULAR DISEASE

The foregoing is not by any means a complete summary of all the interactions by which genes determine phenotypes, in fact the question of genetic mutation has not yet been considered explicitly A mutation which changes the primary structure of the DNA and hence its information content--can be a single base change (point mutation) or can involve the deletion or addition of many bases Since these changes occur in the DNA, they are transmitted from generation to generation However, their expression is a function of all the foregoing considerations and the pattern of inheritance (i e , the pedigree) Thus, X-linked dominant alleles are expressed in males and females X-linked recessive alleles are carried by both males and females but expressed only in males Autosomal (nonsex-linked) dominant genes find expression in males and females whether homozygous or heterozygous for those alleles Finally, an autosomal recessive trait is expressed in both males (or females) only when it exists in the homozygous condition, however, heterozygotes are carriers of the trait Detailed examinations of heterozygotes have revealed certain biochemical abnormalities which do not interfere with normal body function Such findings provide the basis for genetic counciling by making it possible to identify heterozygote carriers of disease traits which, in the homozygote, would be deleterious

The frequency of mutations forms a continuum Rare mutations such as alcaptonuria occur with a frequency of approximately 10^{-6} Alcaptonuria is generally incompatible with life The mutation leading to blood type O has a frequency of 10^{-1} The defects in the enzymes which synthesize blood group antigens A and B are quite obviously compatible with life The requirement of all humans for ascorbic acid is an example of a mutation with a frequency of 100% Thus, mutations are not necessarily deleterious

Mutations need not always be expressed "Silent" mutations arise from base changes in DNA which, when translated during protein biosynthesis, yield the same or a functionally related amino acid (The degeneracy of the genetic code accommodates such events) Thus, a heritable change in DNA need not be expressed in its polypeptide product Alternatively, a mutation may be expressed structurally in a protein but may be "silent" in a functional sense, i e , the mutant protein may possess one or more amino acids which do not alter biological activity This type of structural polymorphism is exemplified by the transferrins (iron-binding plasma proteins) and haptoglobins (hemoglobin-binding plasma proteins)

A mutation can affect the rate of synthesis, and hence the intracellular concentration of proteins Quantitatively, this could lead to the absence or to the overproduction of an enzyme with deleterious metabolic consequences in either case Malfunction in this instance would not be a result of loss of activity due to change in the primary structure of the enzyme, but rather to a mutation in a control gene (such phenomena have not yet been demonstrated in humans)

Most expressed mutations result in loss of activity for the corresponding polypeptide The ensuing metabolic consequences depend on the role that this polypeptide fulfills in the cell as well as the interactions previously discussed The ramifications of an enzyme defect can be demonstrated by considering a generalized cell (Fig 1 126)

Absence or abnormal function of the permease, P_w, precludes the entry of metabolite, W, into the cell Limitation of this metabolite slows down the reaction sequence shown in the interior of the cell Although dietary intake or tissue synthesis of W may be substantial, the defective transport protein (permease) makes for starvation in the midst of plenty

The amino acid transport systems of the various tissues have the following common characteristics

1) The L-isomers of the amino acids are transported more efficiently than the D-isomers
2) Amino acid uptake occurs against an electrochemical gradient
3) Sodium, along with membrane-bound Na^+-K^+ ATPases, is involved in the translocation mechanisms
4) Concentrative uptake exhibits saturation kinetics, competitive and noncompetitive inhibition
5) The transport processes for the individual amino acids are functions of
   a) the length and composition of the aliphatic side chains (R groups)
   b) the anionic and cationic properties of the R groups
   c) the position of the NH_2 groups, α or β

The various amino acids are translocated across cell membranes via group specific transport systems To date, systems for the following groups of amino acids have been identified

dicarboxylic amino acids, dibasic amino

DEFECTS OF AMINO ACID TRANSPORT

The complexities of the genetic regulation of the amino acid transport systems become apparent in certain molecular diseases. Cystinuria is a disease in which the molecular lesion occurs in the transport system for cystine and dibasic amino acids (lysine, arginine, and ornithine), so that the renal tubular reabsorption is depressed. Consequently these amino acids are found in abnormally high quantity in the urine. The most distressing manifestation of this syndrome is the formation of cystine-containing renal calculi.

When this transport system is studied in several tissues obtained from cystinuric patients it is found that there are differences in its function in the gut, kidney, and leukocytes. The gut transport system loses its ability for concentrative uptake of its substrates (lysine, arginine, ornithine, and cystine). In the kidney, the situation is more complicated since there are other systems which transport one or more of these amino acids. In addition to the system which transports all four substrates, there is another system which transports only cystine, and a third system which transports only the dibasic amino acids. Renal clearance studies on cystinuric patients indicate that the former system is the site of the lesion and that the latter two systems are spared. In leukocytes there is no single system for all four substrates, but the cystine transport system is separate from the dibasic amino acid system. Moreover, both systems function normally in cystinuric patients. Thus, as noted earlier, the same gene may have different phenotypic expressions in different tissues.

The different phenotypic expressions of cystinuria are due to genetic variations, i.e., there is multiple allelism with respect to the relevant group specific permease system. The number of possible allelic combinations determine the number of possible genotypes. The genotypes can be ordered into classes on the basis of their phenotypic expression. The different (polymorphic) forms of this syndrome can thus be explained on the basis of genetic heterogeneity. Although these considerations apply to other molecular diseases, it should be emphasized that there are many possible combinations of genetic interactions and abnormal phenotypes (expressed in variations of protein structure and function) for which no prototype has been presented in this chapter.

Cystinuria is a member of the group of diseases known as aminoaciduria. Pathological aminoaciduria is characterized by an increased renal clearance of amino acids which is reflected in the urinary nitrogen content. The pattern of amino acid excretion in this group of diseases reflects the characteristics of the involved transport system and the site of the molecular lesion. A mutation which leads to a change in a carrier molecule, results in the abnormal urinary excretion of a specific amino acid (or group of related amino acids). If the molecular lesion occurs in the energy generating system, or the associated ion exchange system, a general aminoaciduria results. When the energy-generating system is involved, other substances not normally found in the urine will also be present. If the delivery of an amino acid present in the glomerular filtrate exceeds the reabsorptive capacity of its tubular transport system, it will spill over into the urine. Such a saturation aminoaciduria occurs when there is an accumulation of the amino acid in the plasma as a result of excessive intake, overproduction and/or defective metabolism.

Combined (multiple) aminoaciduria results from shared transport systems. An increased filtered load of one amino acid leads to competition for the reabsorptive carrier with the other amino acids of the group sharing the transport system. Thus, the former amino acid is excreted because its carrier is saturated and the others are also excreted because they cannot compete effectively for the saturated carrier.

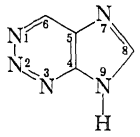
Molecular lesions involving intracellular enzymes lead to precursor accumulation (Fig. 1.126). For example, substance W is not adequately metabolized because of a lesion involving enzyme, E_w. Accordingly the plasma concentration of W and, ultimately, the rate of urinary excretion of W may increase. Alternatively, if the molecular lesion involves enzyme, E_x, both W and X will accumulate with metabolic and excretory consequences depending on the nature of W and X. The disease entity, homocystinuria, is an example of this latter type of disorder in which the enzymatic lesion leads to accumulation of methionine and homocystine.

Accumulation of a precursor, W, may lead to

enhanced utilization of an alternate pathway (see Fig. 1.126, pathway $W \rightarrow V \rightarrow U \rightarrow T$). Increasing concentrations of potentially toxic metabolites along such an alternate pathway—the major metabolic route being impaired—may interfere with the normal cell function. Phenylketonuria (PKU) is an example of this class of disorder. In PKU the absence of phenylalanine hydroxylase leads by an alternate metabolic pathway to the abnormally enhanced production of phenylpyruvic acid, phenylacetic acid, and phenyllactic acid—all of which achieve toxic concentrations. Another consequence of an enzymatic lesion along a major metabolic pathway (see Fig. 1.126, $W \rightarrow X \rightarrow Y \rightarrow Z$) may result in deficit of Z, a physiologically active agent in the body. Goitrous cretinism, due to impairment of one or more enzymes necessary for the synthesis of thyroxin, exemplifies this class of disorders.

Finally, a molecular lesion may destroy feedback control by modifying an allosteric enzyme, so that it is no longer responsive to its inhibitor, Z, thus leading to overproduction of Z.

Space does not permit a more detailed consideration of the aminoacidopathies and proteinopathies. It should be emphasized, therefore, that there is an enormous amount of data available for study in this rapidly expanding area of inquiry, and thus the few examples given above are meant only to serve as signposts to the interested reader.



6 / PHYSIOLOGY OF PURINES AND PYRIMIDINES

This chapter deals with the biosynthesis of purine and pyrimidine bases, their incorporation into nucleic acids, breakdown of these acids, and the further catabolism of the liberated base derivatives Attention will be drawn to disorders of purines and pyrimidines in man, particularly those for which the etiology is understood in terms of enzymatic deficiencies and errors in the metabolic pathways

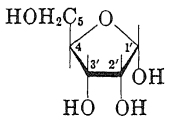
Many other important aspects of the physiology of purines, pyrimidines, and their derivatives not immediately relevant to this chapter, will only be mentioned briefly here These bases, covalently attached to various sugar-phosphates, represent "high energy" compounds One group, the acyclic nucleotides yield upon hydrolysis of the phosphate ester bond a negative free energy of the order of 7 5 kcal /mole This energy is available through coupled enzymatic reactions to drive endergonic biological processes, adenosine triphosphate (ATP), for example, provides energy for such processes as muscle contraction, biosynthesis of proteins, nucleic acids, carbohydrates, and lipids Nucleotides are also important in group transfer reactions The base moiety of the nucleotide determines specificity, e g , uridine nucleotides are necessary in glycogen biosynthesis, cytidine nucleotides in phospholipid biosynthesis, adenosine nucleotides in protein biosynthesis, etc Another group, the cyclic nucleotides, exhibits in comparison to acyclic nucleotides an even greater free-energy of hydrolysis amounting to approximately 12 kcal /mole Adenosine-3′,5′-cyclic monophosphate participates as intracellular mediator in the action of a number of hormones and biogenic amines via activation of cyclic adenosine monophosphate (AMP)-dependent protein kinases Cyclic AMP is also a physiological regulator in the induction of enzyme synthesis in bacteria and in mammals Evidence is emerging to indicate that cyclic nucleotides other than cyclic AMP are involved in similar physiological processes In addition, nucleotides frequently are components of coenzymes, e g nicotinamide adenine dinucleotide (NAD) nicotinamide adenine dinucleotide phosphate (NADP) and flavin adenine dinucleotide (FAD) all of which are involved in redox reactions catalyzed by various dehydrogenases Finally a most important aspect of the physiology of purines and pyrimidines is their function while incorporated in nucleic acids in a highly specific arrangement, as the carrier of the genetic information of all living organisms

Chemically speaking adenine and guanine are derivatives of purine, the structure of which is shown in Figure 1 127*A* Cytosine, uracil, and thymine are derivatives of the pyrimidine nucleus (Fig 1 127*B*) The bases when bonded to the sugar moieties ribose (Fig 1 127*C*) or deoxyribose (Fig 1 127*D*) via glycosidic linkage are referred to as nucleosides The nitrogen of the purine in position 9 or of the pyrimidine in position 1 is attached to the carbon 1′ in the sugar moiety Phosphorylation of a nucleoside in the 5′ position results in the formation of a nucleotide (nucleoside monophosphate), the monomeric unit of nucleic acid We speak of the polymer of ribonucleotides as ribonucleic acid (RNA) and of deoxyribonucleotides as deoxyribonucleic acid (DNA), depending on the nature of the sugar residue; polymerization occurs via ester formation between the 5′-phosphate of one nucleotide and the 3′-hydroxy group of another, etc While cytosine, adenine, and guanine are found in both RNA and DNA, uracil occurs essentially only in RNA and thymine in DNA

Table 1 12 lists the official nomenclature and abbreviations for the most frequent bases and derivatives encountered Trace amounts of unusual bases occur in nucleic acids, particularly in transfer-RNA (t-RNA), these include hypoxanthine, and methylated bases such as 5-methyl-cytosine, 6-methylamino purine, 1-methylguanine, or 2-methylamino-6-hydroxy-

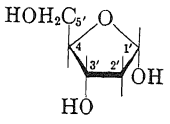
Purine

a



Adenine = 6-Amino-
Guanine = 2-Amino-6-Hydroxy-
Hypoxanthine = 6-Hydroxy-
Xanthine = 2,6-Dihydroxy-

Pyrimidine



b

Cytosine = 4-Amino-2-Hydroxy-
Uracil = 2,4 Dihydroxy
Thymine = 2,4 Dihydroxy-5-Methyl-

Ribose

c

Deoxyribose

d

Table 1 12
Nomenclature of common nucleotides[a]

Base	Nucleotides	Nucleotides (as Salts)	Abbreviations
Adenine	Adenosine	Adenosine-5′-phosphate or 5′-adenylate[b] Adenosine 3′,5′-*cyc* phosphate or *cyc* 3′,5′-adenylate	5′-AMP[b], ADO-5′-P, pA *cyc* 3′,5′ AMP, ADO 3′,5′-P
	Deoxyadenosine	Deoxyadenosine-5′-phosphate or 5′-deoxyadenylate	5′-dAMP[b], deADO-5′-P, pdA
Guanine	Guanosine	Guanosine-5′-phosphate or 5′-guanylate[b]	5′-GMP[b], GUO-5′-P, pG
	Deoxyguanosine	Deoxyguanosine-5′-phosphate or 5′-deoxyguanylate	5′-dGMP[b], deGUO-5′-P, pdG
Cytosine	Cytidine	Cytidine-5′-phosphate or 5′-cytidylate[b]	5′-CMP[b], CYD-5′-P, pC
	Deoxycytidine	Deoxycytidine-5′-phosphate or 5′-deoxycytidylate[b]	5′-dCMP[b], deCYD-5′-P, pdC
Uracil	Uridine	Uridine-5′-phosphate or 5′-uridylate[b]	5′-UMP[b], URD-5′-P, pU
Thymine	Thymidine	Thymidine-5′-phosphate or 5′-thymidylate[b]	5′-(d)TMP[c], THD-5′-P, pT
Hypoxanthine	Inosine	Inosine-5′-phosphate or 5′-inosinate[b]	5′-IMP[b], INO-5′-P, pI
Xanthine	Xanthosine	Xanthosine-5′-phosphate or 5′-xanthylate[b]	5′-XMP[b], XAO-5″-P, pX

[a] Abbreviations are in accordance with the IUPAC-IUB Tentative Rules (*J Biol Chem* 241 52, 1966)
[b] Omission of the 5′-designation is common in this series (e g , adenylate or AMP)
[c] 5′-Thymidylate, the deoxy derivative, is usually abbreviated TMP

purine Many of these unusual bases are more prevalent in viruses and bacteria than in higher organisms

Biosynthesis

The biosynthetic pathway of pyrimidines and purines has been worked out in great detail Generally, the approach was to administer to the experimental animal possible precursors, isotopically labeled, and then to determine the position of incorporation of label in the desired product

BIOSYNTHESIS OF PYRIMIDINES

The in vivo synthesis of uridine-5′-monophosphate, the key intermediate for pyrimidine

nucleotides and deoxynucleotides, entails the formation of a substituted pyrimidine ring (orotic acid) which is subsequently attached to a sugar monophosphate

The various steps leading to the synthesis of uridine-5'-monophosphate are outlined in Figure 1 128 In the first step, carbamoyl phosphate synthetase catalyzes the synthesis of carbamoyl phosphate from glutamine, bicarbonate, and ATP This activated phosphate ester donates its carbamoyl moiety for acylation of the α-amino group of aspartic acid to yield ureidosuccinic acid—a step catalyzed by aspartate transcarbamylase (ATCase) Ureidosuccinic acid undergoes ring closure and oxidation to orotic acid in two subsequent steps Orotidine 5'-monophosphate pyrophosphorylase catalyzes formation of the glycosidic linkage between orotic acid and phosphoribosyl pyrophosphate (PRPP) Irreversible decarboxylation catalyzed

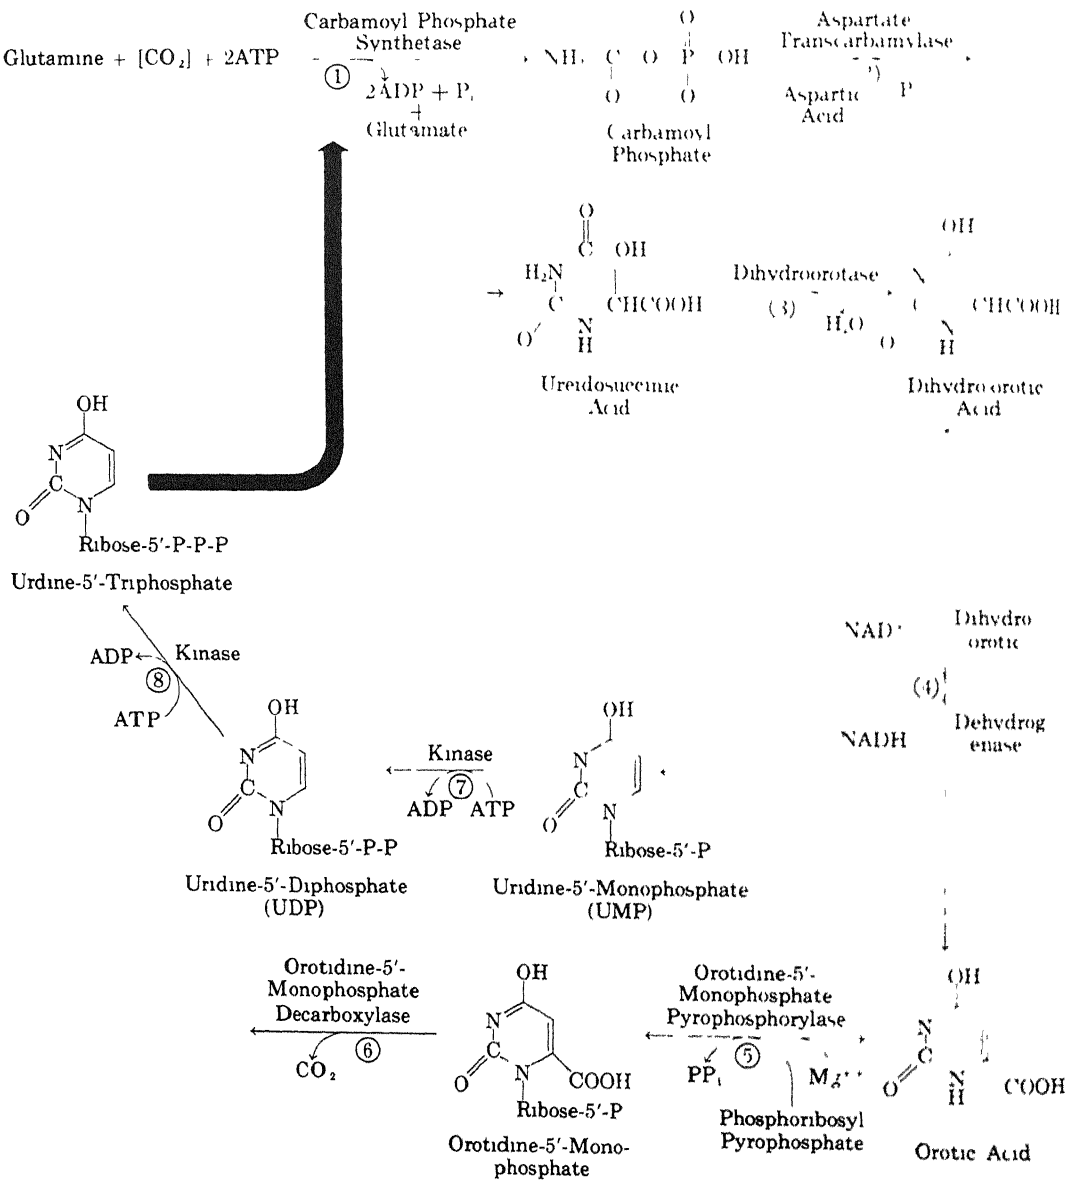

Fig 1 128 Biosynthetic pathway of uridine ribonucleotide Circled numbers indicate individual, known steps in the pathway Heavy arrow indicates feedback inhibition

by orotidine-5′-monophosphate decarboxylase, yields uridine monophosphate (UMP) With the synthesis of UMP, which is readily phosphorylated to the di- and triphosphate, a branching point in the biosynthetic pathway of the pyrimidine nucleotides has been reached On the one hand, part of the uridine nucleotide pool is incorporated into RNA and on the other, part is converted via uridine triphosphate (UTP) to cytidine triphosphate (CTP) (Fig 1 129*a*), the last step in this conversion involves the replacement of the 4-hydroxy group by an amino group, for which a purine nucleotide [guanosine triphosphate (GTP)] is required as cofactor

In addition, the UMP pool serves as starting material for the biosynthesis of deoxyribonucleotides It should be noted that theoretically deoxyribonucleotides could result either from the addition of a pyrimidine moiety to deoxyribose, or conversely, from the reduction of the sugar residue of the pyrimidine nucleotide, experiments in which radioactive ribonucleotides are incorporated intact into DNA favor the latter possibility In contrast to ribonucleotides, the elucidation of the biosynthetic pathway of deoxyribonucleotides in mammals has met with considerable difficulties Though the research in this area is in a state of flux, it is already apparent that the reductase systems are subject to stringent regulatory control dCDP seems to be synthesized in bacterial and mammalian systems via the route UMP → UDP → UTP → CTP → CDP → dCDP (see Fig 1 129*a*)

Studies in *Escherichia coli* would suggest that the remaining pyrimidine deoxyribonucleotide [deoxythymidine monophosphate (dTMP)] is synthesized via phosphorylation of UMP to UDP and reduction of the ribose moiety to deoxyribose This reduction requires several enzymes and cofactors, including two reductase enzymes, (B_1 and B_2), a sulfhydryl protein (thioredoxin), its reductase, and NADPH Finally, dUDP is dephosphorylated to dUMP, which in turn is methylated in position 5 by N^5,N^{10}-methylene-tetrahydrofolic acid in the presence of thymidylate synthetase to yield dTMP (Fig 1 129*b*) An apparently analogous pathway for the synthesis of dTMP is found in Novikoff hepatoma cells, in this mammalian system the conversion of UDP to dUDP likewise requires a reductase enzyme, two enzymes (S and S_b) which can be replaced by thioredoxin and its reductase, and NADPH, among other enzymes (Beck, 1969)

Having outlined the biosynthetic pathway for pyrimidine nucleotides we now consider its regulatory control Generally speaking, there are two types of feedback control inhibition and repression In the first case, a metabolic intermediate, usually an end product, inhibits one or more of the enzymes involved in its own synthesis, most frequently at an early step This is a short-term, rapid control, which prevents accumulation of unused product In the case of repression, the end product, usually a small molecule, decreases the synthesis of one or more enzymes involved in its biosynthetic path by acting at the DNA level, this control assures that proper enzyme concentrations are maintained in the cell In comparison to feedback inhibition, repression is a fine and long-lasting control because it is a response to a continuing situation rather than to momentary fluctuations Although these feedback mechanisms have been elucidated using microorganisms, there is evidence emerging which suggests that they are also operative in mammalian cells Extensive work has led in recent years to a considerable broadening of our knowledge of many aspects of the control mechanism of pyrimidine synthesis Originally, attention was focused on aspartate transcarbamylase (ATCase) (step 2 in Fig 1 128), since this enzyme had been shown to be subject to feedback inhibition in *E coli* (Gerhart and Pardee, 1962) ATCase from rat liver and from Ehrlich ascites tumor cells were reported to be sensitive to feedback inhibition However, later studies on purified liver preparations did not show sensitivity to inhibitors, nor did the enzyme when isolated from erythrocytes or leukocytes—even though in the latter study wide ranges of pH, and of substrate and inhibitor concentrations were tried (Curcie and Donachie, 1964, Prager, et al , 1967) The consensus at present is that ATCase does not play a regulatory role in mammalian systems, and attention has shifted to the first step in the pathway of pyrimidine synthesis, which is catalyzed by carbamoyl phosphate synthetase II (CPSase II) This enzyme, isolated from fetal rat liver, requires glutamine as nitrogen donor, and is subject to inhibition by UTP This latter finding, together with the fact that carbamoyl phosphate synthetase II exhibits a low turnover

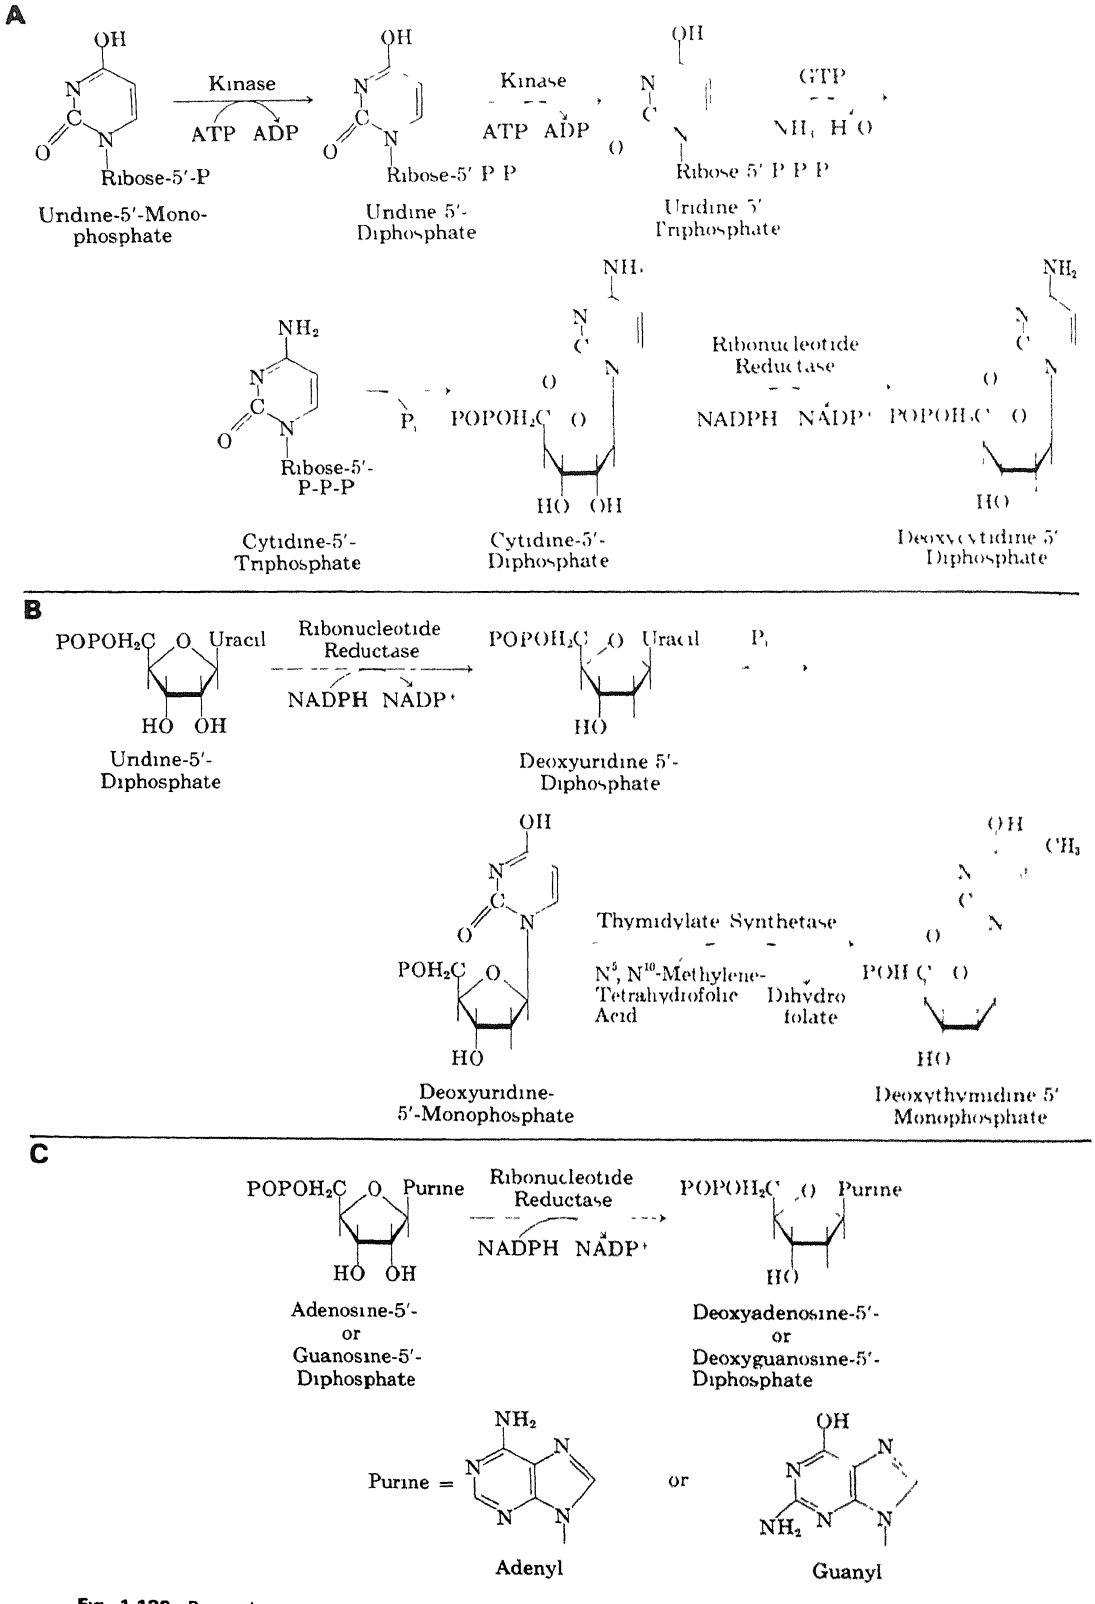

Fig 1.129 Biosynthetic pathways of cytidine ribonucleotide pyrimidine deoxyribonucleotides and purine deoxy ribonucleotides

rate, suggests that this enzyme may play an important regulatory role in the pyrimidine biosynthetic pathway (Hager and Jones, 1967)

It is worth mentioning that the liver of adult rats containd carbamoyl phosphate synthetase activity which requires ammonia as nitrogen donor and *N*-acetyl-L-glutamate as cofactor This carbamoyl phosphate synthetase is not sensitive to pyrimidine feedback inhibition, and evidence indicates that it is important in the urea cycle rather than in the synthetic pathway of pyrimidine From regenerating liver, in which both urea and pyrimidine synthesis are occurring simultaneously, carbamoyl phosphate synthetase activity has been separated into CPSase I (requiring ammonia) and CPSase II (requiring glutamine) (Nakanishi et al , 1968)

A metabolic intermediate can be involved in the regulation of a biosynthetic pathway not only through feedback inhibition but also by induction of increased levels of enzymes necessary to turn the intermediate into product Studies on human diploid cells in culture in which addition of dihydroorotic acid gives rise to increased levels of orotidine-5′-monophosphate decarboxylase (step 6 in Fig 1 128), and possibly also of the enzymes catalyzing the preceding two steps, may serve as an example (Pinsky and Krooth, 1967a, b)

BIOSYNTHESIS OF PURINES

In contrast to the pyrimidine ring, which attaches covalently to the ribose phosphate after its synthesis has been completed, de novo synthesis of the purine skeleton occurs on the ribose phosphate residue Studies with labeled precursors revealed the atoms of the purine skeleton to be derived from the following sources (Fig 1 130)

The first step in the biosynthesis of purine (see Fig 1 131) is the phosphoribosyl pyrophosphate amidotransferase-catalyzed amination of phosphoribosyl pyrophosphate (PRPP), which is an important intermediate and has been implicated as a regulatory factor in the biosynthesis of all nucleotides (recall that it appears also in step 5 of pyrimidine biosynthesis, see Fig 1 128) This step utilizes the amide nitrogen of glutamine, and involves an inversion at C-1 of the ribose moiety yielding 5′-phosphoribosyl-1′-amine This amine is then conjugated with glycine in an ATP-dependent reaction, and the resulting glycinamide ribonucleotide is formylated and subsequently amidated by transference of the amide nitrogen from glutamine The fifth step entails an ATP-dependent dehydration with concomitant ring closure to yield the imidazole portion of the purine The next two steps involve the carboxylation of 5-aminoimidazole ribonucleotide followed by amidation, the nitrogen being derived from the α-amino group of aspartic acid Into this intermediate, 5-aminoimidazole-4-carboxamide ribonucleotide, the last carbon atom is introduced by formylation and then, in a final step, dehydration leading to ring closure completes the synthesis of the hypoxanthine ribonucleotide, referred to as inosinic acid

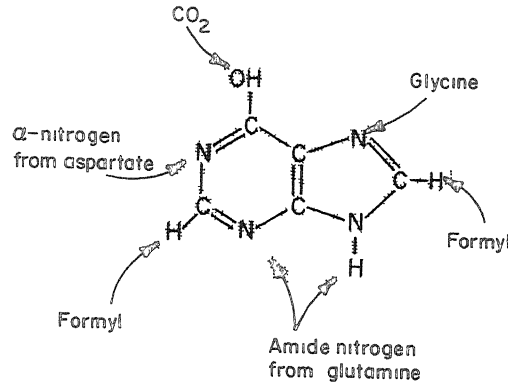

Fig 1 130 Source of atoms in the purine ring

With the synthesis of inosinic acid a branch point in the biosynthetic pathway has been reached (see Fig 1 132) On the one hand, amination of this intermediate in a two-step process which is GTP-dependent, results in adenosine-5′-monophosphate (AMP), on the other, likewise in a two-step process, inosinic acid is oxidized and then, in an ATP-dependent step, aminated to give guanosine-5′-monophosphate (GMP) Synthesis of purine deoxyribonucleotides is catalyzed in in vitro experiments by the same enzymes which reduce pyrimidine nucleosides Control is again stringent and complicated The pathway is outlined in Figure 1 129*c*

Purine biosynthesis is controlled by feedback inhibition at the first committed step, which is the glutamine-dependent amidation of PRPP catalyzed by PRPP-amidotransferase (step 1 in Fig 1 131) (Wyngaarden and Ashton, 1959) Studies of the partially purified enzyme from mammalian tissue showed that AMP, ADP, ATP, GMP, GDP, and inosine monophosphate (IMP) all can act as inhibitors with varying

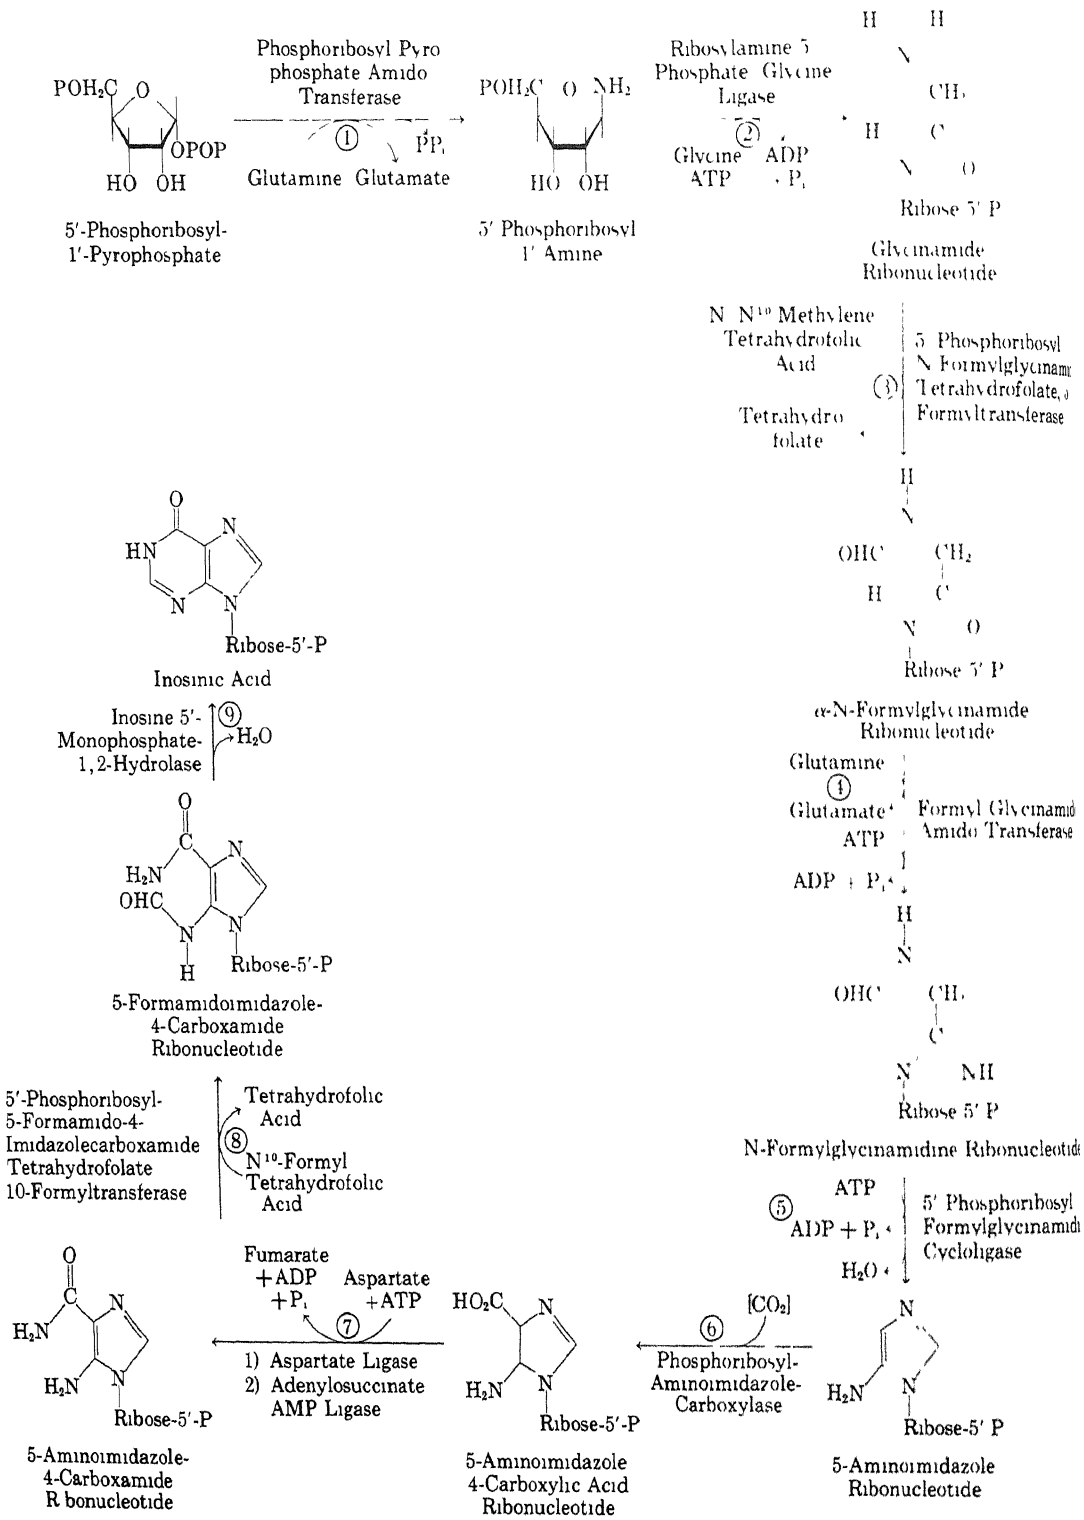

Fig 1 131 Biosynthetic pathway of inosinic acid

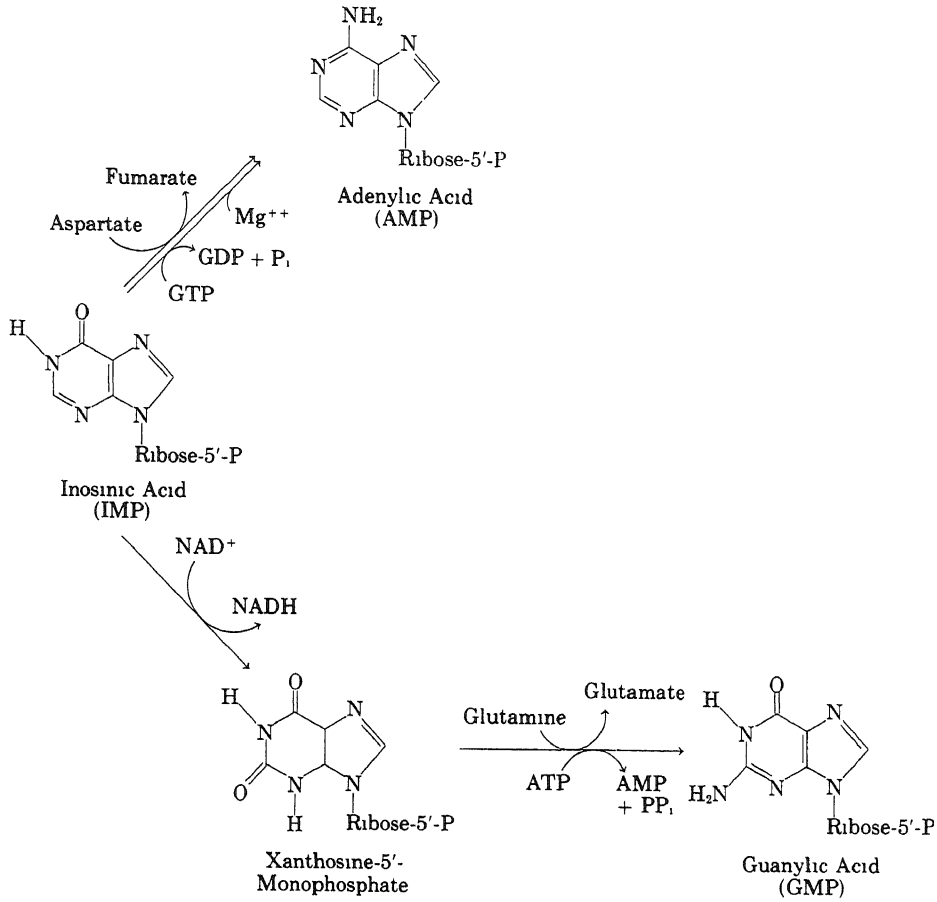

Fig 1 132 Conversion of IMP to AMP and GMP

degrees of efficacy (Caskey et al , 1964) In no case were purine nucleosides or free bases effective as inhibitors of the purified enzyme On the other hand, inhibition in mammalian tumor cells of de novo purine synthesis is obtained not only with nucleotides but also with purine bases and nucleosides It is most likely, in view of the enzyme studies mentioned above, that purine bases and nucleosides are converted to nucleotides within the cell before they can exert their inhibitory effects Pyrimidine bases, which are likewise in cells readily converted to their corresponding nucleosides and nucleotides, are incapable of inhibiting PRPP-amidotransferase, this reveals the inhibition of the transferase as feedback rather than depletion of the substrate PRPP in the course of nucleotide formation Further, the conversion of inosinic acid to AMP requires GTP for energy, and the conversion to GMP requires ATP We may view these reciprocal requirements as a kind of regulatory control In addition, in bacteria, the enzyme involved in the oxidation of inosinic acid is subject to feedback inhibition by GMP (Fig 1.133), (Magasanik, 1958), and one of the enzymes necessary for AMP formation has been shown to be inhibited by a number of purine nucleotides (Wyngaarden and Greenland, 1963)

REUTILIZATION PATHWAYS OF PYRIMIDINES AND PURINES

In addition to engaging in de novo pyrimidine and purine synthesis, many cell types are capable of utilizing preformed bases, derived essentially from breakdown of nucleic acids or from ingested food, for nucleotide formation (Murray et al , 1970) Although a great deal of similarity appears to exist between the types of enzymes involved in the reutilization of pyrimidines and purines, to date more emphasis has

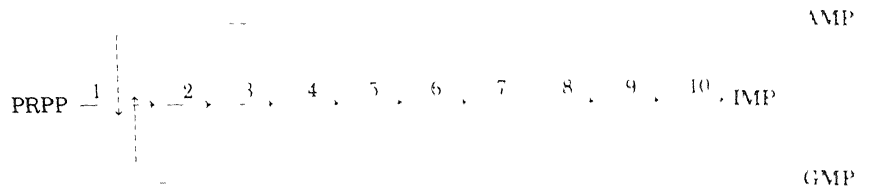

Fig 1 133 Schematic representation of main control points in purine biosynthesis. Circled numbers correspond to steps in the biosynthetic pathway shown in Figure 1 131. Dashed lines indicate regulatory pathways.

been placed on the purines, because of their wider use as therapeutic agents. It was only in recent years, however, that the lack of certain reutilization enzymes was recognized as a cause of serious disorders.

The most important enzymes for both pyrimidine and purine reutilization are *a*) nucleoside phosphorylases, *b*) nucleoside kinases, and *c*) phosphoribosyl transferases (Fig. 1 134). Nucleoside phosphorylases catalyze the reversible reaction

$$\text{nucleoside} + P_i \rightleftharpoons \text{base} + \text{ribose-1-P}$$

These enzymes, possessing broad specificity, have been found in many tissues, such as spleen, liver, and Ehrlich ascites tumor cells. Nucleoside kinases phosphorylate nucleosides to yield nucleotides. Most studies have been performed using adenosine kinase, which is widely distributed in mammalian tissue. Adenosine kinase is fairly specific for adenosine, although it can react with certain adenosine analogs. Phosphoribosyl transferases catalyze the formation of the glycosidic linkage between base and PRPP, resulting in nucleoside monophosphate and PP_i. In mammalian tissue two enzymes have been well characterized to date—one which reacts with adenine and the other with hypoxanthine, guanine, and xanthine.

In summary, preformed bases can be converted to nucleotides either by formation of nucleoside and subsequent phosphorylation, or by direct condensation with PRPP. The specificity of the reutilization pathway enzymes and their mode of control assure that there is no excess of one base or nucleotide at a given time and that de novo synthesis can be kept at its lowest level for maximum efficiency. These pathways also assure that if exogenous purine or pyrimidine is available, it can be utilized to the greatest benefit of the organism. In addition to the above enzymes involved in the reutilization of preformed bases, many additional enzymes exist, likewise carefully controlled,

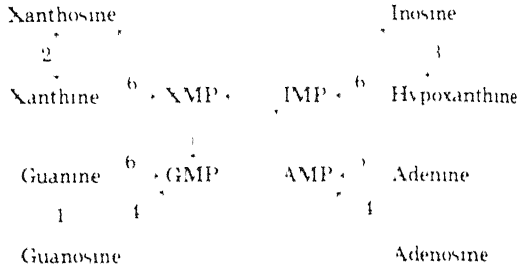

Fig 1 134 Pathways of purine reutilization. The most important enzymes for purine reutilization are: Nucleoside phosphorylases (1, [illegible]); Nucleoside kinases; 4, Adenine phosphoribosyl transferase; 5, Hypoxanthine-guanine phosphoribosyl transferase; 6.

which catalyze the conversion of one pyrimidine to another, and, similarly, of one purine to another.

Incorporation of Purines and Pyrimidines into Nucleic Acids, Their Orientation in Nucleic Acids, and Nucleic Acid Breakdown

The deoxyribonucleoside triphosphates of adenine, guanine, thymine, and cytosine are the substrates for enzyme-catalyzed polymerization which results in deoxyribonucleic acid (DNA), as depicted in Figure 1 135. Similarly, ribonucleoside triphosphates of adenine, guanine, uracil, and cytosine are polymerized by mammalian DNA-dependent RNA polymerase, yielding ribonucleic acid (RNA). The resulting nucleic acid molecules are the genetic information carriers of the living organism. The information transfer reactions, including duplication of DNA, transcription, which is the synthesis of messenger RNA on a DNA template, and translation of the messenger RNA code, are processes in which the formation and cleavage of highly specific hydrogen bonds between purines and pyrimidines play a crucial role. Hydrogen bonds are the result of an associative interaction between an acidic, hydrogen-

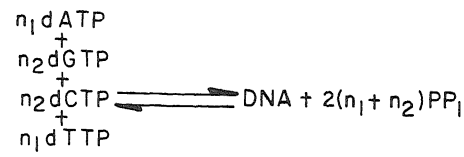

Fig 1 135 Schematic representation of enzymatic DNA synthesis

bearing atom (donor), and an electronegative group (acceptor), such as tertiary nitrogen or carbonyl oxygen

For some time the specificity of purine-pyrimidine pairing (guanine-cytosine, adenine-thymine) was thought to reside in the stereochemical restraints imposed by the helical DNA structure, however, x-ray studies of crystals as well as spectroscopic studies in solution of base derivatives themselves have indicated that the cooperativity of all noncovalent bond interactions, including the hydrophobic bond, ionic bond, but particularly the hydrogen bond, is sufficient to bring about specific base-pairing (Voet and Rich, 1970) For example, several configurations are theoretically possible for the guanine-cytosine base pair (Fig 1 136), but on the basis of the model systems studied, it can be concluded that only one configuration (*b*) occurs This configuration, as opposed to others, derives added stability from the high number of favorable hydrogen bonds In fact, this pairing coincides with the Pauling-Corey modification of the Watson and Crick proposal in the DNA model The elucidation of the information contained in nucleic acids ranks among the great scientific achievements of our time, and the interested reader is referred to pertinent summaries (Taylor, ed , 1963, 1967, Frisch, ed , 1966 and 1969, Crick, 1966, Yanofsky, 1967)

The turnover rate of DNA and all the different types of RNA in mammalian cells is slow Although several enzymes capable of degrading DNA and RNA have been isolated and well characterized, our understanding of the in vivo breakdown of these molecules is at present rather limited

Among the known deoxyribonucleases attention should be drawn to two, both of which are endonucleases, but which differ in their mechanism of cleavage DNase I, which is effective at neutral pH, catalyzes cleavage of nucleotide bonds to form oligonucleotides possessing a free 3′-hydroxy group, but retaining the 5′-phosphate Another type of nuclease, DNase II, has an acidic pH optimum, and catalyzes intranucleotide cleavage to yield oligonucleotides with a 5′-hydroxy and a 3′-phosphate group Both types of deoxynuclease have been isolated from bacterial as well as mammalian sources (Laskowski, 1967) Similarly, microorganisms and mammalian tissue contain ribonucleases which possess different specificities Bovine pancreatic RNase, for example, a well-characterized protein whose complete structure has been elucidated (Wyckoff et al , 1968), is an endonuclease which catalyzes the cleavage of the 3′-phosphate ester as long as a pyrimidine base—rather than a purine—is attached at the 1′-position of the given ribose moiety It appears that DNA and RNA are first converted to oligonucleotides which in turn are catabolized to mononucleotides, possibly by nonspecific phosphodiesterases The 5′-nucleotidases and nucleoside phosphorylases, so far found in all tissues investigated, then complete hydrolysis to the free bases The further breakdown of purines and pyrimidines is discussed in the following sections

DEGRADATION OF PYRIMIDINES

Our present knowledge of the catabolic pathways of cytosine, uracil, and thymine is summarized in Figure 1 137 Much of this information is derived from work with microorganisms and enzymes isolated from mammalian liver A problem in the determination of these pathways has been the lability and short lifetime of some of the intermediates The first step in the degradative pathway of pyrimidines is a reduction to the dihydro derivative Hydrolytic ring scission of the amide bond between positions 3 and 4 gives rise to the corresponding *N*-carbamoyl-β-amino acid These compounds are deacylated to β-alanine in the case of uracil and β-aminoisobutyric acid in the case of thymine That these compounds are susceptible to further degradation by transamination to malonic- and methyl malonic-semialdehyde and eventual retutilization for branched-chain fatty acid synthesis is known from earlier work

DEGRADATION OF PURINES

Because one product of catabolism of purines is uric acid, a compound implicated in several human diseases, the degradative pathway of the purines has been worked out in greater detail than that of pyrimidines Purine catabolism

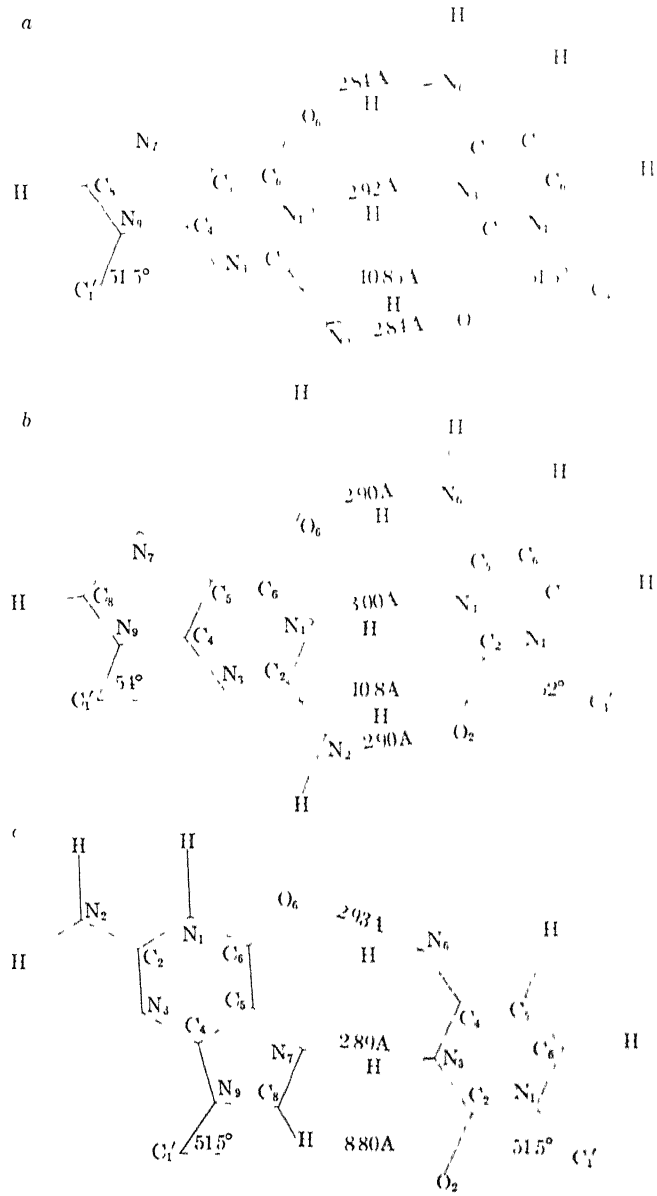

Fig 1 136 Some theoretically possible guanine-cytosine base pairs *a)* Watson Crick model *b)* Pauling Corey modification of Watson-Crick model *c)* model with two instead of three hydrogen bonds

is outlined in Figure 1 138 Guanine is deaminated by guanase to xanthine The analogous reaction is not possible with adenine since animal tissue lacks adenine deaminase, hence, in a three-step reaction adenylic acid or adenosine are likewise converted to xanthine (Balis, 1967) The last of these steps is catalyzed by xanthine oxidase, which also oxidizes xanthine to uric acid (Fig 1 138, steps 3 and 4) Uric acid is the excretory product in man, some primates, reptiles, fowl, insects other than *Diptera*, and in the Dalmatian dog (which cannot reabsorb uric acid) In the ureotelic mammals, primeval vertebrates, marine elasmobranchs, and teleosts, uric acid is further hydrolyzed by uricase to allantoin, a more soluble excretory product Allantoin, in turn, is further degraded to allantoic acid by allantoinase, and then to urea and glyoxylic acid by allantoicase. In the lower forms of life, bacteria and marine inver-

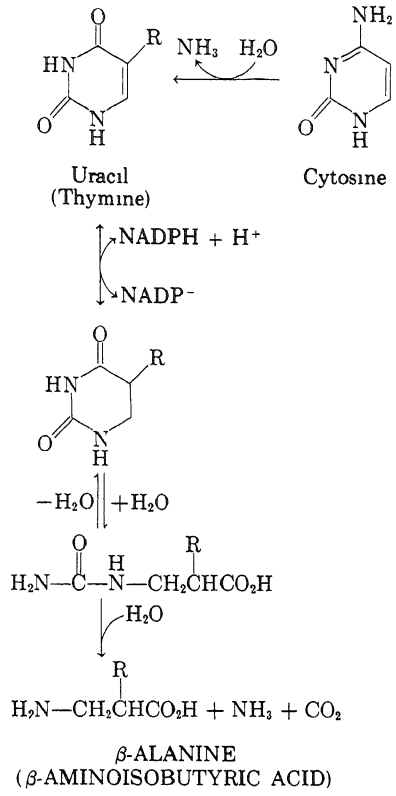

Fig 1 137 Degradative pathway of pyrimidine ribonucleotides Uracil R = H thymine R = CH_3

tebrates, urea is not excreted, but instead is metabolized to carbon dioxide and ammonia It is tempting to speculate that higher animals have lost uricase in the course of evolution, leaving them with the disadvantageous excretion of the slightly soluble uric acid (Gutman, 1965)

Uric acid is not the major pathway of nitrogen excretion in man Instead, the ammonia nitrogen of most amino acids, the major nitrogen source, is shunted into the urea cycle The major amount of uric acid is excreted by the kidney, although uricolytic bacteria present in the small intestine degrade the acid further, as was revealed by administration of labeled uric acid and recovery of label in expired carbon dioxide, as well as in urinary uric acid A greater amount of extrarenal elimination of uric acid appears to occur in patients who are hyperuricemic; this finding has been thought to be a cause and effect relationship, but the increased extrarenal elimination may also be due to undetected impaired kidney function

Disorders of Purine and Pyrimidine Metabolism

GOUT

Primary gout is a genetically determined disorder of purine metabolism characterized biochemically by hyperuricemia Hyperuricemia may be asymptomatic for long periods, in gout it usually becomes clinically significant through recurrent attacks of acute arthritis The arthritic stage rarely begins before puberty in males or before menopause in females Renal calculi can occur at any time, but tophaceous deposits usually appear after the development of acute arthritis Gouty patients may overproduce and overexcrete uric acid, or they may excrete normal amounts In certain cases production may be normal, but defective renal function may result in hyperuricemia which in turn may cause gout (renal gout) Secondary gout is acquired as a complication of hyperuricemia associated mainly with hematological malignancies, or in drug-induced states

One of the major problems in gout is the nature of the triggering mechanism of the acute attack Uric acid is rather insoluble in acidic solutions, although alkalinity increases its solubility At blood pH (7 44) it is present as the sodium salt, which is likewise insoluble but frequently forms supersaturated solutions The events leading to initial crystallization of sodium urate from supersaturated fluid are poorly understood, but once crystals form they are phagocytized by numerous polymorphonuclear cells in the synovial fluid It has been recently shown that the phagocytosis of urate crystals, but not of diamond dust particles, results in the elaboration of a chemotactic substance by the polymorphonuclear cell (Phelps, 1969) It now seems likely that the primary action of colchicine in aborting gouty inflammation is its inhibition of motility of the polymorphonuclear cells by interference with the formation of protoplasmic gels (microtubules) (Malawista, 1968)

The most common definition for hyperuricemia is statistical, i e , any value over two standard deviations from the normal mean is defined as high The upper limit of normal has been found to be 6 3 to 6 4 mg /100 ml in males, and 5 8 mg /100 ml in females (by the uricase method) These values depend somewhat on the technique used for measurement, colorimetric methods giving higher values than enzymatic ones Another widely used measure-

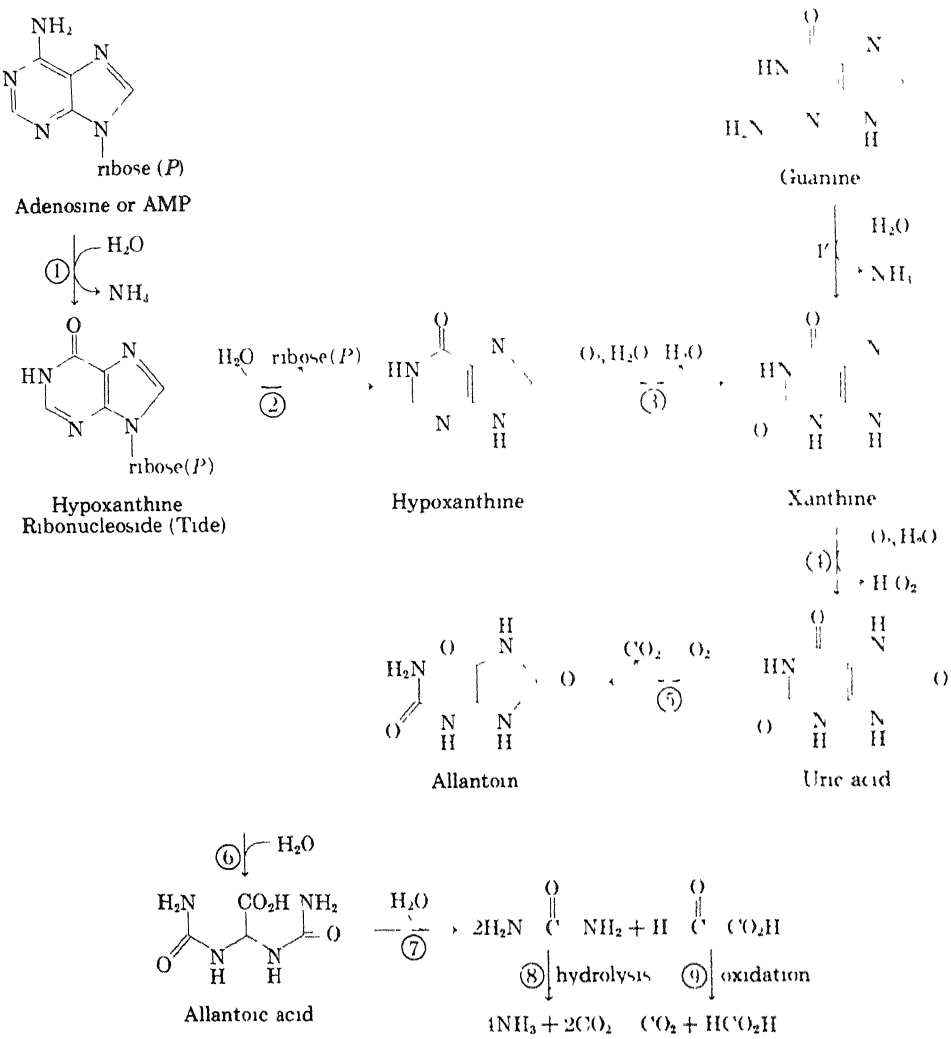

Fig 1 138 Degradative pathway of purine ribonucleotides Circled numbers indicate steps see text

ment is that of the "miscible pool" of uric acid, determined by isotope dilution of urinary uric acid, after an injection of the labeled compound In normal males the pool contains about 1200 mg , with a turnover of approximately 700 mg /day The serum uric acid concentration in 98% of gouty patients was found to be above 7 mg /100 ml by the uricase method In these subjects the miscible pool was generally as high as 2000 to 4000 mg , and in cases of severe gout could reach 18,000 to 31,000 mg. (Wyngaarden, 1966) There is some speculation that urate may exist in bound form in plasma, and that a deficiency in binding may cause the excess (Sorenson, 1969). In this chapter the intention is to relate causes of gout as they are understood in terms of disorders in the basic biochemistry of the metabolic pathways of purines described above

Uric acid is formed from purines, which are liberated as a result of enzymatic degradation of tissue and dietary nucleoproteins and nucleotides, and is also formed by de novo purine synthesis. The immediate precursors of uric acid are hypoxanthine and xanthine, which are both acted upon by xanthine oxidase The rate of purine synthesis in normal and gouty patients is routinely studied by measuring incorporation of ^{15}N- or ^{14}C-glycine into uric acid In contrast to normal subjects, patients with primary gout show enhanced uric acid production. The pattern of incorporation of label into uric acid is characterized by a rapid and excessive rise, followed by a fairly rapid decline

This pattern is indicative of a "shunt pathway" for uric acid synthesis, i e , a major portion of the newly synthesized purine is diverted from incorporation into nucleic acids and instead is catabolized to uric acid

Most forms of primary gout (metabolic gout) are a result of overproduction of uric acid caused by accelerated de novo purine synthesis, which may or may not be accompanied by overexcretion It is to the cause of the increased synthesis that we address ourselves below

In 1964, an X-linked hereditary disease, now known as the Lesch-Nyhan syndrome, was first reported Its clinical features are developmental regardation, spastic cerebral palsy, choreoathetosis, and self-mutilating, aggressive behavior (Bland, 1968) The patients have markedly increased serum uric acid levels, usually in the range of 15 mg /100 ml , and excretion of uric acid is so high (in terms of milligrams uric acid per kilograms body weight) that these children would be classified as overexcretors even if they were adults Incorporation studies with ^{14}C-glycine indicate an overproduction up to 20 times control, which is about 10 times the uric acid level in gout From other studies it is known that hypoxanthine is normally recycled to a much greater extent than xanthine, and therefore the ratio xanthine hypoxanthine is always greater than one In the Lesch-Nyhan syndrome, more hypoxanthine than xanthine is excreted This fact indicates that hypoxanthine is probably the major precursor of uric acid in the syndrome The explanation of this finding is that all patients exhibiting the syndrome totally lack the enzyme hypoxanthine-guanine phosphoribosyl transferase (PRT), which catalyzes the transfer of the ribose-5′-phosphate moiety of 5′-phosphoribosyl-1′-pyrophosphate to the free purine bases, hypoxanthine and guanine (Fig 1 134, step 6) The absence of the enzyme is especially notable in the brain, where activity is normally high The conclusion which can be drawn is that lack of this enzyme evokes a detrimental increase in purine synthesis There are at least two possible mechanisms *1)* a decrease in GMP formation could result in diminished feedback inhibition of phosphoribosyl amidotransferase, *2)* a decreased utilization of PRPP may increase its availability for de novo synthesis (both Fig 1 131, step 1)

Because of the similarity of the Lesch-Nyhan syndrome to gout, it was natural to assay for PRT in gouty patients Seegmiller and his colleagues carried out extensive work both in vitro, on cultured human fibroblasts, and in vivo (Kelley et al , 1969) They found a decrease in PRT activity in a substantial number of gouty subjects The decrease is the same within families, but the absolute amount of decrease is different between families All patients with a lack or defect of PRT produce excessive quantities of uric acid, with a reflection in the urinary excretion in most cases PRT-deficient patients show the "shunt" pattern of incorporation Isolated mutant enzymes show varying degrees of heat stability that are quantitatively different from normal enzyme In the course of the studies it was consistently found that the patients had an abnormally high level of adenine phosphoribosyl transferase (A-PRT) The significance of this observation has not been determined, although it is tempting to speculate that the lack of GMP derepresses this enzyme, since GMP can be converted to AMP through IMP Cultured fibroblasts from the enzyme-deficient subjects showed an increase in purine synthesis to four times normal, and in some cases an increase in free intracellular PRPP, probably due to decreased utilization Fibroblasts deficient in PRT also showed that amidotransferase activity could be *activated* by hypoxanthine or guanine, unlike the situation in which the nucleotides of these bases serve as inhibitors This activation could provide another possible mechanism for increased purine synthesis de novo, especially since intracellular nucleotide concentrations seem to be normal, so that feedback inhibition should not be diminished These studies on gouty overproducers of uric acid indicate that the enzyme PRT, formerly believed to be a rather unimportant "salvage" enzyme, may play an important role in control of purine metabolism Whether the loosening of this control causes increased synthesis by raising the concentrations of substrates (PRPP, hypoxanthine, and guanine), or by decreasing inhibition, or both, will most likely be determined in the near future

Most of Seegmiller's gouty patients produced quantities of uric acid comparable to those discussed above, but had normal PRT activity This fact demonstrates that primary gout is the phenotypic expression of a heterogeneous group of genetic abnormalities Other possible causes will now be discussed

Decreased utilization of PRPP has already been implicated, however, the erythrocytes of

some gouty patients show an increased capacity for the synthesis of this substrate (Hershko, et al , 1968) The overall effect of increased synthesis of PRPP is the same as its decreased utilization, both phenomena leading to accelerated de novo purine synthesis The increased PRPP synthesis is linked to enhanced levels of endogenous ribose-5'-P, its immediate precursor

Some experiments have demonstrated that excessive purine synthesis in gouty patients can be modulated by adenine, indicating that derangements of the regulatory mechanism are quantitative rather than qualitative Also, in vitro leukocyte studies showed that while ^{14}C-glycine incorporation was on the average 1 8 times higher in gouty than normal cells, hypoxanthine was incorporated to the same extent in both cell types, and still inhibited excessive purine synthesis In these examples feedback inhibition and PRT activity are both normal, however, Rosenbloom, Henderson, and Kelley (1968) did demonstrate two patients with normal PRT activity and a defect in feedback inhibition (Fig 1 131, step 1) Incorporation of ^{14}C-glycine by skin fibroblasts was less sensitive to exogenous adenine and hypoxanthine in these patients than in normal individuals (Rosenbloom et al , 1968)

It has been postulated that in gouty patients increased quantities of glutamine are available for the first step of purine biosynthesis in the liver due to decreased glutaminase activity This decreased activity could impair the renal formation of ammonia and result in unduly acid urine This postulate was advanced in an attempt to explain the development of uric acid stones in gouty patients and their rarity in nongouty hyperuricemic patients Earlier observations had indicated that uric acid stone formation (urolithiasis) resulted chiefly from hyperexcretion of uric acid, however, approximately three-quarters of gouty patients with stones excrete normal amounts of uric acid Although direct studies have failed to confirm a deficiency of glutaminase in renal tubules, there is a persistent undue acidity of the urine of patients with primary gout accompanied by an absence of early morning and postprandial alkaline tides This finding correlates with reduced ammonia formation, 25 to 30% less than expected in relation to the urinary pH It is this persistent excessive acidity of the urine which is currently thought to be the major factor in stone formation (Yu and Gutman, 1967)

In summary a deficiency of PRT activity can cause uric acid overproduction in gout, and while it is rather rare it provides a rational explanation for overproduction in these particular patients The enzymes of de novo purine biosynthesis are under strict regulatory control, however, occasionally a loosening of this control does occur PRT deficiency contributes to this occurrence Probably no one specific cause of hyperuricemia and gout may be postulated, but the various biochemical lesions leading to the disease have either been pinpointed or are under focused investigation Clinically gout and, in general, hyperuricemia are treated with allopurinol, a purine analog which effectively inhibits xanthine oxidase in vitro and in vivo, and which also appears to inhibit de novo purine synthesis The consistent reduction in uric acid synthesis in response to allopurinol is a result of both actions

XANTHINURIA

Xanthinuria is a rare disorder of purine metabolism characterized by excretion of xanthine as the major end-product of purine metabolism Oxypurine levels of the serum are elevated, and uric acid levels are low Because xanthine is the chief purine metabolite excreted, it was thought that there might be a lack of xanthine oxidase activity (Fig 1 138, steps 3 and 4) This fact has been confirmed by direct assay Hypoxanthine does not accumulate under these conditions because of its efficient reutilization Xanthine oxidase, a flavin protein containing molybdenum and iron as cofactors, is in mammals normally found in the liver, small intestinal mucosa and possibly bone marrow. The complete absence of xanthine oxidase in patients with xanthinuria provides a clear demonstration of a specific biochemical lesion as the cause of a disease, although for this particular disorder no broader clinical manifestations have been reported except for the occasional passing of a xanthine stone

HEREDITARY OROTIC ACIDURIA

Hereditary orotic aciduria is a rare disease characterized by retarded growth and development, megaloblastic anemia, and excessive ex-

cretion of orotic acid. The detection in urine of orotic acid, a known intermediate in pyrimidine biosynthesis, suggested that there might be a block in the biosynthetic pathway subsequent to orotic acid formation (Fig. 1.128). The first patient discovered with this abnormality was therefore treated with yeast pyrimidine nucleotides. His improvement led to assay for the enzymes of pyrimidine biosynthesis in samples of his cultured erythrocytes and those of his family. Low levels of both orotic acid pyrophosphorylase and orotidine monophosphate decarboxylase activities were found (Fig. 1.128, steps 5 and 6) (Smith et al., 1961). Increased incorporation of labeled precursor in these patients suggested accelerated de novo pyrimidine synthesis, probably due to release of end-product inhibition. This disease is a good example of how an hereditary disorder can be pinpointed and treated. Once the complete biosynthetic and catabolic pathways of a particular compound are known, the excretion of an intermediate metabolite strongly suggests that a step subsequent to its formation has been blocked. The lack of two enzymes, as noted in this case, might indicate an abnormality in the genetic regulatory mechanism. Treatment of orotic aciduria has been limited to replacement therapy with uridine (Becroft et al., 1969). Success of treatment depends on the efficiency of reutilization pathways for pyrimidines. The higher efficacy observed with uridine as compared to uracil suggests that the more important reutilization path in man is normally the two-step one involving the nucleoside phosphorylase and nucleoside kinase. A problem with uridine treatment has been that the blood-brain barrier may not be permeable to the nucleoside, causing continued pyrimidine starvation in the brain which may explain the intractable mental retardation. Treatment does reduce the excretion of orotic acid, however, so that the exogenous nucleoside re-establishes feedback control. The pyrimidine reutilization pathways, here useful in control of disease, may well be recognized to be essential in normal metabolism as has been found in the case of purines.

7 / NUCLEIC ACIDS AND GENE ACTIVITY

Nucleic acids are macromolecules present in all living cells They were first isolated from pus cells by Friedrich Miescher in 1869 Complete hydrolysis of nucleic acids yields a mixture of basic substances called purines and pyrimidines a sugar and phosphoric acid The nucleic acids are classified into two main categories, according to the sugar they contain Those containing D-ribose are called *ribonucleic acids* or RNA Those containing D-2-deoxyribose are called *deoxyribonucleic* acids or DNA The pyrimidines commonly found in nucleic acids are *uracil* (U), *thymine* (T), and *cytosine* (C), the major purines are *adenine* (A) and *guanine* (G)

Deoxyribonucleic Acid

The first serious consideration that DNA can carry genetic information arose from Avery's experiments (1944) on bacterial transformation Bacterial transformation may be defined as the transfer of genetic characteristics to a recipient cell by means of DNA isolated from a donor cell population The phenomenon of bacterial transformation was observed for the first time in *pneumococcus* All virulent pneumococci form smooth colonies (S-type) when cultured on agar, because of a distinctive polysaccharide capsule on the cell surface Avirulent strains of pneumococci do not have the ability to form the polysaccharide capsule when cultured on agar, and hence form rough colonies (R-type) Griffith made the observation in 1928 that the addition of heat-killed pneumococci of the S-type into a suspension of live avirulent pneumococci caused a small fraction of these bacteria to be transformed into pathogenic cells Subsequently Avery, McLeod, and McCarty (1944) in a now classical experiment showed that pneumococci of the R-type can be transformed in vitro into the S-type by means of DNA prepared from R-type cells Confirmation that nucleic acids are the carriers of genetic information came from studies with viruses From these studies it was shown that *viral genes* are also nucleic acids

STRUCTURE OF DNA

The Covalent Backbone of DNA The deoxyribonucleic acids are polynucleotides in which the fundamental units the nucleotides, are linked to one another with 3′–5′ phosphodiester bonds Thus the covalent backbone of DNA is made of alternating deoxyribose and phosphate groups To this backbone the purine and pyrimidine bases are attached like side chains (Fig 1 139) The structure of polynucleotides is often represented schematically as shown in Figure 1 140 It can be seen that a polynucleotide has a *3′-end* and a *5′ end* These ends are very important in establishing directions of synthesis of DNA or RNA, as well as in direction of reading of RNA during protein synthesis

A shorthand way of writing nucleic acid sequences is to symbolize the bases by their initial letter and the phosphate group by the letter p A p positioned to the left of the base designates the 5′-position, if p appears to the right of base designates the 3′ position Finally, the prefix d- symbolizes deoxyribonucleic acid sequences Thus, d pApTpCpCpT symbolizes a deoxypentanucleotide in which *a*) the 5′ end has a free phosphate group *b*) the four phosphodiester bonds are between 3′A—5′T, 3′T—5′C, 3′C—5′C, 3′C—5′T, and *c*) the 3′-end has a free —OH

Base Composition of DNA Application of quantitative chromatographic methods in the analysis of various DNA preparations enabled Chargaff (1951) to draw the following extremely important conclusions

1) The base composition of DNA varies from species to species

2) DNA preparations obtained from various tissues of a given species have the same base composition, which is characteristic for that species

3) The base composition of DNA of a species does not change with age or nutritional state

4) In every DNA examined the number of adenine residues was equal to the number of thymine residues, that is, A = T Similarly it

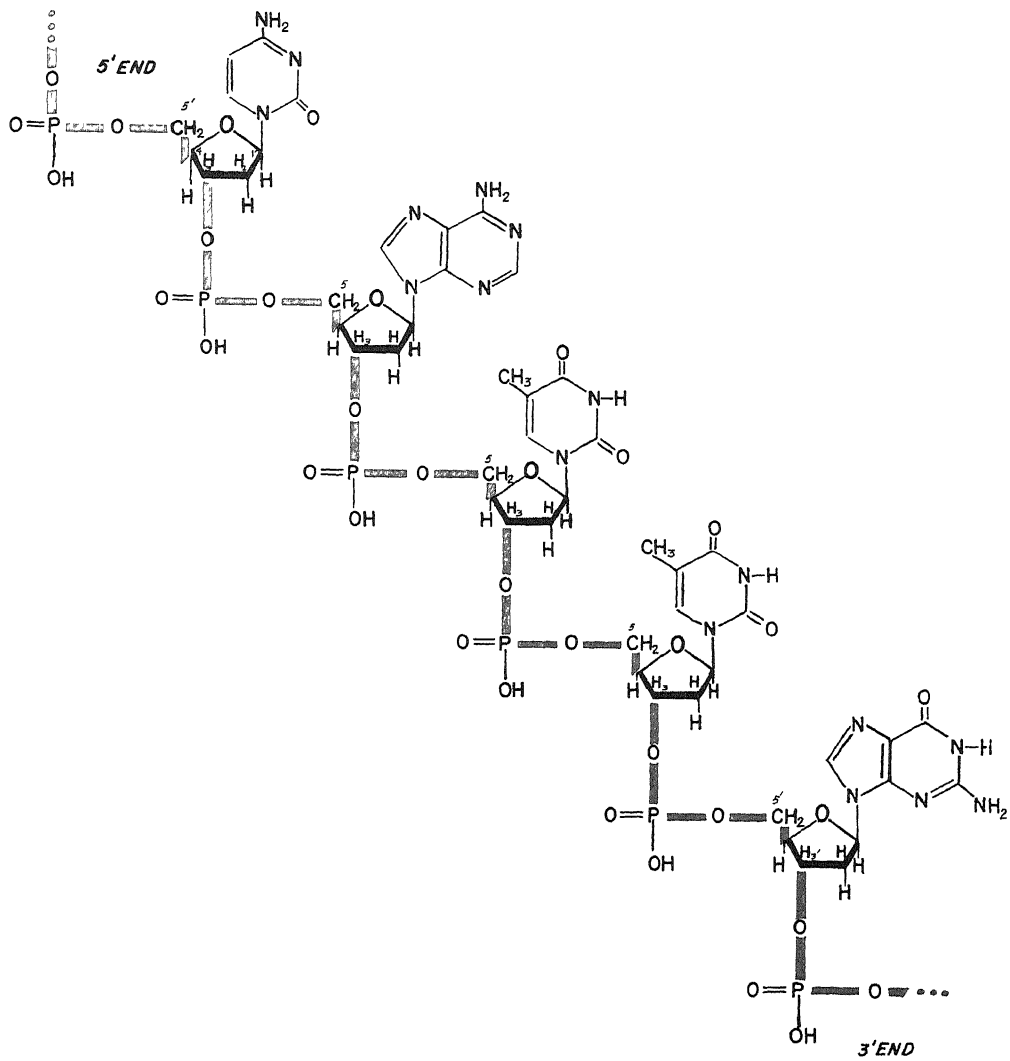

Fig 1 139 Structure of a portion of a DNA chain with hypothetical base sequence 5' to 3', cytosine-adenine-thymine-thymine-guanine

was found that G = C, and therefore A + G = C + T In other words the sum of the purine residues is equal to the sum of the pyrimidine residues These relationships apply to all double stranded DNA but not the single stranded ones

Three-Dimensional Structure of DNA. Application of x-ray crystallographic techniques to fibers of highly purified DNA enabled Wilkins and his colleagues to obtain important data on the three-dimensional structure of DNA DNA was found to possess two periodicities—a major one corresponding to a regular spacing every 3 4 Å along the fiber axis, and a secondary one every 34 Å (Fig 1 141) The crystallographic data together with the equivalence of bases in DNA described by Chargaff set up the stage for the understanding of the 3-D structure of DNA In 1953 Watson and Crick proposed a model for DNA which accounted for all the observed chemical and physical properties of DNA The characteristics of the Watson-Crick model are the following

1) DNA consists of two right-handed helical polynucleotide chains, coiled around the same axis to form a double helix

2) The two polynucleotide chains (strands) are antiparallel, in the sense that the 3'—5' phosphodiester bonds run in opposite directions

3) The bases of the chains are stacked on the

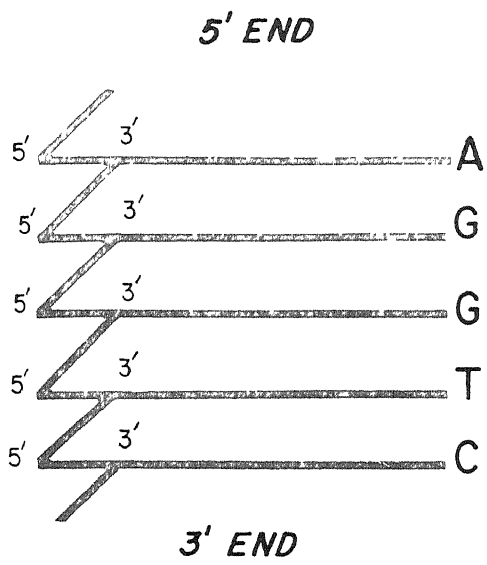

Fig 1 140 Schematic representation of a polynucleotide chain

inside of the double helix The planes of bases are parallel to each other and perpendicular to the long axis of the duplex

4) The bases of one chain are paired with hydrogen bonds with the bases of the other strand This pairing occurs between bases lying in the same plane Only certain base pairs can be accommodated, these are A-T and G-C (Fig 1 142) In other words A always pairs with T and G always pairs with C

5) The bases are stacked on top of one another and at a distance of 3 4 A There are exactly 10 bases per complete turn of the double helix (34 A)

6) The double helix has one major groove and a minor one (Fig 1 143)

Generally speaking the hydrophilic sugar residues and charged phosphate groups are on the outside of the DNA molecule whereas the hydrophobic bases are stacked within the double helix where they are shielded from water

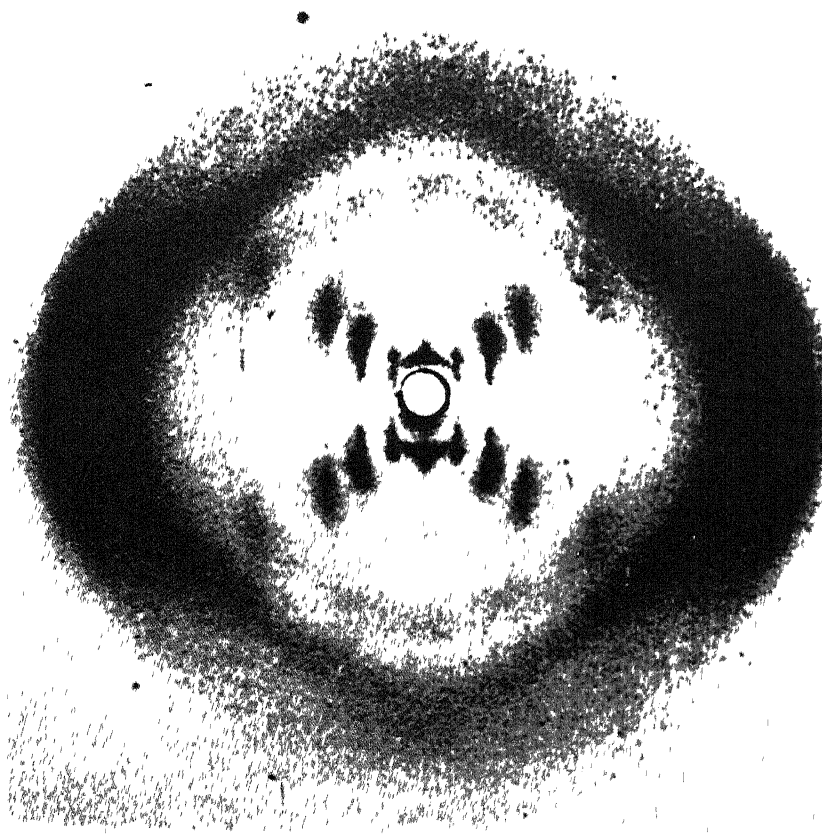

Fig 1 141 X-ray diffraction photograph of DNA The helical form of DNA is indicated by the pattern of x-ray reflections crossing in the middle From Franklin and Gosling, 1953

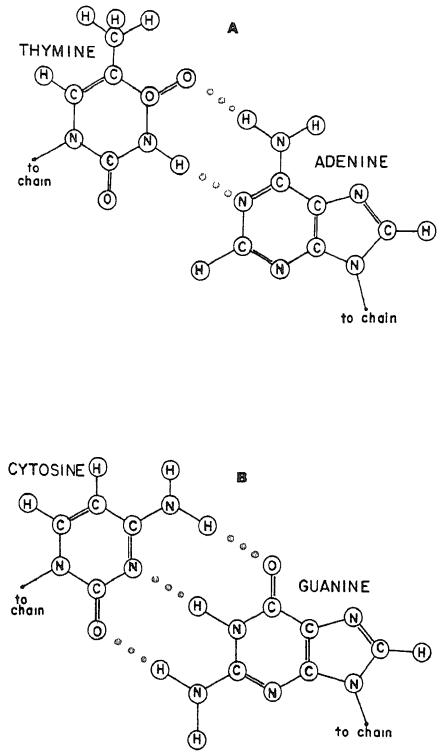

Fig 1 142 Base pairing in DNA through specific hydrogen bonding *a)* Thymine-adenine *b)* Cytosine-guanine

DNA carries the genetic information in the form of the base sequences This coded information is translated through certain mechanisms into amino acid sequences This means that the genetic information for the precise sequence of amino acids incorporated into proteins is stored in DNA in the form of base sequences

The complementary double helical structure of the Watson-Crick model of DNA suggests that the molecule can be accurately self-replicated Indeed it is evident that each strand can serve as a template for the synthesis of the other strand The complementarity of the DNA strands and the specific and accurate base pairing are the key features for the DNA-replication

Size and Shape of DNA Molecules. Intact DNA molecules are extremely large in size In fact native DNA molecules of bacteria are so large that they are easily broken by shear force, during their isolation The bacterial virus T2 contains one DNA molecule of MW = $1\,3 \times 10^8$ The single chromosome of *Escherichia coli* consists of a single DNA duplex MW = 2×10^9 having a contour length of almost 1 mm Eukaryotic cells contain several chromosomes and each chromosome may contain one or more extremely large DNA molecules Although very little is known about the size and shape of the DNA molecules of higher organisms they are believed to be much larger than those of bacteria Although, initially, the experimental evidence suggested that DNA molecules were *linear*, as the techniques of handling DNA

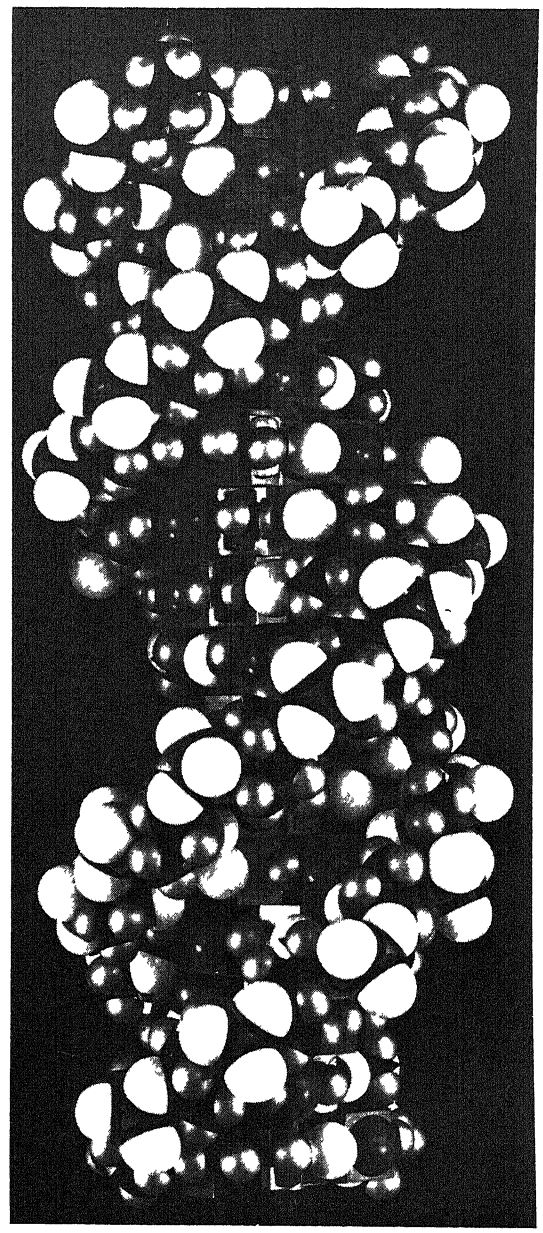

Fig 1 143 Space-filling model of DNA Courtesy of M H F Wilkins

preparations were refined the picture emerged that many DNA molecules are normally present in a *circular form*. DNA from λ phage has been found to be linear when isolated from the virus but circular when inside the host cell. This suggests that the linear and the circular forms are interconvertible. It is possible in this case that the circular form is assumed during replication of the phage DNA, whereas the linear form is necessary for the injection of DNA through the narrow tail of the phage into the host cell. Circular DNAs are found not only in viruses but also in bacteria. Thus the single chromosome of *E. coli* consists of a single circular DNA duplex. Finally, in certain viruses as for example the ϕ 174 the DNA is a circular single strand (Fig. 1.144).

THE GENETIC ORGANIZATION OF DNA

The relative positions of different genes on chromosomes can be determined by genetic experiments. The phenomenon of *genetic recombination* provides the basis for the *chromosome mapping* experiments. Genetic recombination occurs between homologous chromosomes which specifically attract each other and form pairs. Following pair formation, sometimes the chromosomes break at the same point and recombine crosswise (*crossover*). In bacteria crossover and genetic recombination

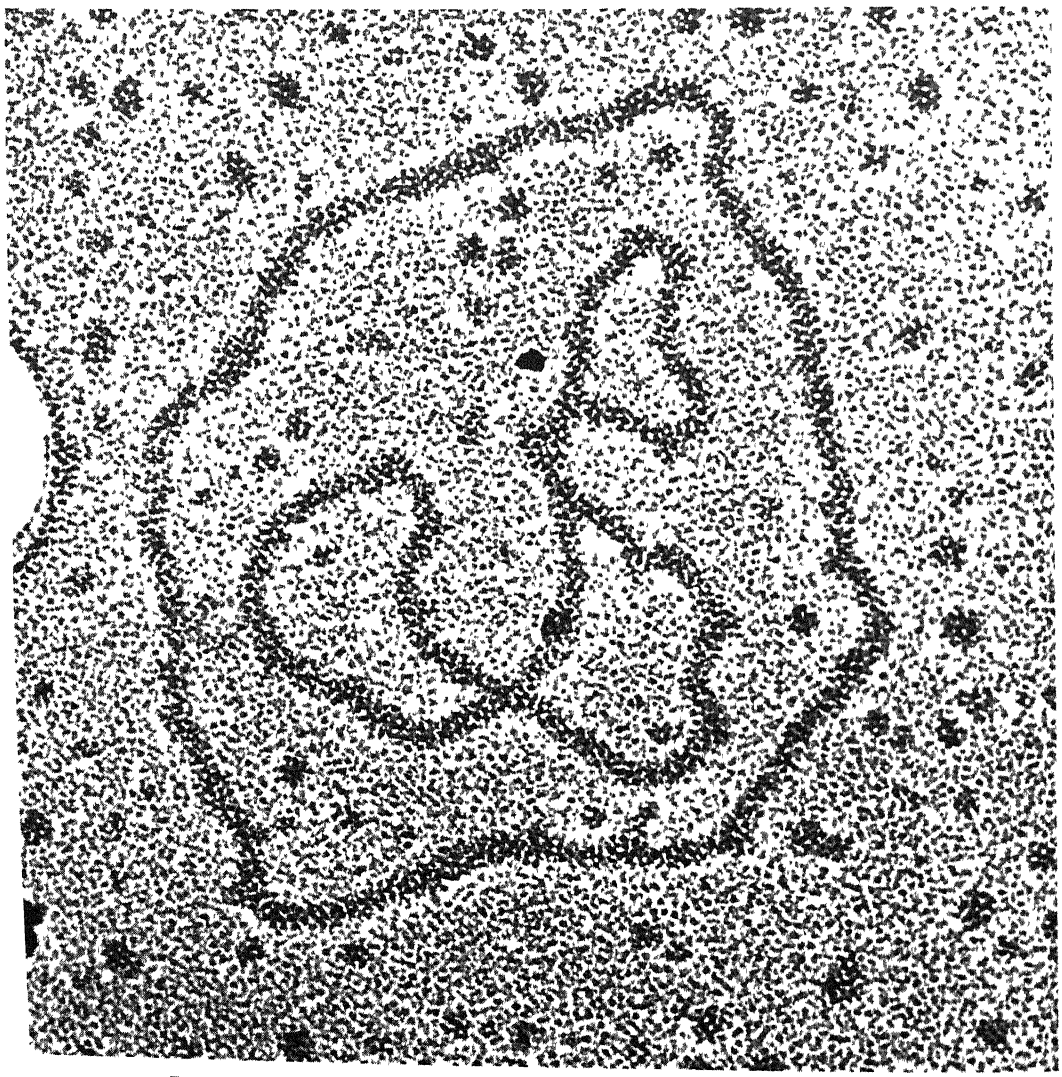

Fig. 1.144 Electron micrograph of DNA from ϕ×174 phage. From Lehninger 1970.

usually involve the intact chromosome of an acceptor cell and a chromosome fragment from a donor cell Transfer of the DNA fragment to the acceptor cell occurs, for example, during bacterial mating (*conjugation*), when a segment of the chromosome of one cell is transferred to the other, transfer also takes place during *transformation* (see Avery's (1944) experiment) The identity of the transferred and recombined genes can be deduced from the induced changes in the acceptor cell Consider for example R-type pneumococcus transformed in vitro into the S-type by means of DNA In this case some of the transferred genes control the formation of the characteristic polysaccharide capsule of the S-type pneumococcus

By employing techniques that permit analyses of these phenomena, various genes have been located on the chromosome, and detailed genetic maps for viruses and bacteria have been deduced These and other studies have provided the proof that one gene controls one protein The early "one gene - one enzyme" hypothesis thus became an established fact Since a protein may consist of more than one polypeptide chain, a more correct statement is "one gene - one polypeptide chain " For example, the protein tryptophan synthetase of *E coli* consists of four polypeptide chains, two of one type, called A, and two of another, called B The A and B polypeptides are coded for by two adjacent genes Usually but not always, genes coding for different polypeptide chains (subunits) of a protein are adjacent on a chromosome

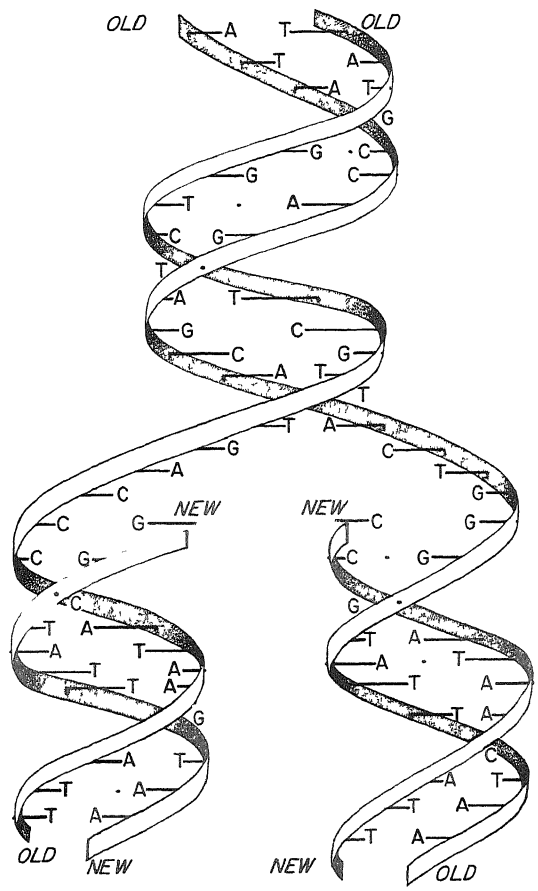

Fig 1 145 Semiconservative replication of DNA according to Watson-Crick (Watson 1970)

DNA REPLICATION

The Semiconservative Model of DNA-Replication Watson and Crick (1953) postulated that DNA can self-replicate and that the key to this process lies in the complementarity of the strands and the accuracy of the specific base pairing According to the proposed mechanism, the strands of the original duplex separate Each strand, as it separates, serves as a template for the synthesis of a new complementary strand The newly synthesized strand, together with the parental strand, forms a daughter DNA molecule (Fig 1 145) This process is called *semiconservative replication* Such a model of DNA replication was supported by the classical Meselson-Stahl (1958) experiment *E coli* bacteria grown in a medium containing the heavy isotope ^{15}N have denser DNA than when they are grown under normal conditions with ^{14}N The "heavy" DNA can be separated from the "light" DNA by equilibrium density gradient centrifugation in CsCl solution In the Messelson-Stahl experiment *E coli* cells grown in ^{15}N-medium were transferred to ^{14}N-medium One generation after the transfer, all the DNA was found to have hybrid density i e , between the densities of the "heavy" and the "light" DNA, after two generations, half of the DNA had hybrid density and half was light (Fig 1 146)

The Moving-Fork Mechanism Use of tritiated thymidine during replication results in tritium labeled DNA This DNA can be visualized by autoradiography (Fig 1 147) Autoradiographs of this kind revealed that the new strands of DNA are synthesized as the parental strands separate In the autoradiograph in Figure 1 147, one can observe the entire rep-

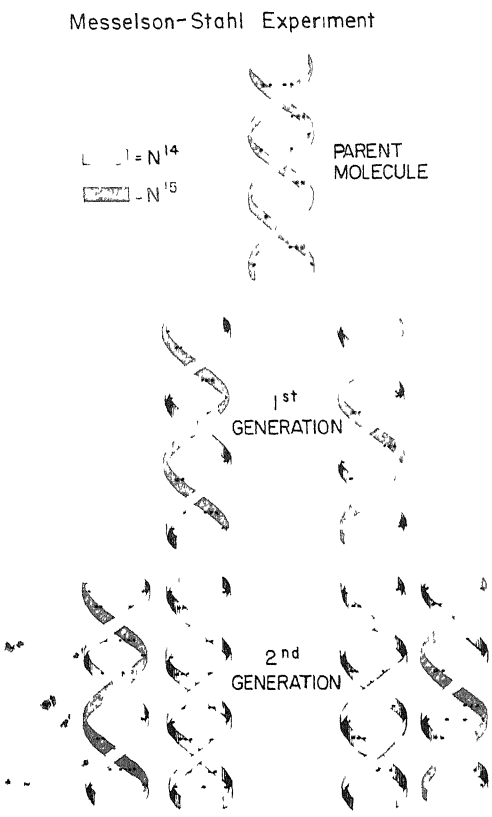

Fig 1 146 Replication of N^{15}-DNA (heavy) in the Messelson Stahl experiment In first generation each daughter molecule contains one heavy strand (N^{15}) and a light one (N^{14}) In second generation two DNA molecules are hybrids and two are light These results present solid evidence in favor of semiconservative replication

licating chromosome of *E coli* Studies of autoradiographs of DNA isolated at various stages during the replication process enabled Cairns (1963) to observe the following *a*) the DNA molecule appears as a continuous double stranded circle, *b*) the replication appears to be sequential from a fixed starting point, *c*) the synthesis of daughter strands is accomplished by a moving-fork mechanism, and *d*) behind the moving fork one can observe the two separated daughter duplexes, which are joined again at the initiation point The fork moves at a rate of 27μ min $^{-1}$ which corresponds to the addition of 10^5 nucleotides to each synthesized strand Studies in bacterial and viral systems on the duplication of certain genes, showed that replication of DNA always initiates at *starting points* uniquely placed relative to known genetic loci Replication proceeds sequentially in a unique direction relative to the starting point The starting points remain invariant over repeated cycles of replication It appears that the complex processes of DNA replication and DNA repair (which also requires synthesis of new material) involve several enzymes such as *DNA polymerase DNA-ligase* and specific *endonucleases* Recent information implicates a *membrane bound enzyme* as the principal enzyme of replication The function and role of all these enzymes in DNA-replication and DNA repair is considered below

DNA Polymerase DNA polymerase (A Kornberg 1969) catalyzes the addition of mononucleotide units to 3′ end of a DNA at a rate of 1000 nucleotides per minute per molecule of enzyme DNA polymerases have now been isolated from a variety of bacterial and animal cells All these enzymes catalyze the following reaction

$$n_1\text{dATP} + n_2\text{dGTP} + n_3\text{dCTP} + n_4\text{dTTP} \xrightleftharpoons{\text{DNA, Mg, Enzyme}} \text{DNA} \begin{bmatrix} (\text{dAMP})_{n_1} \\ (\text{dGMP})_{n_2} \\ (\text{dCMP})_{n_3} \\ (\text{dTMP})_{n_4} \end{bmatrix} + (n_1 + n_2 + n_3 + n_4)\text{PP}$$

$$\downarrow \text{Pyrophosphatase}$$

$$2(n_1 + n_2 + n_3 + n_4)\text{P}_i$$

In the reaction shown above for each phosphodiester bond synthesized, a pyrophosphate bond is broken and a pyrophosphate group is released This reaction has a slightly positive free energy. The reaction is driven to completion because splitting of the high energy bond of pyrophosphate by the pyrophosphatase releases additional energy. The reaction requires preformed DNA whose function is considered below, and takes place only in the presence of all four deoxyribonucleosides 5′-triphosphates The 5′-diphosphates and 5′-monophosphates cannot substitute for the 5′-triphosphates

The *E coli* DNA polymerase consists of about 1000 amino acid residues (MW 109,000) The enzyme appears to be an end-to-end protein, and there is no evidence for protein subunits or prosthetic groups There is evidence that within the active center of the enzyme there are several sites: *1*) a site for the template, *2*) a site for the primer, *3*) a site for the 3′-OH of the growing chain, and *4*) a site for the 5′-triphosphates (Fig 1 148). The synthesis proceeds from the 5′ → 3′ direction. A 5′-tri-

phosphate enters the appropriate site and is oriented so that it can be brought into direct contact and form a base pair with the template (Fig 1 148) When the correct base pair is formed, a nucleophilic attack by the 3′-OH on the innermost phosphate takes place and a

Fig 1 147 Autoradiography of an *E coli* chromosome *A* represents the moving fork Behind the moving fork one can observe the two separated daughter duplexes These duplexes are joined again at the initiation point *B* Reproduced from Cairns 1963

phosphodiester bond is formed At the same time a new 3'-OH replaces the old one and the enzyme moves (relative to DNA) and binds to the new primer terminus Again another 5'-triphosphate enters the triphosphate site and the polymerization step is repeated The reaction will be completed with the addition of the last base A (Fig 1 148) At that point it is evident that there is no template to continue polymerization in the 5' → 3' direction

DNA polymerase can quickly form a complete linear duplex from a DNA molecule as depicted in Figure 1 149*A* On the other hand, an intact linear duplex is inert and does not support replication since there is no template in the direction of 5' → 3' (Fig 1 149*B*) Similarly inert is a circular single or double stranded DNA

The Biological Function of DNA Polymerase Despite the accumulated knowledge on the structure and in vitro action of DNA polymerase, the involvement of this enzyme in the replication of DNA in vivo is still unclear However, DNA polymerase definitely plays a primary role in the DNA repair mechanism Several distinct types of DNA repair processes are known to exist The best known type is the repair of the thymine dimers (Fig 1 150) These dimers are formed by exposure of bacteriae cells to ultraviolet light If unrepaired, this damage is normally lethal It is proposed that repair proceeds with the following steps First, a specific endonuclease introduces a nick close to the damaged area, then an exonuclease excises a small region including the thymine dimer, the excised part is synthesized by DNA polymerase, finally, the last phosphodiester bond is catalyzed by the DNA ligase As one could expect, mutants which lack DNA polymerase are extremely sensitive to ultraviolet radiation Also, xeroderma pigmentosum, a human disease characterized by extreme sensitivity to ultraviolet light, involves defective DNA repair mechanisms This defect seems to be in the first step of the repair mechanism, namely the endonuclease step

Membrane Bound DNA-Replicase. Recent information suggests that the DNA-replicase is a cell membrane-bound enzyme Indeed isolated membrane fractions from bacteria catalyze DNA synthesis This enzymatic activity differs from that of DNA polymerase It is known that the bacterial chromosomes are attached to invaginated areas of the cell membrane, *the mesosomes* Isolated DNA cell membrane complexes from a DNA polymerase deficient mutant can catalyze the continuation of semiconservative replication of bacterial or phage DNA, and the rate of this reaction is comparable to rates of replication observed in vivo

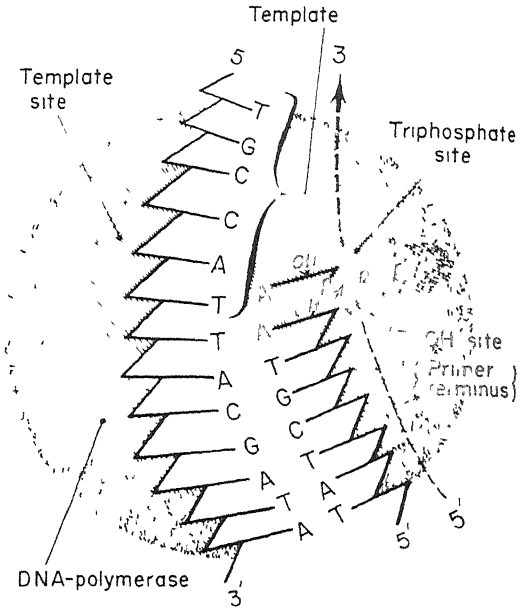

Fig 1 148 Binding sites and the mechanism of action of DNA polymerase A dATP molecule enters the triphosphate site and pairs with *T* This event triggers the nucleophilic attack of the 3' OH of the primer terminus on the innermost pyrophosphate bond of dATP A new phosphodiester bond will form and a new 3' OH primer terminus will appear A movement of the enzyme relative to DNA will bring the triphosphate site opposite to A of the template The polymerization step will be repeated with dTTP Note that the newly synthesized strand is antiparallel with the template strand Redrawn from Kornberg 1969

DNA Ligase. This enzyme can join the 3'-end with the 5'-end of two DNAs with the formation of a phosphodiester bond This enzyme can also join the two ends of a single stranded DNA to form a DNA circle The role of this enzyme in DNA replication is still uncertain However, the enzyme seems to participate in DNA repair processes as well as in the phenomenon of recombination of genes during crossing over

Replication of Single Stranded DNA Molecules. The replication of single stranded DNA molecules proceeds via the formation of a DNA duplex Phage $\phi \times 174$ for example possesses a single stranded circular DNA chro-

mosome, called the "+" *strand* Immediately after the "+" strand enters the host cell, it serves as a template for the synthesis of the complimentary "−" *strand* This synthesis is carried out by the enzymes of the host cell The phage DNA is now double stranded "+ − " The "+ −" duplex is called the *replicative form* The "−" strand of the "+ −" duplex serves as a template for the synthesis of "+" strands This phase of the life cycle of phage is carried out by a specific enzyme coded for by a phage gene The exclusive selection of the "−" strand as a template probably occurs because that strand contains specific base sequences which act as a signal and are recognized by the enzyme It is notable that recently Goulian, et al (1967) achieved the remarkable feat of enzymatically synthesizing a biologically active $\phi \times 174$ in a test tube

CONTROL OF DNA REPLICATION

DNA replication is an extremely complex process which requires and is under the control of a number of genes Thus, about 20 genes are involved for the replication of the relatively simple T4-phage Initiation of replication is dependent on protein biosynthesis It appears that certain protein(s) called initiation protein(s) act on a unique starting signal on DNA to begin a round of replication Thus, DNA itself, through specific genes, controls its own rate of replication

Structure, Synthesis, and Function of RNA

A given DNA molecule contains several genes According to accumulated genetic evidence, one gene codes for amino acid sequences of one polypeptide, and, therefore, we must assume that only one of the two DNA strands of the gene carries the genetic information Although DNA carries the genetic information, DNA itself is not the template on which proteins are synthesized Instead, DNA serves as a template for the synthesis of RNA by the enzyme, RNA *polymerase* This process is called *transcription* Only one strand of a gene is transcribed, that which carries the genetic information The RNA strand that is thus synthesized then serves as template for the synthesis of the protein (*translation*) The above statements can be summarized as follows

$$\text{DNA} \xrightarrow{\text{Transcription}} \text{RNA} \xrightarrow{\text{Translation}} \text{Proteins}$$

RNA STRUCTURE

The building blocks of RNA are the mononucleotides adenosine monophosphate (AMP), guanine monophosphate (GMP), cytosine

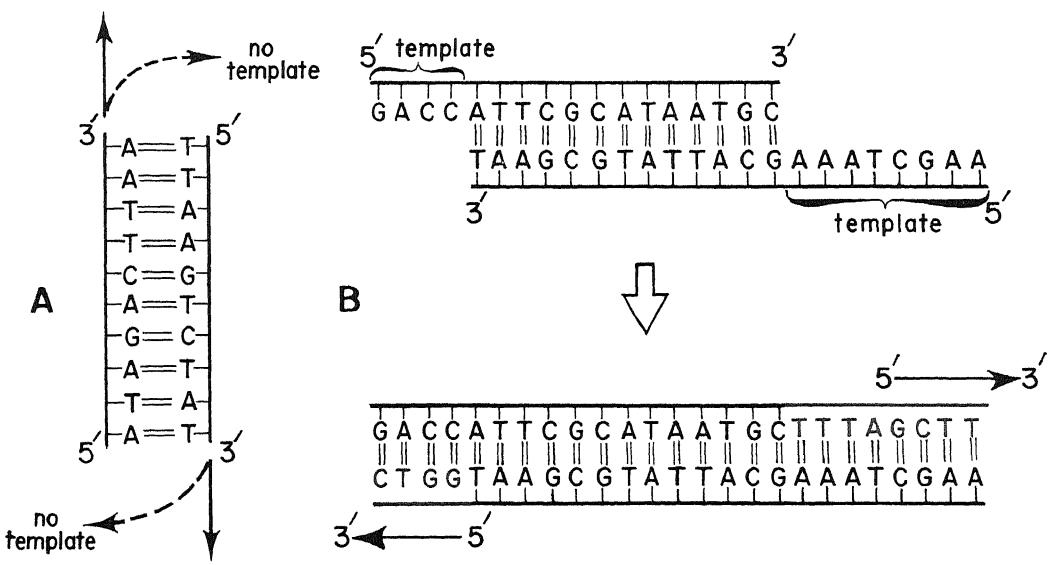

Fig 1 149 A complete linear duplex *A* is inert for replication by DNA polymerase because there is no template from which the enzyme can get instructions In contrast DNA molecules of the type depicted in *B* are excellent primer-templates for the polymerase

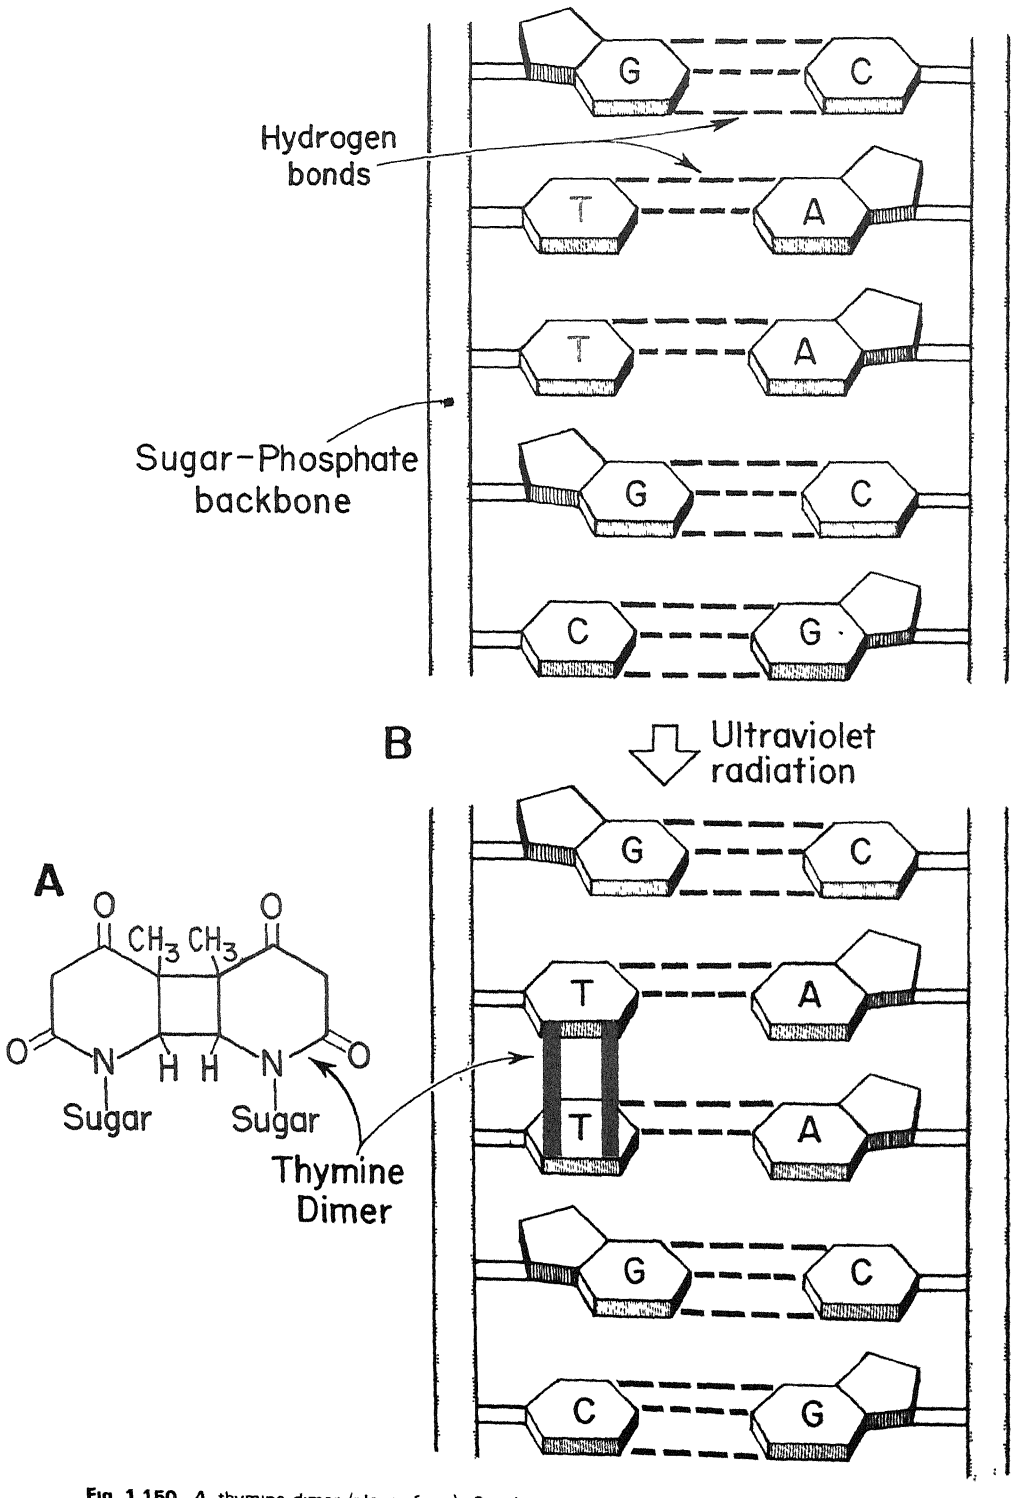

Fig 1 150 *A* thymine dimer (planar form) *B* schematic representation of thymine dimer formation

monophosphate (CMP), and uridine monophosphate (UMP) Note that in RNA uridine is found instead of thymine The fundamental units, the mononucleotides, are linked to one another with 3′,5′-phosphodiester bonds Thus in RNA as in DNA the covalent backbone is made of alternating ribose and phosphate groups To this backbone the purine and pyrimidine bases are attached as side-chains (Fig 1 151) RNA is usually single stranded In some cases RNA occurs in a form of two complementary strands which form a double helix In a duplex RNA the number of adenine residues is equal to the number of uridine residues, or A = U Similarly G = C and, therefore, A + G = C + U This composition can be explained if one assumes a Watson-Crick model for RNA in which the bases of one RNA strand are paired by hydrogen bonds to the bases of the other strand As in the case of DNA, only certain base pairs can be accommodated within the RNA duplex, these are A – U and G – C

RNA BIOSYNTHESIS

The biosynthesis of RNA is effected by the enzyme RNA *polymerase* For this synthesis,

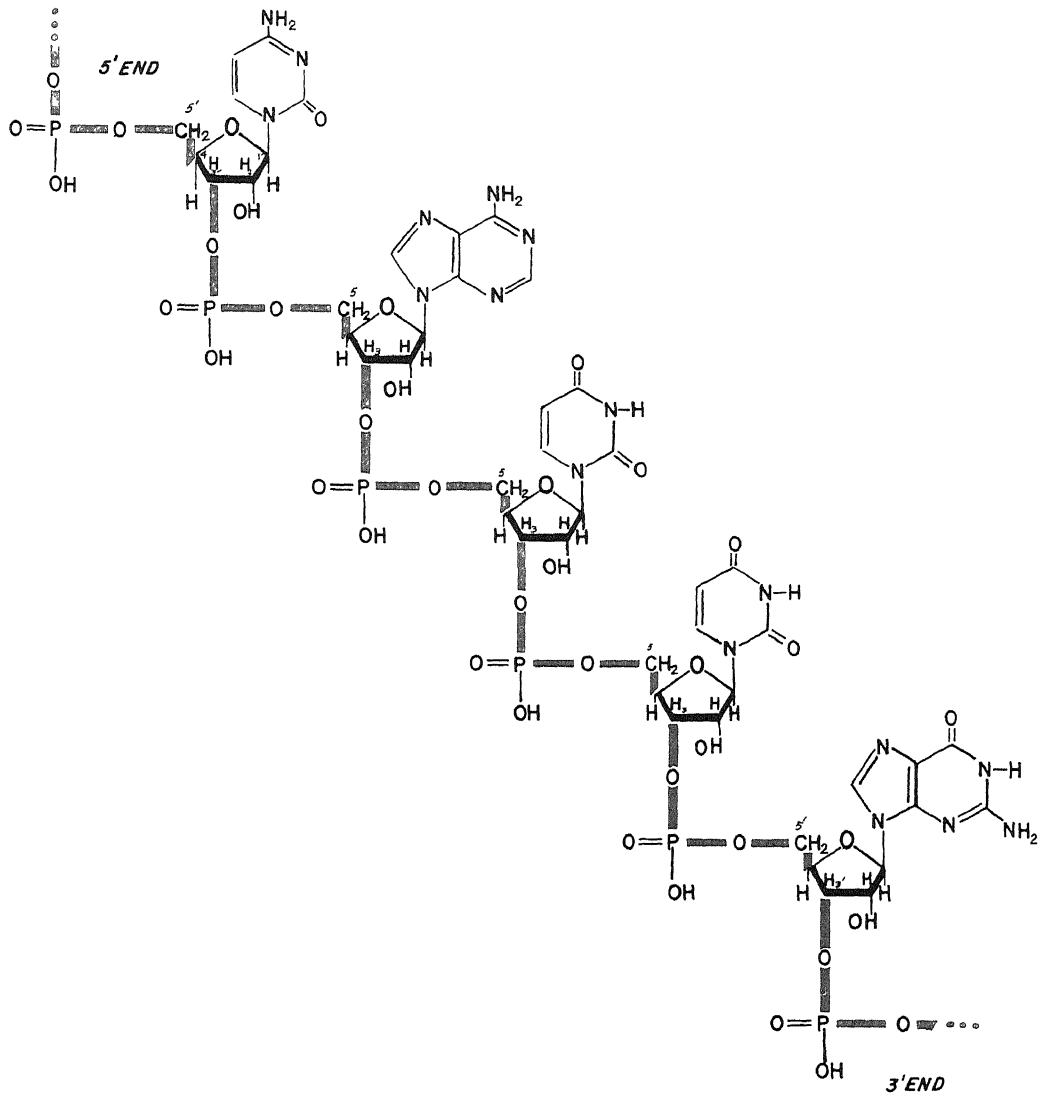

Fig 1 151 Structure of a portion of an RNA chain with hypothetical base sequence 5′ to 3′ cytosine-adenine uridine-uridine-guanine

the enzyme takes instructions from a DNA template The reaction catalyzed is the following

$$\begin{matrix} n_1ATP \\ n_2GTP \\ n_3CTP \\ n_4UTP \end{matrix} \xrightleftharpoons{\text{DNA } Mg^{++} \text{ Enzyme}} \begin{bmatrix} (n_1AMP) \\ (n_2GMP) \\ (n_3CMP) \\ (n_4UMP) \end{bmatrix} + (n_1 + n_2 + n_3 + n_4)PP$$

$$\downarrow \text{Pyrophosphatase}$$

$$2(n_1 + n_2 + n_3 + n_4)P_i$$

For each phosphodiester bond synthesized, a pyrophosphate bond is broken and a pyrophosphate group is released This reaction also has a slightly positive free energy The splitting of the high energy bond of pyrophosphate by the pyrophosphatase releases additional energy and ensures that the reaction is driven toward the direction of RNA synthesis The reaction requires all four ribonucleoside-5-triphosphates, as well as DNA to function as a template The 5'-diphosphates and 5'-monophosphates of ribonucleosides cannot substitute for the ribonucleoside 5'-triphosphates

Bacterial RNA polymerase is composed of protein subunits Five major subunits have been identified and designated as β', β, α, ω, and σ These subunits aggregate specifically with secondary bonds to form the complete enzyme or *holoenzyme* $\beta'\beta\alpha_2\omega\sigma$ (MW 470,000) Removal of σ (*sigma factor*) from the holoenzyme by column chromatography on phosphocellulose leads to the isolation of the $\beta'\beta\alpha_2\omega$ aggregate or *core enzyme* The core enzyme catalyzes the formation of the internucleotide phosphodiester bonds equally well as the holoenzyme Recent evidence suggests that the in vitro synthesis of RNA by the RNA polymerase, proceeds with the following steps *1) template binding, 2) chain initiation, 3) chain elongation,* and *4) chain termination* As noted above, only one strand of the DNA-duplex is transcribed in vivo, the strand that carries the genetic information Recent studies in vitro show that the holoenzyme also selects and transcribes only one strand In contrast, the core enzyme shows no strand selectivity with a variety of DNA templates Strand selection and binding of RNA polymerase to DNA template are effected through *start signals* (specific base sequences along the DNA molecule), such signals are recognized by the sigma factor

Once the RNA polymerase is bound to DNA template initiation of RNA synthesis appears to involve the binding of two 5' triphosphonucleotides to the enzyme This is followed by formation of a phosphodiester bond and elimination of pyrophosphate according to the reaction

$$ppp'A' + ppp'G' \rightarrow ppp\ ApG'$$

RNA chains start either with pppA or pppG when phage DNAs are used as templates Elongation of the initiated chain proceeds toward the direction 5' → 3' A nucleotide 5'-triphosphate enters the appropriate enzyme site and is oriented so that it can be brought into direct contact and form a base pair with the template (Fig 1 152) When the correct base pair is formed, a nucleophilic attack by the 3'-hydroxyl end of the RNA chain to the innermost phosphate takes place and a phosphodiester bond is formed Thus the polymerization reaction proceeds by the addition of 5'-triphosphates to the 3' hydroxyl end of the growing RNA chain The enzyme adds 40 to 100 nucleotide units per sec The pairing rules are ADNA pairs with URNA, TDNA pairs with ARNA, GDNA pairs with CRNA, and CDNA pairs with GRNA At some point of the elongation process in vitro the σ factor is released from the polymerase and the remaining core enzyme continues the polymerization This observation led to the proposal of the "*sigma cycle*" According to this postulate, the released σ factor combines with another core enzyme and initiates another round of transcription Thus, the σ factor may be critical in the regulation of the transcription process although, it is not known at the present time if the release of sigma factor also occurs in vivo (See section on regulation of gene activity below)

Once the strand selection is made, RNA polymerase moves quickly along the DNA molecule, separating the two strands over a short local region and utilizing one strand as a template The RNA as it is synthesized forms a transient hybrid duplex with its DNA template As the transcription of a region of the template is finishing, and the enzyme moves out of this region, the separated DNA strands come back together and form the original duplex with concomitant expulsion of the RNA from the hybrid duplex The expulsion of the RNA strand by the DNA strand occurs because

DNA-DNA duplexes are energetically more stable than DNA-RNA duplexes

Specific sequences of DNA (*stop signals*) induce the termination of the polymerization process Another termination mechanism involves the protein *factor ρ* The mechanism by which factor ρ triggers termination of RNA synthesis is not yet known

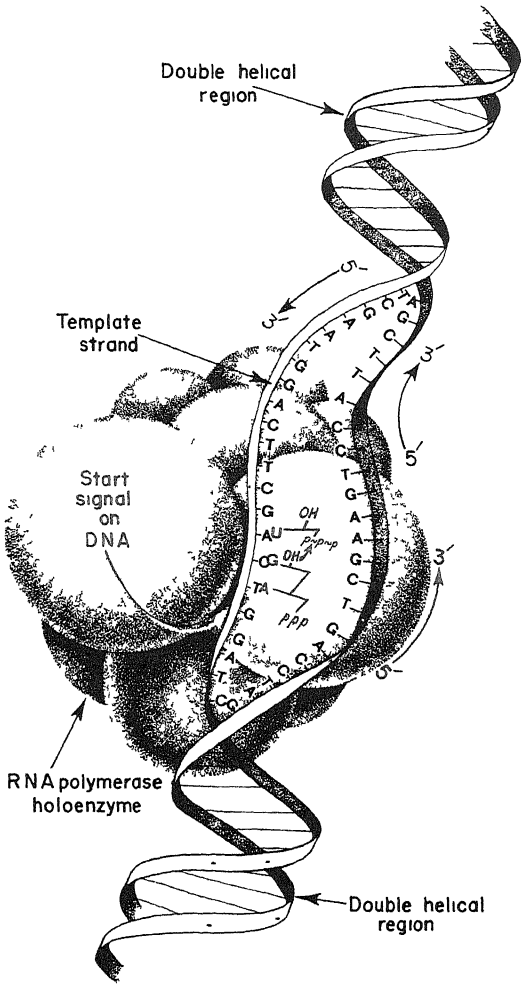

Fig 1 152 Schematic representation of DNA transcription by RNA polymerase The sigma factor of polymerase recognizes the start signal on DNA and the enzyme binds to template Binding at the start signal leads to opening of DNA strands over a short local region This is followed by binding on the enzyme of ATP and GTP and formation of the first phosphodiester bond (initiation) This yields the dinucleotide pppApG Initiation is followed by elongation A UTP molecule enters the appropriate site and pairs with *A* This event triggers the attack of 3′-OH on the innermost pyrophosphate bond of UTP A new phosphodiester bond will form and a new 3′-OH primer terminus will appear A movement of the enzyme relative to DNA will bring the triphosphate site opposite to *C* of the template The polymerization steps will be repeated again and again until a stop signal on DNA or a ρ-factor will induce the termination of the transcription process

Recent studies on RNA polymerases from eucaryotic cells reveal a variety of molecular forms of the enzyme These forms have been designated as RNA polymerase I, II, III, and IV RNA polymerase I is found in the nucleolus, II and III in the nucleoplasm, and IV in the mitochondria RNA polymerase I has a molecular weight in the range of 500,000 to 700,000, and this suggests that the enzyme most probably consists of subunits Similarly, RNA polymerase II (MW about 700,000) consists of several subunits Studies on the protein subunits of eucaryotic polymerases will probably reveal the existence of factors analogous to bacterial sigma factor through which template strand selection is effected

Inhibition of RNA Biosynthesis.

Actinomycin D, a peptide antibiotic, selectively inhibits DNA dependent RNA synthesis This inhibition is exerted in intact animals and cell cultures, as well as with purified enzyme systems, in vitro The observed inhibition is due to the binding of the antibiotic to DNA through hydrogen bonds This binding, because of stereochemical reasons, takes place between the phenoxazine ring of actinomycin and guanine residues in the minor groove of DNA As a result, the peptide chains of the antibiotic fill the minor groove of DNA and sterically prohibit the RNA polymerase from transcribing DNA

Rifamycin is another antibiotic which inhibits RNA biosynthesis Rifamycin binds specifically to the β-subunit of RNA polymerase and produces a block in RNA chain initiation The antibiotic *streptolydigin* inhibits RNA synthesis by blocking the chain elongation process Finally, the toxin α-amanitin reacts specifically with eucaryotic RNA polymerase II and blocks RNA synthesis

RNA Replicases (RNA-dependent RNA polymerases) RNA replicases are the enzymes of replication of the RNA viruses The enzymes are coded by viral genes and catalyze the formation of RNA strands from the ribonucleoside-5′-triphosphates on RNA templates, thus they are referred to as the name RNA dependent-RNA polymerases

The replicases are usually formed immedi-

ately after the infection of a cell by an RNA virus. A replicase is highly specific for the RNA virus by which it is coded. Only this viral RNA serves as a template for the enzyme, the specificity is due to specific nucleotide sequences of the RNA which are recognized by the enzyme.

Recent studies have uncovered yet another enzyme, the *RNA-dependent* DNA polymerase or reverse transcriptase. This enzyme catalyzes the synthesis of DNA on RNA templates. The precise role of this enzyme is not yet known.

THE VARIOUS RNA CLASSES AND THEIR FUNCTION

Messenger RNA (mRNA) In 1961 Jacob and Monod introduced the messenger RNA hypothesis. They proposed that genetic messages of DNA are transcribed faithfully into messenger RNA whose function is to carry the information to the site of protein synthesis and serve as a direct template for that synthesis. Since then the existence of mRNA has been verified experimentally. The mRNAs are, therefore, the transcription products of genes. An mRNA can contain the complete message of one gene coding for one polypeptide chain or of several genes coding for several polypeptide chains. In the latter case, the mRNA is called *polygenic* or *polycistronic*. The mRNAs represent an heterogeneous population of RNA molecules of different chain length. This heterogeneity is expected since the various mRNAs are the templates of different proteins. To separate and identify a specific messenger RNA is an extremely difficult task because of the heterogeneity of mRNAs and because mRNAs constitute less than 1% of the total cellular RNA. However, certain messengers such as the mRNAs coding for chains of hemoglobin and various viral mRNAs have been successfully isolated.

Ribosomes and Ribosomal RNA. Cell fractionation of liver tissue obtained from rats injected with radioactive amino acids enabled Zamechnik (1960) to identify the intracellular site of protein synthesis. It was found that protein synthesis is associated with the cellular fraction of *microsomes* (Fig. 1-153). Moreover, incubation of microsomes in vitro, in the presence of the cytoplasmic *soluble fraction* (cytosol), ATP, GTP, and labeled amino acids, results in amino acid incorporation into proteins. This in vitro system constitutes a *cell free system* for protein synthesis. Treatment of microsomes with sodium deoxycholate yields ribonucleoprotein particles, the *ribosomes*, which can be isolated by centrifugation. Most of the ribosomes in the eucaryotic cell are attached to the endoplasmic reticulum, although some are free in the cytoplasm (Fig. 1-154). Ribosomal preparations can substitute for microsomes in the cell free system of protein synthesis. Actually, ribosomes by themselves cannot support protein synthesis, indeed the active units of protein synthesis in ribosomal preparations are aggregates of ribosomes called *polysomes*. Polysomes are formed from the specific association of a mRNA molecule with ribosomes.

A ribosome consists of two subunits, one is large and one small. Bacterial ribosomes have a sedimentation value of 70S (Svedberg units) and their subunits have values of 50S and 30S. Eukaryotic ribosomes have a sedimentation constant of 80S and their subunits have values of 60S and 40S. Ribosomes, suspended in buffers containing less than 10^{-4} M Mg^{++}, dissociate into their subunits, raising the Mg^{++} concentration to 5×10^{-4} M causes the subunits to associate again into functional ribosomes. Dissociation and association of ribosomes and their subunits also occurs in vivo in association with the process of protein synthesis, and involves special factors (see chap. 5). The

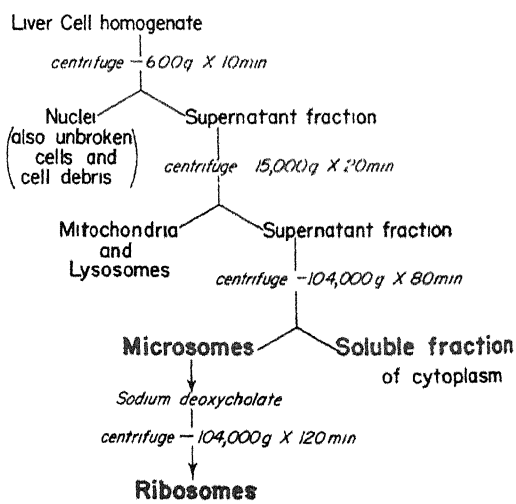

Fig. 1-153 Fractionation of liver cells by differential centrifugation. Cells are homogenized in isotonic sucrose buffers pH 7.4 containing Na^+, K^+, and Mg^{++}. For the isolation of "active" microsomes or ribosomes all operations must be performed at 0.2°.

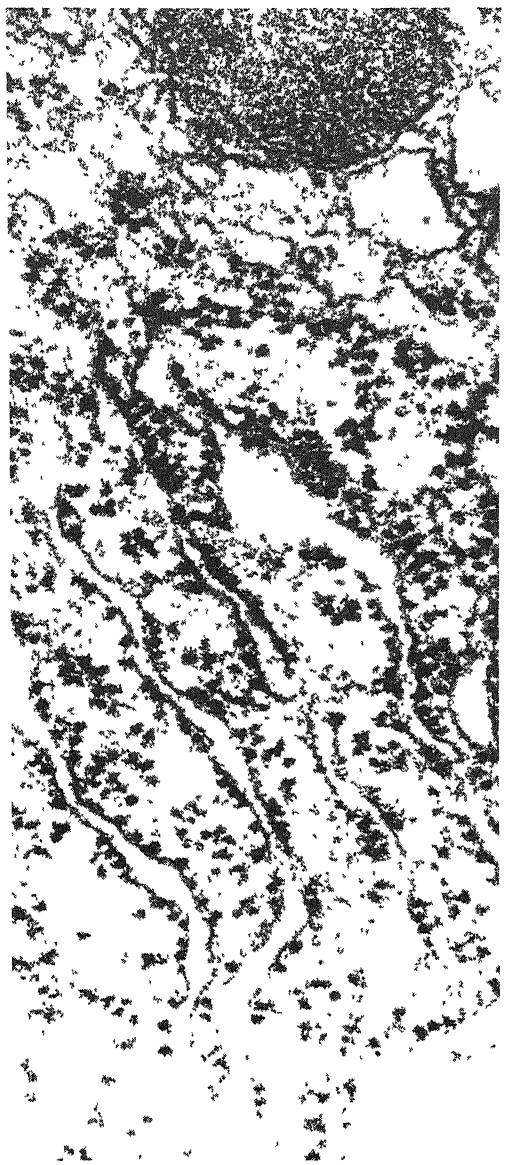

Fig 1 154 Electron micrograph of a section of rat liver cell Most of the ribosomes are attached to the endoplasmic reticulum and some are free in the cytoplasm

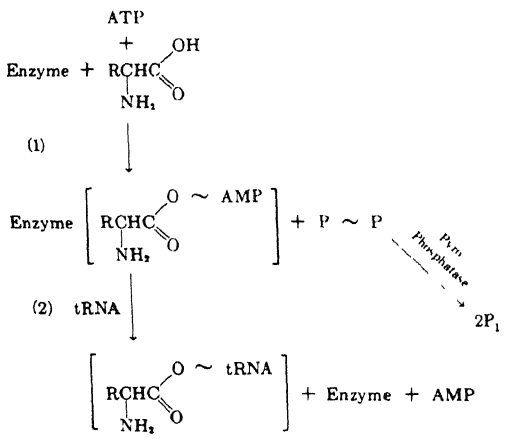
ribosomal subunits are composed of ribosomal RNA (rRNA) and proteins The 50S subunit consists of one molecule of 23S rRNA (MW 1,200,000), one molecule of 5S rRNA and about 35 different proteins The 30S subunit, consists of one molecule of 16S rRNA (MW 600,000) and 20 different proteins Under certain conditions, mixing of the separated proteins from the 30S subunit together with 16S rRNA leads to reconstitution of biologically active 30S subunits (Nomura, 1973) This demonstrates that the complex 30S subunit structure (and most probably the ribosome itself) represents a self assembling system, in which the various components bind to one another in some specific manner and assume the proper conformation The rRNAs from subunits of eukaryotic ribosomes have sedimentation values of 28S, 18S, and 5S

The ribosomal RNAs are synthesized on DNA templates A *ribosomal gene* codes both the 23S (28S) and 16S (18S) rRNAs In a given cell there are several copies of the ribosomal genes In fact the number of ribosomal genes increases from bacteria to insects, to mammals, to amphibians, this increase roughly parallels the observed increase of DNA per cell from species to species For example, mycoplasma possesses a single ribosomal gene, and bacteria have from 5 to 10 In eukaryotic cells the number increases tremendously reaching tens of thousands in some amphibians which possess the highest amount of DNA per cell The ribosomal genes of eukaryotes are serially repeated and clustered in one locus in the nucleolar DNA Hybridization experiments show extensive cross reaction of bacterial ribosomal RNA with DNAs from eukaryotic cells This constitutes evidence that ribosomal genes were conserved to a large extent over the course of evolution

The large number of ribosomal genes is most probably necessary to provide sufficient template to satisfy the demand for ribosomes In eukaryotic cells, ribosomal genes are transcribed to give a *precursor RNA* (45S) which undergoes specific cleavages to yield both the 28S and the 18S rRNA



Transfer RNA (tRNA) and the Activation of Amino Acids There are many tRNAs in a cell These tRNAs bind covalently with the various amino acids, and then participate in the process of protein synthesis A given tRNA is specific for a given amino acid The tRNAs have a MW of about 25,000 Each tRNA is composed of a single chain of approximately 80 nucleotides, covalently linked, with many hydrogen bonded base pairs This base pairing causes the chain to form several loops

Elucidation of the primary structure of yeast alanine tRNA was achieved in 1965 by Holley and his colleagues Since then other tRNAs from various species have also been sequenced When tRNA sequences are written in a way

that produces the highest number of base pairs, a 'cloverleaf" form appears (Fig 1 155) This cloverlead form consists of four 'loops", one of which contains the *anticodon* site (see below "Genetic Code") All tRNAs terminate at the 3'-end with the —CCA sequence This is the site of amino acid attachment

The tRNAs contain in their structure many unusual bases, the precise role of which is not yet known The three-dimensional structure of tRNA has not yet elucidated However, now that tRNAs have been obtained in crystalline form, the elucidation of their 3-D conformation through x-ray crystallography appears feasible The various tRNAs are coded by specific genes and, therefore, are synthesized on DNA templates

Since the naturally occurring amino acids in proteins are 20, there must be at least 20 kinds of tRNA molecules Actually there are more than 20 (see section on degeneracy of the genetic code) A transfer RNA binds the appropriate amino acid with a single covalent bond This reaction is catalyzed by specific amino acyl synthetases as follows

The reaction proceeds in two steps In the first step ATP and the amino acid react on the catalytic site of the enzyme to give the enzyme bound intermediate amino acid ~ AMP During this reaction a high energy pyrophosphate bond is broken and a high energy anhydride

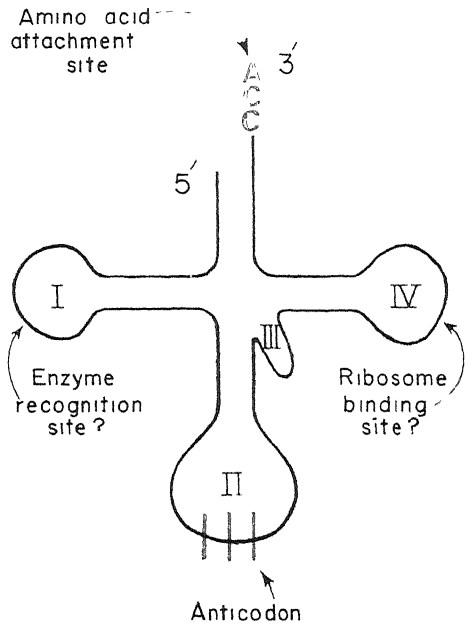


Fig 1 155 Standard orientation of a tRNA in the cloverleaf form

linkage is formed In the second step the amino acyl group is transferred from AMP to the 3'-OH end of tRNA The ester linkage between the amino acid and tRNA is a high energy bond The splitting of the high energy bond of pyrophosphate by the pyrophosphatase releases additional energy This event ensures that the amino acid activation reaction is driven to completion The presence of Mg^{++} in the reaction is an absolute requirement Each amino acid is activated by a specific amino acyl synthetase Almost all the synthetases have been isolated and all possess one or more —SH group which is essential for catalytic activity All synthetases have a molecular weight of about 100,000 with the exception of phenylalanine amino acyl synthetase which has about 180,000

The synthetases must possess at least three binding sites, *a*) specific site for the amino acid, *b*) specific site for tRNA, and *c*) site for ATP Obviously, each tRNA must also possess an *enzyme recognition site* This site has not yet been identified and located in the cloverleaf form of sequenced tRNAs, although it is suspected to be in the area of loop I (Fig 1 155) The very high specificity of the enzyme for a particular amino acid and its appropriate tRNA makes it very unlikely in vivo ($p <$

0 0001) that a tRNA could be charged with the "wrong" amino acid

The Genetic Code

In as much as the genetic information for ordering amino acids in polypeptide chains, is stored in DNA in the form of base sequences, a relationship between bases and amino acids must exist Since there are only four bases and twenty amino acids, a one-to-one or even two-to-one correspondence between bases and amino acids is not possible A three-to-one correspondence on the other hand yields 64 base triplets to code for 20 amino acids This constitutes a *triplet code* in which the three consecutive bases coding for one amino acid constitute a *codon* Crick and his colleagues obtained evidence for such a triplet code from genetic experiments Pioneering work by Nirenberg and his colleagues resulted in the complete elucidation of the code This feat was achieved experimentally by the use of artificial mRNAs, which permitted the complete assignment of codons to the various amino acids

ENZYMATIC SYNTHESIS OF POLYNUCLEOTIDES (ARTIFICIAL MESSENGERS)

Synthetic polynucleotides can be obtained enzymatically with the use of the enzyme *polynucleotide phosphorylase* This enzyme, found in bacteria, catalyzes the following reaction

$$\begin{matrix} n_1\text{ADP} \\ n_2\text{GDP} \\ n_3\text{CDP} \\ n_4\text{UDP} \end{matrix} \xrightarrow[\text{Mg}^{++}\ \text{Enzyme}]{\text{RNA primer}} \text{RNA}-\begin{bmatrix} (\text{AMP})_{n_1} \\ (\text{GMP})_{n_2} \\ (\text{CMP})_{n_3} \\ (\text{UMP})_{n_4} \end{bmatrix} + (n_1 + n_2 + n_3 + n_4)\text{P}_i$$

The reaction requires the 5′-diphosphates of ribonucleosides, the enzyme cannot utilize the 5′-diphosphates of deoxynucleosides In the reaction, a primer RNA strand furnishes the 3′-hydroxyl end of which the enzyme adds additional residues However, because the enzyme does not utilize a template, the residues added do not follow a specific sequence pattern Using only uridine 5′-diphosphate in the reaction, one obtains a polyuridylic acid product (*poly U*) By analogous means, one can prepare *poly A*, *poly C*, and *poly G* By using two of the diphosphonucleotides, for example 5′-UDP and 5′-GDP, one can prepare mixed copolymers *poly U, G* The base composition of the copolymers reflects the ratio of the original concentrations of the UDP and GDP precursors Thus, if the original ratio was 5 1 UDP to GDP then the poly U, G copolymers contain five times more U residues than G

ASSIGNMENT OF CODONS

In 1961, Nirenberg and Matthaei discovered that incubation of poly U together with ribosomes and the other factors of the cell free system for protein synthesis promotes the incorporation of phenylalanine into protein Phenylalanine was the only amino acid incorporated out of 19 tested Further investigation revealed that the product formed was polyphenylalanine Thus, it became apparent that poly U codes for phenylalanine and the codon UUU was tentatively assigned to this amino acid From subsequent experiments with poly A and poly C, the codon AAA was assigned to lysine and the codon CCC to proline This line of experimentation was pursued with mixed copolymers such as poly U, G Poly U, G contains the following eight codons UUU, UUG, UGU, GUU, UGG, GUG, GGU, and GGG The relative frequencies of occurrence of these codons can be calculated because it depends on the U G ratio Thus, in a poly U, G (5 1) the relative frequencies of occurrence are UUU = 100, (UUG, UGU, GUU) = 20, (UGG, GUG, GGU) = 4, and GGG = 0 8 Poly U, G (5 1) as expected promotes the incorporation of several amino acids in a cell free system The amino acids and their relative amount of incorporation were found to be phenylalanine = 100, valine = 20, cysteine = 20, leucine = 20, glycine = 4, and tryptophan = 4 It appears then that the codon for phenylalanine is UUU, the codon for valine, cysteine, and leucine is U_2G and the codon for glycine and tryptophan is UG_2

Such experiments with mixed copolymers permitted the determination of composition of the codon of several amino acids but did not allow the deduction of the sequences of the different nucleotides within the assigned codons Thus, there is not way to tell whether the codon for valine which has a composition of U_2G is UUG, UGU, or GUU Determination of the nucleotide sequences of codons was

achieved with the aid of the binding assay of Nirenberg and Leder (see Nirenberg, 1968) The assay rests on the specific binding of an amino acyl-tRNA on the mRNA-ribosome complex Thus poly U mixed with ribosomes binds only phenylalanyl-tRNA More important was the finding that instead of poly U, one can use the trinucleotide UpUpUp and still observe specific binding The use of the assay with trinucleotides of known sequences resulted in the determination of the nucleotide order in the codons Thus, it was found that the trinucleotide GpUpUp promotes valyl-tRNA binding, establishing that the codon for valine with the base composition U_2G is actually GUU

Development of techniques for the synthesis of polyribonucleotides of known sequences provided another tool for the study of the coding problem (Khorana, 1968) For example, the use of the synthetic messenger CpUpC p UpCpU p CpUpC containing the alternating codons CUC and UCU was found to code for a polypeptide in which serine and leucine residues alternate Thus, with the use of homopolymers, mixed copolymers, copolymers of known sequences, and trinucleotides the genetic code was totally deciphered (Table 1 13)

The genetic code is degenerate, i e , there is more than one codon assigned to one amino acid Thus, UUU and UUC are both assigned to phenylalanine and the codons GUU GUC, GUA, and GUG are assigned to valine Degeneracy in the case of the phenylalanine and valine codons involves the third base This type of degeneracy is the most frequent Some amino acids have codons with identical bases in the first two positions In all these cases, the third position is filled *only* by purines or *only* by pyrimidines For example, asparagine is coded for by AAU and AAC, and lysine by AAA and AAG Note that in the case of asparagine the third position is filled only by the pyrimidines, U or C, whereas in the case of lysine the third position is filled only by the purines, A or G

Sixty-one out of 64 codons have been assigned to the twenty amino acids while the remaining three UAA (ochre), UAG (amber), and UGA (umber) do not correspond to any amino acid (*nonsense codons*) The nonsense codons are signals for polypeptide chain

Table 1 13
Codon assignments for amino acids

	U	C	A	G

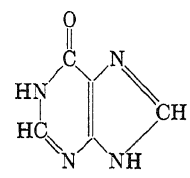
termination From all evidence to date, it appears that the genetic code is *universal* for all organisms

RECOGNITION OF THE CODONS THE ANTICODON

It is now well established that the insertion of amino acids into the growing polypeptide chain is mediated through tRNA molecules Furthermore, codon recognition is not effected by the amino acid, but it rests with the tRNA This was proved elegantly with the following experiment Cysteine was charged enzymatically to the appropriate tRNA

$$\text{Cysteine} + \text{ATP} + \text{tRNA}_{\text{cyst}} \xrightleftharpoons[\text{Amino acyl Synthetase Mg}^{++}]{} \text{Cysteinyl} - \text{tRNA}_{\text{cyst}} + \text{AMP} + \text{PP}$$



The cysteinyl – $tRNA_{cyst}$ was then transformed by reduction, to alanyl – $tRNA_{cyst}$ Thus, an activated alanine was produced in attachment to the tRNA for cysteine Cell free systems from reticulocytes incorporate amino acids into the hemoglobin chains Use of alanyl -$tRNA_{cyst}$ in such a system afforded the isolation of hemoglobin chains having alanine in the positions regularly occupied by cysteine The implication of this experiment is that the specificity of codon recognition of the amino acyl tRNA is in the tRNA, and if a tRNA molecule is charged with the "wrong" amino acid, this will produce translational "errors " Essentially, these kinds of error do not occur in vivo because there is a high degree of specificity of the amino acid activation reaction

Recognition of the codons is effected by the anticodons on the tRNA molecules, these anticodons are composed of three nucleotides The recognition was originally thought to be through regular Watson-Crick base pairs formed by the interaction of a codon with its anticodon This concept, which requires a specific anticodon for each of the sixty-one codons and, therefore, a specific tRNA for each codon, was not substantiated experimentally for it was found that a tRNA could recognize more than one codon To explain these observations, the "wobble hypothesis" has been introduced According to this hypothesis, the codon-anticodon interaction involves hydrogen bond formation due to base pairing Starting from the 3'- of the anticodon, the first two nucleotides form regular Watson-Crick type base pairs with the two nucleotides of the codon starting from the 5'- The third nucleotide at the 5'- end of the anticodon has more freedom of movement and thus pairing is not necessarily confined to the known pairing rules (Table 1 14) Thus, the two codons of tyrosine, UAU and UAC, are both recognized by one tRNA bearing the anticodon $^{3'}AUG^{5'}$ The "wobble" at the third position permits G of the anticodon to pair with either C or U (Fig 1 156)

Table 1 14
Pairing rules at the wobble position (Crick 1966)

Nucleotide at the "Wobble" Position of the Anticodon (5'-end)	Nucleotide at the Third Position of the Codon (3'-end)
Adenine	Uracil
Guanine	Uracil or Cytosine
Uracil	Adenine or Guanine
Cytosine	Guanine
Inosine	Adenine, Uracil, or Cytosine

In many cases the third base of the anticodon is found to be *Inosine* (I)

Inosine

The "wobble" hypothesis predicts that I could pair with A, U, or C Thus, three of the four codons of valine, GUA, GUU, and GUC are recognized by one tRNA bearing the anticodon 'CAI (Fig 1 157)

Support in favor of the "wobble" concept has steadily accumulated with the elucidation of sequences of more and more tRNAs and identification of their anticodons Up to now more than 12 anticodons have been identified, none of which contradicts the "wobble" concept

GENETIC EVIDENCE FOR THE CODE

Single amino acid changes in proteins result from a mutation involving change of one nu-

cleotide within one codon Consider for example the underlined single base changes in the following codons

1 (Leu) CUU → UUU (Phe)
2 (Ser) UCU → UUU (Phe)
3 (Tyr) UAC → UUC (Phe)

Replacement of leucine by the phenylalanine was found to occur at position 10 of mutant-TMV protein Replacement of serine by the phenylalanine was found to occur at position 138 and 148 of mutant-TMV protein Finally replacement of tyrosine by phenylalanine was found in position 35 of the β-chain of an abnormal hemoglobin From the catalogue of the assigned 64 codons (Table 1 12) it can be calculated that the possible single base changes that can lead to another amino acid are 75 Up to now, 54 of these possible changes have been identified in amino acid replacement data from various proteins

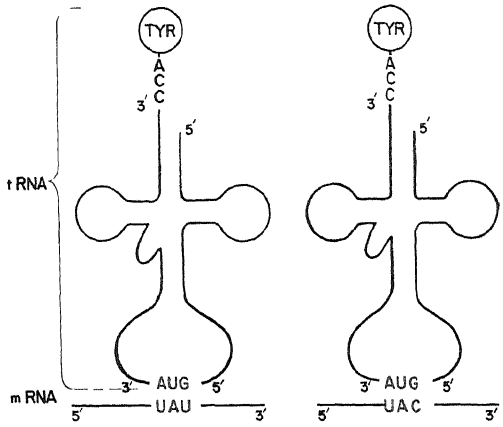


Fig 1 156 Pairing of codon and anticodon in a diagram that illustrates significance of wobble at the third position

Confirmation of the Code from Phage R17 RNA Sequences Advances in the biochemical technology of nucleotide sequence determination provided the tool for the dramatic elucidation of sequences of a viral RNA Sequence studies on the phages R17 and Qβ are now in progress

The nucleotide sequence of the gene for the coat protein of R17 phage has been already elucidated and affords direct comparison with the known amino acid sequence of that protein The findings are consistent with the concept of a triplet-degenerate code In the sequence of the coat protein gene, 38 different codons were encountered, they code for amino acids in agreement with the previously described assignments

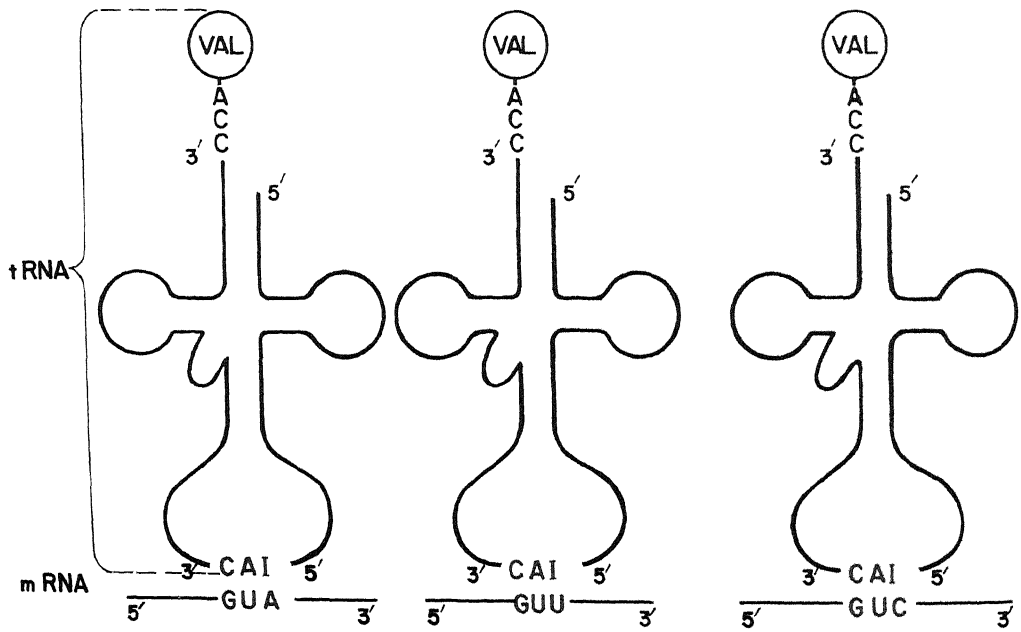

Fig 1 157 Codon-anticodon pairing that illustrates three possible combinations at the third position based upon wobble

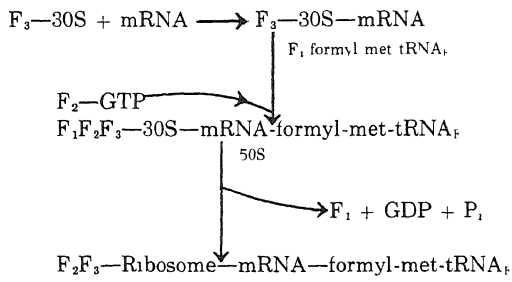
Function of RNA in Protein Biosynthesis

The biosynthesis of proteins on mRNA templates is an elaborate process during which the genetic message is faithfully translated into a polypeptide chain The direction of translation of mRNA is from 5′ → 3′ The synthesis of a polypeptide chain starts from the amino terminal end and proceeds toward the carboxyl terminal end Peptide biosynthesis appears to proceed in a series of steps These have been designated as *1*) peptide chain *initiation*, *2*) peptide chain *elongation*, and *3*) peptide chain *termination*

PEPTIDE CHAIN INITIATION



The process of peptide chain initiation in bacteria involves formyl-methionyl-$tRNA_F$ (F-met-$tRNA_f$), ribosomal subunits, the initiation signal of mRNA, the initiation factors F_1, F_2, F_3, and GTP The majority, if not all, bacterial polypeptides are initiated with *N-formyl-methionyl residues* The formylation of methionine takes place after the formation of methionyl-tRNA There are two tRNAs for methionine, $tRNA_F$ and $tRNA_M$ Methionyl-$tRNA_f$ can be formylated by transfer of a formyl residue from N^{10}-formyl-tetrahydrofolate to methionyl-$tRNA_F$

Transformylase
N^{10}-formyl-tetrahydrofolate

Methionyl-$tRNA_M$ cannot be formylated enzymatically and its function is to insert methionine residues at internal positions in the polypeptide chain

Although peptide chain initiation starts with formyl-methionine, bacterial proteins isolated from the cells do not have this residue at the *N*-terminus and frequently do not even start with methionine This occurs because the formyl residue is removed by the specific enzyme, deformylase, after the peptide chain has been initiated Methionyl residues are cleaved by another specific enzyme not yet isolated

Both the $tRNA_F$ and $tRNA_M$ have been sequenced recently and both bear the same anticodon [3] UAC[5] This anticodon matches the methionine codon AUG which is the *initiation* codon Initiation begins with the formation of initiation complex The complex is formed by the 30S and 50S ribosome subunits, the mRNA, the F-met-$tRNA_F$, three protein *initiation factors* F_1, F_2, F_3, and GTP as follows

Factor F_3 is required for the binding of 30s subunit to mRNA, whereas factor F_1 promotes the binding of F-met-$tRNA_f$ to the initiation complex Factor F_2 catalyzes the cleavage of GTP to GDP and inorganic P in the presence of ribosomes

Although met-$tRNA_M$ possesses the same anticodon as F-met-$tRNA_F$, it does not bind to the initiation codon AUG, it binds to the AUG codon only when this codon specifies methionine residues within the polypeptide chain It appears then that the specificity for the binding at the initiation position lies with the initiation factors, especially F_1 which interacts only with the F-met-$tRNA_f$ and not with the met-$tRNA_M$ Conversely, met-$tRNA_F$ (without the formyl group) does not participate in the peptide elongation process because it is discriminated by the T_u factor (see "elongation process")

After initiation, the direction of translation of mRNA is from 5′ → 3′ This does not mean that the initiation codon must be at the 5′- end Thus, the mRNA may possess, starting from the 5′- end, a number of nucleotides which precede the initiation codons Those immediately preceding the initiation codon do not have any coding function but have an initiation function Indeed, this area may represent a "*sticky point*" for the attachment of the 30S subunit as shown in Figure 1 158 In a polygenic messenger there may be the picture showing in Figure 1 159 A 30S subunit may attach directly to "*sticky point*" next to protein B and initiate the translation of protein B, thus by passing protein A

ELONGATION OF POLYPEPTIDE CHAINS

At the completion of the initiation process a ribosome is properly registered with the mRNA, and the initiator F-met-$tRNA_f$ is in

the *peptidyl site* ("P") of the complex (Fig 1 160*A*) The "P" site is formed by participation of the 30S and 50S subunits as well as the initiation codon At that state of the initiation the codon next to the initiation codon is a part of the amino acyl site ("A") of the ribosomes Site "A," as site "P," is formed by participation of the 30S and 50S subunits and the mRNA codon which is next in line to be decoded (Fig 1 160*A*) The subsequent events which ultimately will lead to peptide bond synthesis take place in three steps

Step One Binding of the Amino Acyl-tRNA In that step, the proper amino acyl-tRNA enters and binds to the "A" site (Fig 1 160*B*) This binding is effected by a protein factor The factor isolated from *E coli* is designated as T_u factor The T_u factor forms a complex with amino acyl-tRNA and GTP T_u + amino acyl-tRNA + GTP → T_u-amino acyl-tRNA-GTP The appropriate T_u complex binds to the "A" site to match the codon and immediately GTP breaks down to GDP and P_i which are released together with the binding enzyme (Fig 1 160*B*) The same T_u factor binds apparently all amino acyl-tRNAs The T_u factor does not bind to uncharged tRNAs, F-met-$tRNA_i$ and met-$tRNA_i$ (deformylated) Factors analogous to T_u exist also in eukaryotic systems, for example the *amino acyl transferase* I which has been isolated from liver tissue

Step Two· Peptide Bond Formation In this step a peptide bond will be formed between the amino group of the incoming amino acid and the activated carboxyl terminal of F-methionine (Fig 1 160*B* and *C*) This reaction is catalyzed by the enzyme *peptidyl transferase* which is an integral part of the 50S subunit

It appears that the enzyme has at least two binding sites, *a*) a site for all -CCA termini of the peptidyl-tRNAs, which is also the site of the initiator-tRNA, and *b*) a second site for the -CCA termini of the aa-tRNAs The first site is always filled by peptidyl tRNAs except at initiation of protein synthesis when it is filled by F-met-$tRNA_i$ Note also that in both cases (peptidyl or initiator tRNA) the α amino group of the amino acid attached to the tRNA is not free Therefore, one of the basic differences in specificity between the two binding sites of the

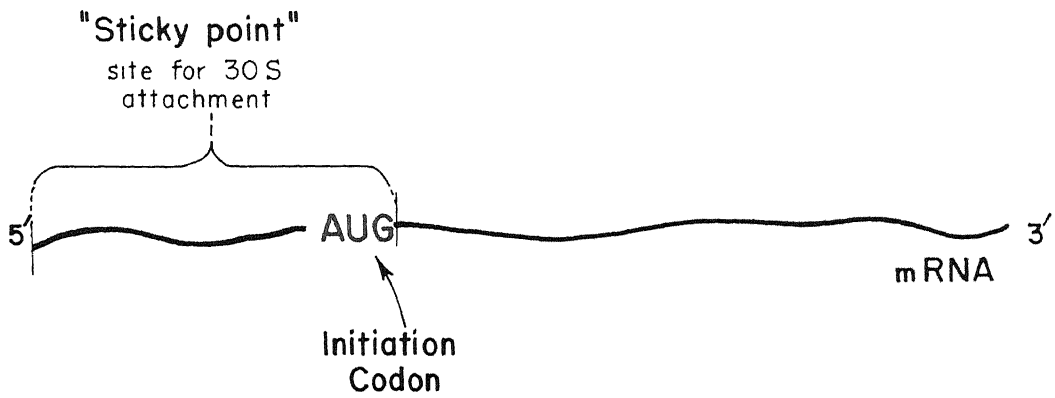


Fig 1 158 Diagram to illustrate location of 'sticky point' for attachment of a 30 S subunit in region of nucleotides possessing an initiation function

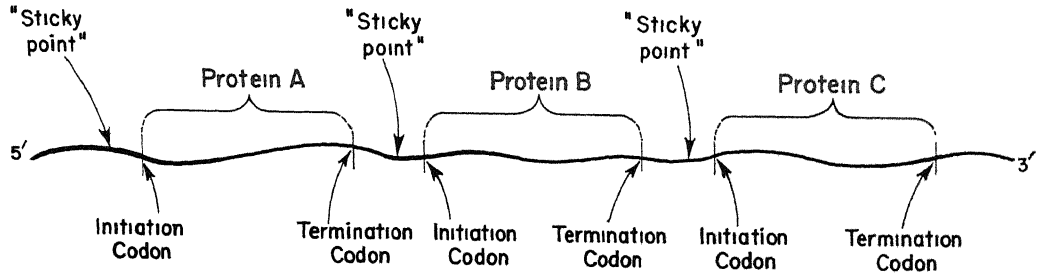

Fig 1 159 Location of 'sticky points' in a polygenic messenger RNA

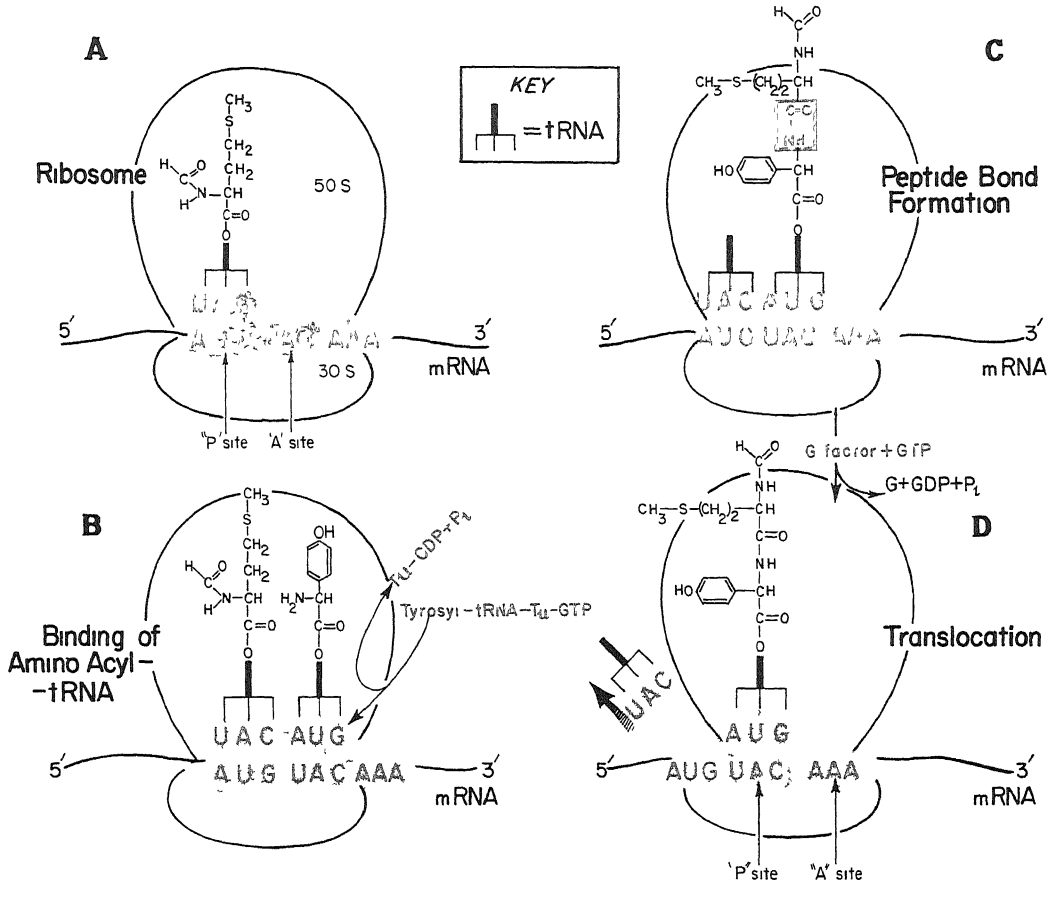

Fig 1 160 Steps in peptide bond formation (see text)

enzyme is that the first site cannot, but the second site can bind an aa-tRNA with a free amino group It is via this specificity of the enzyme that one can reasonably explain the special need for an initiator tRNA with a blocked (formylated)α amino group After peptide bond formation the peptidyl-tRNA is attached to the "A" site of the ribosome-mRNA complex (Fig 1 160*C*)

Step Three. Translocation. In this step the main event is the translocation of the peptidyl-tRNA from the "A" to the "P" site This event requires the *translocation factor* (*translocase*) and GTP During this step, a GTP molecule is cleaved to GDP and P_i At the end of this step the peptidyl tRNA is at the "P" site and the mRNA has moved (relative to the ribosome) by one codon (Fig 1 160*D*) The "A" site, occupied now by the codon to be decoded next, is empty and ready to accept another amino acyl-tRNA as in step one *The translocase* from *E coli* is designated also as the G-factor and the enzyme from rat liver is designated as *transferase II*

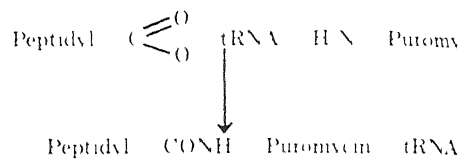
PEPTIDE CHAIN TERMINATION

When the synthesis of a peptide chain is completed, the peptide is released from its attachment to the tRNA and to the ribosome-mRNA complex Chain termination is signaled by the nonsense codons UAG, UGA, and UAA The termination process is effected by the protein *termination factors* R_1 and R_2 Factor R_1 effects chain termination signaled by the UAA or UAG codon, whereas factor R_2 elicits the termination response with codons UAA and UGA

INHIBITION OF PROTEIN SYNTHESIS BY ANTIBIOTICS

Several antibiotics inhibit protein synthesis by interfering with steps of this process The

antibiotic chloramphenicol binds to the peptidyl transferase and hinders sterically the binding of the CCA terminus of aa-tRNA to the enzyme The result is inhibition of peptide bond formation and consequently of protein synthesis This antibiotic affects only bacteria ribosomes, not 80S eukaryotic ribosomes



Sparsomycin binds also to peptidyl transferase in a site overlapping that of the chloramphenicol site, and thereby inhibits protein synthesis in an analogous manner This antibiotic affects both bacterial and eukaryotic ribosomes

Cycloheximide (actidione) acts similarly but affects only eukaryotic 80S and not bacterial ribosomes

Streptomycin has two effects on protein synthesis *a*) it inhibits the peptide elongation process, and *b*) it causes *misreading* on certain codons Thus, for example, the antibiotic induces the misreading of codon UUU (phenylalanine) to be read as AUU (isoleucine) The streptomycin effects on protein synthesis are due to the binding of the antibiotic to the 30S ribosomal subunit This binding occurs close to the "A" site and alters the conformation of the site This conformational alteration results not only in inhibition of protein synthesis but also in misreading of codons

Streptomycin Resistance of certain bacterial strains is due to mutations at the streptomycin locus of the genome These mutations cause changes in the 30S ribosomal subunits making them resistant to streptomycin As a result the effect of the antibiotic is greatly reduced It has been recently demonstrated that the component controlled by the streptomycin locus is one of the proteins of the 30S subunit This protein is involved in the fidelity of translation of the genetic message These observations point out the fact that ribosomes participate in protein synthesis not only by providing the necessary surfaces for attachment and binding of the mRNA, tRNAs, and enzymes, but also by influencing the fidelity of translation

Puromycin, another antibiotic, has a structure similar to that of the terminal amino acyl-AMP residue of amino acyl tRNA It therefore binds to the peptidyl transferase next to the peptidyl tRNA The enzyme then catalyzes the formation of a peptide bond between the amino group of puromycin and the activated carboxyl group of the peptidyl-tRNA

The growing peptide is thereby released from the ribosome Thus puromycin elicits premature termination of the growing peptide chain The incomplete polypeptide chain ends in a puromycin residue

POLYRIBOSOMES

After peptide chain initiation the translation of the genetic message proceeds with concomitant movement of the mRNA relative to the ribosome As a result, the initiation end of the mRNA becomes vacant and ready to accept another ribosome and so on This allows a given mRNA to accomodate several ribosomes at the same time Each ribosome constitutes a condensing site through which the mRNA molecule moves with successive exposure of codons and at which a polypeptide chain is growing (Fig 1 161) Such ribosome mRNA aggregates have been isolated and are called *polyribosomes* or *polysomes* A polyribosome can contain a few or many ribosomes The number of ribosomes per polyribosome depends primarily on the length of the messenger RNA strand The longer the mRNA is, the more ribosomes can be accomodated Thus one mRNA strand functions as a template for the synthesis of several molecules of a polypeptide chain at the same time Obviously, at any moment the molecules of the polypeptide being synthesized along the length of the mRNA are shortest near the initiation end, and are close to completion near the termination end (Fig 1 161) Thus the polyribosome arrangement increases the efficiency of utilization of the mRNA molecules A polyribosome functions continuously with ribosomes attaching at the initiation end and ribosomes leaving at the termination end (Fig 1 161) The mRNA serves as a template until its breakdown by specific nucleases This breakdown begins at the initiating end of mRNA Thus, existing ribosomes on the messenger are not interfered with and the translation of the message is completed However, initiation of further polypeptide chain assembly is prohibited

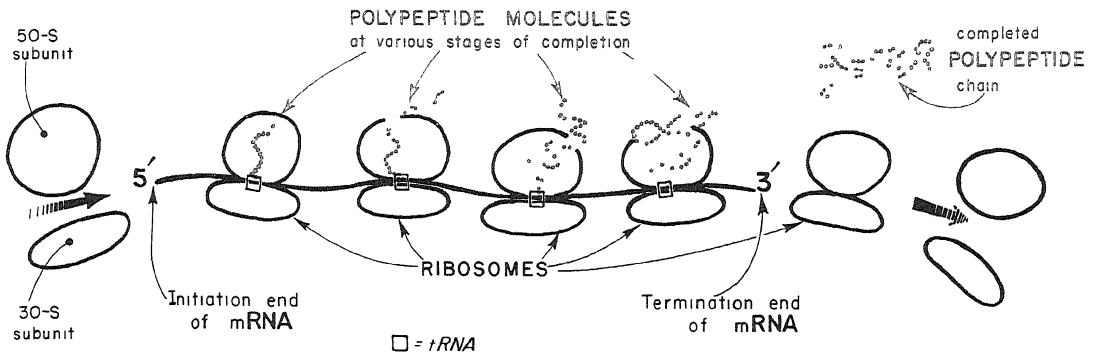


Fig 1 161 Structure and function of a polyribosome (see text)

ASSEMBLY OF POLYPEPTIDE CHAINS INTO PROTEINS

If a gene controls the primary structure of a given polypeptide chain, and if the conformation of the polypeptide chain, viz , its specific folding, is determined by its amino acid sequences (see also chap 5), obviously then the genetic control is extended not only to the primary structure of the polypeptide but also to its specific native functional conformation This folding takes place simultaneously with the synthesis of the polypeptide on the ribosomes Some proteins consist of several chains (subunits), and the assembly of these subunits takes place after the completion of their synthesis On this theme there may be several variations, the most important of which are the following

1) The protein consists of one polypeptide chain In this case the meaning of polypeptide and protein are synonymous

2) The protein derives from the synthesized polypeptide chain by chemical modification of this chain For example, insulin derives from proinsulin by enzymatic cleavage (Fig 1 162*A*)

3) The protein consists of more than one polypeptide chain The assembly of the subunits to form the protein may be accomplished through covalent disulfide bonds as in the case of γ-globulins (Fig 1 162*B*) Most of the time, however, the assembly of the subunits of a protein involves noncovalent forces (Fig 1 162*C*) This is because the subunits "fit" so that their arrangement has minimum free energy

Very often a nonprotein moiety binds to the protein to give a functional unit For example, the enzyme tryptophan synthetase is a complex of pyridoxal phosphate and the protein (Fig 1 162*C*)

The Molecular Basis of Mutations

Any alteration of the base sequence in a gene represents a mutation Such alterations are derived from transitions, transversions, deletions, or insertions of nucleotides within the base sequences of the gene These changes can occur spontaneously or can be induced by mutagenic agents such as x-rays, radioactivity, ultraviolet light, chemical mutagens, etc

MUTATIONS DUE TO TRANSITIONS OR TRANSVERSIONS

A *transition* is a change of one purine base into the other, or one pyrimidine base into the other, a *transversion* is a change of a purine base to a pyrimidine base and vice versa For example

Transition	A↔G,	C↔T (U)
Transversion	A↔C	A↔T (U)
Transversion	G↔C	G↔T (U)

The replacement of one nucleotide by another results in the change of one codon to another Such a change leads to one of the following three possibilities *a*) the codon produced still codes for the same amino acid (*silent mutation*), *b*) the codon produced codes for a different amino acid (*missense mutation*), and *c*) the codon produced is a termination codon (*nonsense mutation*) In the case of missense mutation, the resulting amino acid replacement could lead to a modification of the function of the protein or even complete loss of

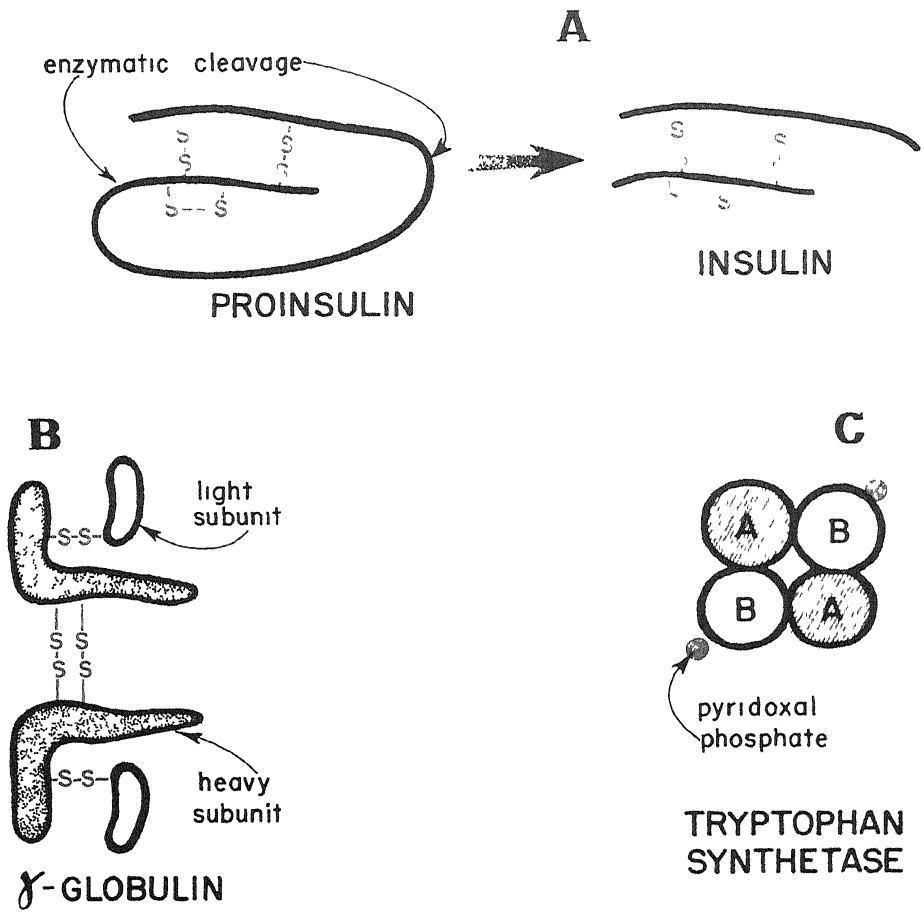

Fig 1 162 Synthesis and assembly of proteins (see text) *A* conversion of proinsulin to insulin *B* a γ globulin molecule consists of four subunits two heavy and two light These subunits are held together by covalent disulfide bridges *C* tryptophan synthetase This enzyme consists of two pairs of subunits *A* and *B* in addition a molecule of pyridoxal phosphate is bound to each B subunit The subunits are held together by noncovalent forces

its activity In the case of a nonsense mutation, the termination codon produced somewhere within the gene will trigger the premature termination of the translation process and result in the formation of an incomplete polypeptide chain

The molecular mechanisms producing transitions can be understood on the basis of improper base pairing In DNA, A pairs always with T, and G pairs with C This pairing occurs with the bases in the *keto form* The bases can undergo *tautomerization* from the keto to the *enol* form When the bases are in the *enol* state their pairing characteristics change Thus, for example adenine in the enol state could pair with cytosine Under physiological conditions, the keto form is predominant and tautomerization to the enol form is rare Watson and Crick (1953) suggested that spontaneous mutations might result from such tautomeric shifts The occurrence, of course, of this type of spontaneous mutations is extremely low Mutations due to improper pairing can be induced by chemical mutagens such as 5-bromouracil (BU) and 2-aminopurine (AP) These *base analogues*, because of their structural similarity to the regular DNA bases, can be incorporated into DNA during replication The analogues, however, undergo frequent tautomerization from the keto to the enol form, and thus BU for example, could pair with either A or G In this manner BU may be correctly incorporated opposite A during DNA replication, but during some later round of replication may pair with G because of tautomerization Ultimately this will result in the replacement of an A-T pair by

a G-C pair as follows

original
A-T pair
A G-C pair
replaces the
original A-T pair
Transition

Alternatively BU may be mistakenly incorporated opposite G but in the next replication may pair correctly with A This will produce an A-T pair at a site formerly occupied by a G-C pair

An A-T pair
replaces the
original G-C pair
transition
Original
G-C pair

Several other mutagens act by altering the bases chemically Monofunctional alkylating agents act by alkylation of bases Ethyl ethanesulfonate for example alkylates guanine residues at position 7 This alkylation increases the rate of tautomerization and causes G to pair occasionally with T Other agents, such as HNO_2 and hydroxylamine, oxidatively deaminate the bases and thus change their pairing properties For example, HNO_2 converts adenine to hypoxanthine which behaves like G, pairing with C The mechanisms responsible for the induction of transversion are not well understood However, transversions are known to occur spontaneously in phages Also many of the abnormal human hemoglobins involve amino acid replacements which can be explained by a single base transversion

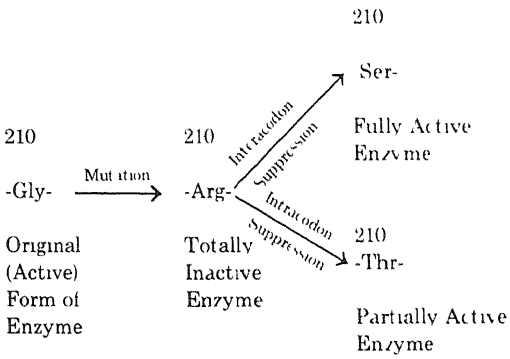
READING FRAME SHIFT MUTATIONS INSERTION OR DELETION

These mutations result from *insertion* or *deletion* of one base Consider, for example, the following nucleotide sequence· AAA-AGU-CCA-UCA-G The codons of this segment are read as underlined If, however, a deletion of the A at position 4 occurred, the message read would then be AAA-GUC-CAU-CAG- Note that after codon AAA there is a change in the *reading frame* These kinds of mutations lead obviously to gross structural changes in the coded proteins Deletion of one nucleotide followed by insertion of one nucleotide in the same gene constitutes a *double frame shift* mutation Clearly, in the nucleotide segment between the deletion and insertion, the reading frame is still out of phase However, after the point of insertion, the reading frame is restored to the original Double frame shift mutations have been observed in the enzyme, lysozyme, of the T4 phage

Original sequence -Lys-Ser-Pro-Ser-Leu-Asn-Ala

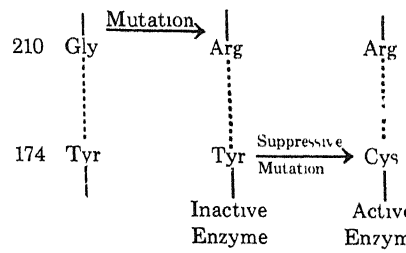
Double frame shift-mutation -Lys-Val-His-His-Leu-Met-Ala

deletion insertion



Thus, deletion of one nucleotide from the codon for serine changes the reading frame up to asparagine Insertion of one nucleotide prior to the codon for alanine restores the reading frame

Reading frame shift mutation can be produced in phages by dyes of the acridine series (proflavin, 5-amino-acridine) These dyes can intercalate noncovalently between the planar rings of the bases of DNA The intercalation produces a doubling of the distance between successive bases of DNA As a consequence, during replication an extra nucleotide may be incorporated to match the acridine molecule Thus, an extra nucleotide is inserted into the new strand Subsequent replication of the strand will result in a double strand with an extra base pair During replication a molecule of the dye could similarly interpose itself between the bases of the growing chain in such a way that it matches a nucleotide of the template This can cause the replication enzyme to skip that nucleotide The result is, of course, deletion of one nucleotide Deletions and insertions could also arise by mispairing during *crossing over* and *recombination* of genes



REVERSION AND SUPPRESSION

True reversion of a mutation is due to a correction of the nucleotide change back to the original sequences *Suppression* of a mutation is due to a new mutation, which compensates phenotypically for the original one There are two main types of mutations causing suppressions, intragenic and extragenic *Intragenic* suppressions involve a mutation within the originally mutated gene, whereas *extragenic* suppression involves mutations in a different gene An intragenic suppression could involve an *intracodon compensation* This compensa-

tion could lead to an amino acid replacement which is less detrimental to the protein function For example, mutational replacement of the glycine by arginine at position 210 in tryptophan synthetase of *E coli* leads to an inactive enzyme Further *intracodon mutation* could result in substitution of the arginine by serine (or threonine) The enzyme is now fully active, and thus there is compensation for the effect of the original mutation

Intragenic suppression of a reading frame shift mutation can be compensated for by a second deletion or insertion which restores the reading frame except for the segment between the two mutations Finally, intragenic suppression can involve a second amino acid substitution at some distance from the original change For example, the mutation Gly → Arg at position 210 of tryptophan synthetase results as we have seen in an inactive enzyme A new mutation Tyr → Cys at position 174 produces an active mutant enzyme

Extragenic suppression involves mutation in the anticodon of a tRNA Nonsense mutations, for example, due to formation of the termination codon, UAG, can be suppressed by a mutation in the gene coding for the tyrosine tRNA This mutation changes the anticodon of tRNA tyrosine from ^{3}AUG^{5} to ^{3}AUC^{5} The changed anticodon now matches the nonsense codon

Anticodon tRNA-tyrosine $(^{3}AUG^{5}) \xrightarrow[\text{Mutation}]{\text{Suppressive}} (^{3}AUC^{5})$ $5'—UAG—3'$

Therefore, instead of premature termination of the translation process due to the AUG codon, the synthesis of the polypeptide continues and a tyrosine is inserted in the growing polypeptide chain The change of the tRNA for tyrosine raises the obvious question of how the tyrosine codons are continued to be read Clarification of that point came with the discovery that two different genes code for two tyrosine tRNAs which have the same anticodon One of the two tyrosine tRNAs (*major*) occurs in large amounts compared to the other tRNA (*minor*) The suppression mutation occurs only in the minor tyrosine tRNA

A nonsense suppression of the UAG and UGA codons does not interfere with the normal growth of the cell, presumably because it does not prevent the regular polypeptide termination process When the sequences for the coat protein of the RNA phage R17 were worked out, it was noted that termination was signalled by two successive stop codons UAAUAG This observation prompted the speculation that termination may be signalled by *two stop codons* If this is the case, it may explain why nonsense suppressions due to UAG and UGA codons have no effect on regular chain termination Nonsense suppression of the UAA type interferes with cell growth Whether this interference operates at the level of the normal termination process is not known at the present time Suppressions of missense mutations have also been observed This type of suppression again involves a mutant tRNA

Regulation of Gene Activity

Encoded in the genetic material of every organism is the information necessary for the production of each polypeptide chain (enzyme, structural protein, etc) that will be needed at various stages of development and under various environmental conditions Even the chromosome of a relatively simple organism, the bacterium *E coli*, codes for 2000 to 4000 different polypeptide chains, and mammalian chromosomes contain very much more information By regulating gene activity, a cell avoids a wasteful production of proteins, con-

fines its synthetic activity to the assembly of those proteins that are needed at a given time, and coordinates its metabolic activities in accord with the external environment In fact, single genes or whole sets of genes can be "turned on and off" at the transcriptional level as required during differentiation or environmental changes Cells can also regulate the *rate of gene transcription* and exert certain controls at the *level of translation* Finally, the activity of the proteins themselves in the cell can be regulated by interaction with small molecules or by actual enzymatic modification The discussion that follows is primarily concerned with microbial systems of regulation of transcription, translation, and protein function It is in these relatively simple systems that basic mechanisms have been most elaborately defined While problems of regulation in higher organisms will certainly involve a greater degree of complexity and additional factors, the fundamental concepts elucidated in microorganisms provide a foundation for approaching and ultimately solving such problems

TRANSCRIPTIONAL CONTROLS

Induction and Repression: The Operon Many enzymes, the *constitutive enzymes*, are produced by cells at all times The synthesis of other enzymes is under control, and they are said to be either inducible or repressible *Repressible* enzymes—those commonly involved in biosynthesis—are synthesized *except* when some specific substance (often the product of the metabolic pathway in which the enzyme functions) is present For example, production of the enzymes for tryptophan biosynthesis is "turned off" (repressed) by tryptophan *Inducible* enzymes, which are commonly catabolic enzymes, are *not* synthesized except when the inducer (often the substrate for the enzyme) is present For example, the enzyme β-galactosidase which hydrolyzes lactose and other β-galactosides is synthesized in response to the presence of such compounds in the medium In the absence of inducer, *E coli* cells contain only 1 to 10 units of β-galactosidase per mg of cell protein, whereas in the presence of inducer, the levels of this enzyme reach 10,000 units per mg of protein This increase represents de novo enzyme synthesis rather than activation of a pre-existing enzyme

Jacob and Monod (1961) devised a general model to explain how the production of groups of enzymes that are related in function can be controlled coordinately The genes which code for functionally related enzymes, the *structural genes*, are often linked together on the chromosome Structural genes for the three enzymes that are induced by lactose and other β-galactosides, for example, are linked on the genome of *E coli* They are the *z* gene codes for β-galactosidase, the *y* gene for a permease that facilitates entry of substrate into the cell, and the *a* gene for galactoside acetylase (Fig 1 163) Involved in the control of transcription of these three structural genes are two other genetic elements, the *operator* and the *regulatory gene* As shown in Figure 1 163, the structural genes are directly linked to the DNA segment of the operator The operator and its contiguous structural genes are controlled by the product of the regulatory gene The regulatory gene, the operator, and the linked structural genes constitute a unit of regulation called the *operon* The product of the regulatory gene is a protein called the *repressor* The repressor is produced continuously by the regulatory gene and binds to the operator This turns off transcription of the structural genes of the operon (Fig 1 163*A*) When a β-galactoside (*inducer*) is present, a complex between the inducer and repressor molecules is formed The repressor no longer binds to the operator, and transcription of the structural genes can then occur (Fig 1 163*B*) These controls bring about the synthesis of the enzymatic machinery for lactose metabolism only when actually needed, i e , in the presence of lactose

Among the many kinds of evidence for the Jacob-Monod "Operon Theory" is that obtained from the study of mutants As the model predicts, certain mutations in the regulatory gene or in the operator region lead to constitutive production of the enzymes of the operon For example, a mutation in the regulatory gene could result in mutant repressor molecules that can no longer bind to the operator Such a mutant would have a free operator and hence be able to transcribe the operon even in the absence of inducer (Fig 1 164) Recently, crucial evidence in support of the operon model was provided by the purification of the repressor protein for several operons, including that for the lactose operon by Gilbert and Muller-

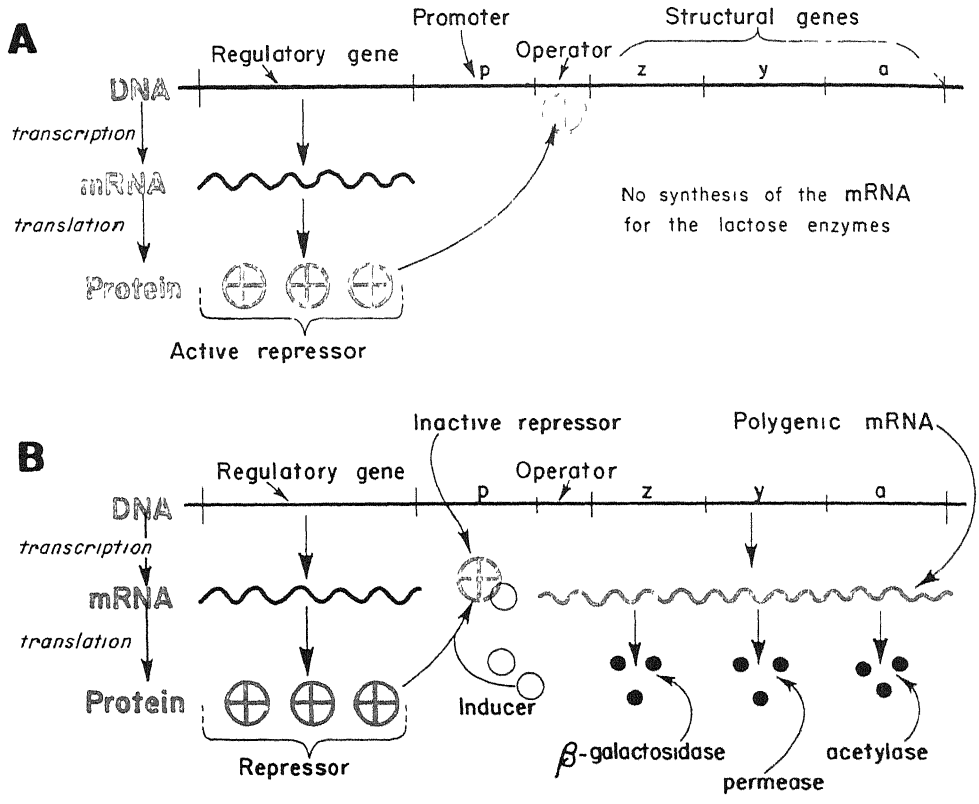


Fig 1 163 The lactose operon of *E coli* in the absence and presence of inducer (see text) *A inducer absent* In this case the repressor binds to the operator and as a result the transcription of the structural genes is blocked *B, inducer present* In this case the inducer binds to the repressor rendering it inactive As a result the structural genes are open for transcription

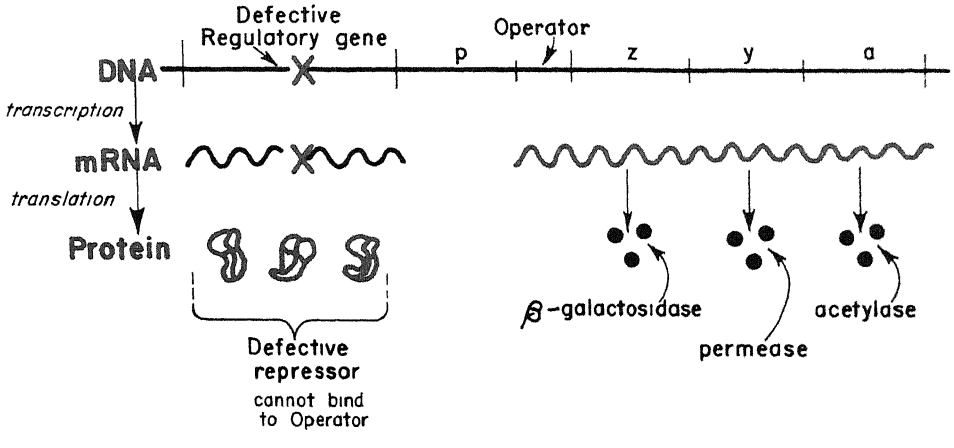

Fig 1 164 Effect of a mutation in the regulatory gene on the function of the lactose operon in *E coli* The mutant repressor cannot bind to the operator and as a consequence the system is open for transcription at all times

Hill (1966) As predicted, the repressor has binding sites for both DNA and inducer Moreover, purified repressor inhibits the transcription of the lactose operon in an in vitro system

The operon model can be used to explain repressible as well as inducible enzyme systems For example, the genes for the five polypeptide chains required for tryptophan

biosynthesis are linked to each other and to an operator region on the *E coli* chromosome (Fig 1 165) There is also a regulatory gene which produces a repressor However, the repressor is *inactive* unless another small molecule, the *corepressor*, is present to change the repressor into its active form Tryptophan or its product acts as the corepressor for the tryptophan operon, thus turning off transcription of the enzymes for its own synthesis, a clearly economical control

In the two kinds of regulatory models described above repressors function—either alone or in interaction with a corepressor—to prevent transcription of an operon, this is called *negative control* There are some groups of enzymes whose operons are apparently subject to *positive control* Such a system is exemplified by the operon controlling the enzymes for arabinose metabolism in *E coli* This operon contains three structural genes coding for three enzymes, an operator region, and the C gene which is a regulatory gene (Fig 1 166) As with the lactose operon, an inducer (in this case, arabinose) is required for transcription of the operon Genetic analysis reveals, however, that unlike the case of the lactose repressor, the C gene product is *required* for induction It is hypothesized that the "C" protein forms a complex with arabinose Interaction of this complex at the operator is required for transcription of the operon

Genetic analysis of mutants has revealed another important regulatory region, the *promoter* In the lactose operon, for example, the region of the promoter (P) lies next to the operator on the other side from the structural genes (Fig 1 163) Promoters are signals along the DNA molecule recognized by the RNA polymerase As a consequence, the enzyme binds to the promoter Such a binding of the enzyme on the promoter is a prerequisite condition for commencement of the transcription process Since binding of the polymerase to the

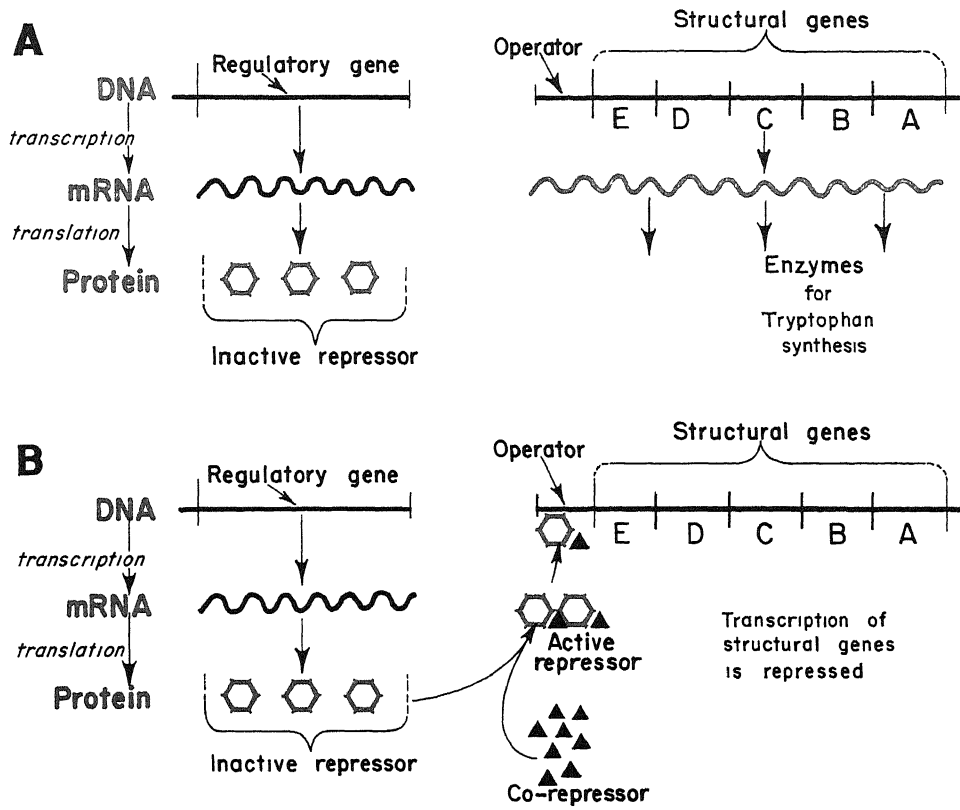

Fig 1 165 The tryptophan operon in *E coli* in the absence and presence of co-repressor (see text) *A corepressor absent* In this case the repressor synthesized by the regulatory gene is inactive and as a result the structural genes are open for transcription *B corepressor present* In this case the corepressor binds to the repressor to produce an active component which then binds to the operator thus transcription is blocked

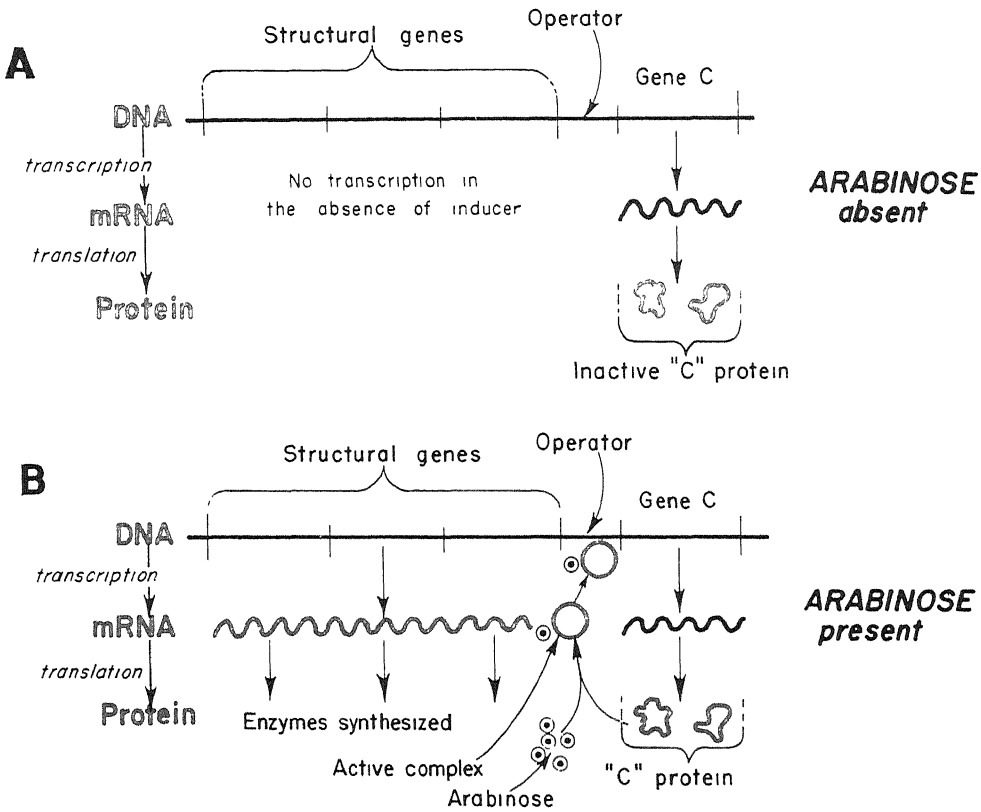

Fig 1 166 Positive control the arabinose operon in *E coli A arabinose absent* In this case the inactive C protein cannot promote transcription of structural genes *B arabinose present* In this case the arabinose forms an active complex with protein C which promotes transcription of structural genes

promoter is the rate-limiting step of the transcription process, mutations in the promoter region affect the *rate of transcription*

A number of regulatory mechanisms appear to act via control of transcription at the promoter For example, in both bacteria and higher organisms the synthesis of many catabolic enzymes is sensitive to the presence of glucose Since glucose is an excellent source of intermediary catabolites and energy for most organisms, it is economical for cells to repress the wasteful synthesis of enzymes for other substrates when glucose is present This phenomenon was given the name *catabolite repression* Catabolite repression in bacteria involves cyclic adenosine monophosphate (cyclic AMP) and a protein which complexes with cyclic AMP The protein is called *CAP or crp protein* The cyclic AMP-CAP complex is a positive control element which is required for proper binding of RNA polymerase to the promoters of certain operons These are the operons that are subject to catabolic repression Such operons require cyclic AMP and CAP for transcription even in the presence of inducer Clearly, lowering of cyclic AMP levels or mutation of the CAP protein would prevent normal transcription Glucose causes catabolic repression by lowering the levels of cyclic AMP within the cell As would therefore be expected, the repressive effect of glucose can be overcome by the addition of large amounts of cyclic AMP

Control by RNA Polymerase. As noted earlier, bacterial RNA polymerase is compounded of several subunits designated as β', β, α, ω, and σ The subunits aggregate specifically to form the holoenzyme, β', β, α_2, ω, σ Strand selection and binding of RNA polymerase to a DNA template is effected through promoters along the DNA molecule The promoters are recognized by the σ-factor of RNA polymerase Once binding of the enzyme to the promoter region is effected, the polymerase will tran-

scribe genes continuously until a *stop signal* on DNA induces the termination of the polymerization process

There are many promoters within a given genome Even the relatively simple T4 phage appears to possess several promoters The intriguing possibility exists that there are differences between promoters and that different promoters require different σ-factors for recognition The "catabolic sensitivity" of some promoters (see above) suggests that such differences exist, as does the discovery that σ-factors are involved in the coordinated expression of the genome of the T4 phage, a phage which contains several genes The proteins coded by these genes are needed at various times during the life cycle of the phage inside the host cell For example, the enzyme lysozyme is needed at the very end of the life cycle of phage, to produce the lysis of the host cell, and thus liberate the viral particles It would be detrimental to viral replication if the gene for lysozyme were transcribed immediately after injection of the phage into the host cell since it would produce a premature lysis of that cell

After the DNA of T4 phage is injected into an *E coli* cell, the various viral genes are expressed in a coordinate fashion as follows the "early" genes are transcribed first, then the "delayed early" genes, and finally the late genes The early genes are transcribed by the *E coli* RNA polymerase Presumably, the promoter(s) of the early genes are recognized by the σ-factor of the host cell However, the promoter(s) of the delayed early and late genes cannot be recognized by the host σ-factors Indeed, one of the early genes codes for a specific σ-factor which recognizes the promoter(s) of the delayed early genes but not of the late genes In turn, one of the delayed early genes codes for a second viral σ-factor specific for the promoters of the late genes

In the case of transcription of the late genes of T7 phage a specific T7 polymerase is needed The enzyme appears to be a linear end-to-end protein (no subunits) of 110,000 MW The T7 polymerase does not bind *E coli* holoenzyme or core enzyme and is insensitive to rifamycin The enzyme is highly active with the T7 DNA, but it does not transcribe other DNA templates

Another kind of control at the transcriptional level is exerted by modification of the RNA polymerase core enzyme Recent studies on bacterial sporulation suggest that the transition from the vegetative form to the spore involves changes in RNA polymerase Thus, a modified polymerase is found in *Bacillus subtilis* at the onset of sporulation The change of enzyme is due to a modification of the β-subunit The modified enzyme does not contain σ-factor, presumably because it cannot bind it Thus, the cessation of the transcription of the genes expressed in the vegetative state coincides with the "inactivation" of the vegetative enzyme (negative control) Activation of the genes expressed at the spore stage is effected by a new σ-factor Whether the new σ-factor binds to the modified vegetative enzyme or to an altogether new polymerase enzyme is not yet known

Therefore, *specific promoters*, *sigma factors*, and *changes in the "core" enzyme* can all contribute to the coordinated regulation of genes at the transcriptional level

It has also been suggested that many operons may be under the control of further positive control elements which react with the polymerase to change its ability to initiate transcription at certain promoters Indeed, there is now evidence for a *psi factor* which exerts specific positive control over the transcription of ribosomal RNAs Moreover, there is a small molecule, guanosine tetraphosphate (ppGpp), whose accumulation inhibits the psi factor, and thus decreases the production of ribosomal and transfer RNAs

Finally, in addition to the protein factors, sigma, and CAP mentioned above, there is a protein factor required for termination of transcription in certain in vitro systems This factor, the *rho factor*, may well have a regulatory function or at least be involved in the normal process of transcription in vivo

TRANSLATIONAL CONTROLS

In addition to controls of gene activity at the transcriptional level, gene expression may also be regulated by controls acting at the translational level These controls ultimately affect the amount of a given protein produced by its messenger RNA, thus inhibition of translation of a given messenger or changes in the rate of its translation lead to changes in the amount of the protein coded by this messenger For example, the RNA phage R17 codes for three proteins the attachment protein, the coat protein

and the RNA replicase protein necessary for viral replication (Fig 1 167) The production of the coat protein is about 10 times greater than the production of the other two proteins This difference is due to the greater affinity of ribosomes for the initiating signal of the coat protein than for the attachment protein The conformation of the initiating site of the RNA replicase gene makes it unavailable for ribosomes binding, the site becomes accessible to ribosomes only when the ribosomes moving across the coat protein gene induce a change in its conformation (Fig 1 167) Thus, translation of the replicase gene depends on translation of the coat protein gene Therefore, the affinity of ribosomes toward initiating sites of mRNAs can be an important determinant of the rate of translation of a given gene

Another very important control device is exerted at the translational level by specific repressor proteins Such repressors bind to mRNA and inhibit translation For example, in the case of phage R17 translation, the synthesized coat protein subunits are specific repressors of the RNA replicase gene The synthesis of this enzyme stops The replicase already synthesized serves for the viral replication, and thus a wasteful synthesis is avoided Control by repressors acting at the translational level may be of great importance for eukaryotic systems (see "Tomkins theory" below)

There are many possibilities for control other than those already described Control by breakdown of mRNA, for example, clearly occurs at least in some systems The actual nuclease which hydrolyzes mRNA in vivo is unknown, however, recent experiments with *E coli* have identified the gene specifying this enzyme Elucidation of the nature of the regulation of mRNA degradation should prove to be of great interest

Finally there are innumerable controls related to the activity of proteins themselves (*post-translational controls*) Some of the most

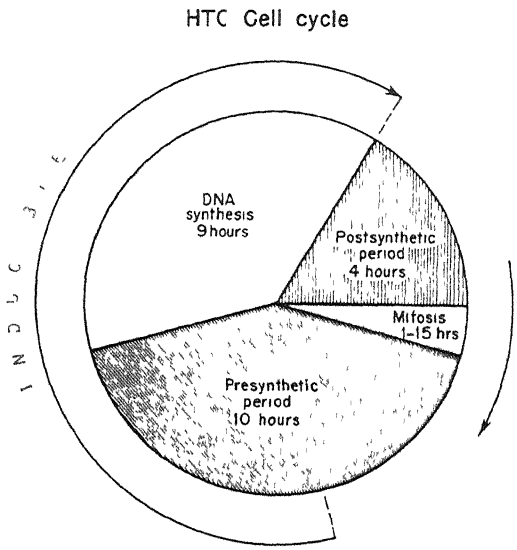

Fig 1 168 The cell cycle of rat hepatoma cells in tissue culture (*HTC*) showing periods during which tyrosine amino transferase can be induced by adrenal steroids Redrawn from Tomkins et al 1969

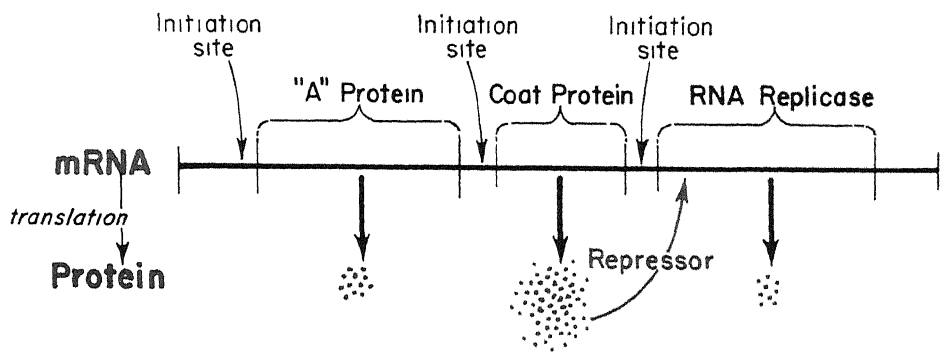

Fig 1 167 Single stranded RNA of phage R17 a polygenic messenger RNA The rate of translation of the coat protein gene is greater than that of the A-protein and the replicase because the conformation at the initiation site of that gene facilitates the attachment of ribosomes much more readily than the conformation of the other two sites In fact the conformation of the initiating site of replicase renders this gene unavailable for translation and it is only when the ribosomes move across the coat protein approaching the replicase region that an appropriate conformational change is induced in the latter region rendering it available for translation Furthermore the coat protein is a specific repressor of the replicase gene inasmuch as it binds to that gene and thereby blocks its continued translation

important of these include feedback inhibition of enzyme function by allosteric mechanism, and actual modification of proteins by phosphorylation, adenylation, or limited proteolysis

SOME COMMENTS ON CONTROL IN HIGHER ORGANISMS

Fundamental differences between regulation in bacterial (*prokaryotic*) and higher (*eukaryotic*) cells are likely to result from the important differences in cellular organization The elaborate organization of the chromosomes in eukaryotic cells poses certain problems We do not know, for example, what regulatory role may be played by the *histones*, the highly basic proteins to which much of the DNA is bound We also do not know the mechanism for selecting some of the many mRNAs that are transcribed in the nucleus to be transported into the cytoplasm for translation or even the mechanism of this transport

A variety of technical advances offers the promise of facilitating experiments on regulation in mammalian cells hitherto regarded as "impossible " For example, it is now possible to cause *fusion* between cells of different types and different activities, by means of certain viruses (usually Sendai virus) Experiments with fused cells have already provided indications that positive control elements are involved in both DNA and RNA synthesis in mammalian cells The general increase in the availability of tissue culture cell lines which are capable of specific synthetic activities in vitro has opened up broad new areas of study As a case in point, Tomkins and his colleagues (1969) have studied the effect of adrenal steroids on the synthesis of the enzyme tyrosine aminotransferase in cultured rat hepatoma cells (HTC cells) This enzyme is induced by steroids, but only during certain periods of the cell cycle (Fig 1 168) Tomkins has proposed a theory of induction of enzymes in mammalian cells which involves two genes—a structural gene for the induced enzyme and a regulatory gene The product of the regulatory gene, the repressor, binds to the mRNA of the structural gene and reversibly inhibits its translation Furthermore, it is assumed that the mRNA can only be degraded when its translation is inhibited by the repressor Thus, the repressor has a dual effect *a*) it inhibits messenger translation, and *b*) it promotes messenger degradation According to the theory, in the presence of the inducer the repressor is inactivated This results in mRNA translation, prevention of mRNA degradation, and increase synthesis of the enzyme (induction) Transcription of the structural gene itself also seems to be directly increased by hormone action These events take place only during particular (inducible) periods of the cell cycle During the noninducible phases, the transcription of both structural and regulator genes is repressed The pre-existing messenger is more stable during this phase of the cell cycle and its translation continues Obviously, inducers have no effect in this phase of the cell cycle

The complex regulatory processes of the coordinate and selective expression of the various genes lead not only to harmonious cell function, but also to changes as required during cell differentiation Selective, sequential and coordinate gene expression is achieved, therefore, by events taking place at the transcriptional, translational, and post-translational levels These events are triggered by molecular signals emanating from the internal or external cell milieu In a sense it is the dynamic balance existing between the genes and their environment that ensures their selective, timely, and coordinate expression

Digestion

2 / CONTROL OF FOOD AND WATER INTAKE

The energy requirements of the body are met by the food that is consumed and absorbed If an excess of food were consumed continually and there were no change in the energy expenditure there would be a consistent weight gain A shortage in the energy value of the food assimilated would result in a steady weight loss The fact that the average adult maintains a constant weight or gains or loses weight very slowly is sufficient evidence that a balance is usually maintained between the energy expended by the body and the energy content of the food that is assimilated The precision of this adjustment can be appreciated when we realize that the addition of 500 mg of dry food (less than one soda cracker) to each meal would cause an increase in weight over a 10-year period of more than 10 lb , if there were no compensatory increase in energy expenditure Of course some people do gain weight but it is believed that this is usually the result of some abnormality affecting the control of food intake

The balance between food intake and energy output is maintained by control of both the food intake and the output of energy There is an immediate effect of the excess food through its specific dynamic action, which results in an increase in energy output This, however, is rarely sufficient to account for all the energy contained in the excess food eaten If it were, there would never be a gain in weight If an individual consumes a certain measured excess of food at each meal over a period of time, he will gain weight steadily but the gain in weight will result in an increase in his basal metabolic rate which, if the excess food intake is not too great, will ultimately increase the metabolism to a point where the energy output will again equal the energy of the food, including the excess In this way a new balance is established at a higher weight level In addition, there is apparently another mechanism, less well understood, which, in some cases at least, balances the energy output against the food intake, even when this is in excess In experiments on dogs at the University of Illinois, it was found that dogs which were maintaining a constant weight on the amount of food which they ate voluntarily could be given an excess over this amount, through a gastric fistula, amounting to 33% of their voluntary food intake, without either diminishing their voluntary food intake or causing a gain in weight (Share et al , 1952) Evidently the animals had some means of metabolizing the excess food without increasing their total body mass This suggests that there is some mechanism for adjusting the total body metabolism to the energy content of the food consumed, even though it is in excess of the need, however, we are concerned here with the other aspect of the adjustment of food consumption to energy output, that is, the regulation of food intake

There are several methods to demonstrate the fact that food intake is controlled in some manner so as to equal the energy requirements of the animal Healthy animals, when allowed all the food which they wish to eat, will consume only as much as is necessary to meet their energy requirements and to maintain their weight, or their normal growth if they have not already attained their adult weight If the caloric value of the food is increased, the amount consumed will be diminished so as to maintain a normal intake of food calories If, on the other hand, the caloric value of the food is decreased by dilution with inert material, the animal will usually consume more food, up to the limit of its capacity, in order to maintain an adequate caloric intake This mechanism may be tricked by human devices into permitting an excess food intake, as in the experiments of Share and his coworkers described above, but usually it works very well Adjustment of food intake to energy expenditure is illustrated in Figure 2 1

Hunger and Appetite

Since eating is a voluntary act, control of food intake must be accomplished through con-

scious sensations which indicate whether food is needed or if enough food has been consumed The sensations which cause food to be eaten are described as hunger and appetite These terms have never been precisely defined in the scientific sense, but in a general way we recognize that hunger is the sum of the sensations aroused by the physical need for food Appetite, on the other hand, is a psychic or emotional desire to eat, and may or may not be associated with the need for food Cessation of eating is also a voluntary act, and is induced by a conscious sensation called satiety when a sufficiency of food has been eaten The mechanisms of hunger and satiety are probably inborn and dependent upon the inherent organization of the nervous system Appetite, on the other hand, is acquired, and is probably dependent upon pleasurable past experiences associated with eating For example, an individual who is hungry will eat almost any wholesome food so long as it is reasonably palatable When he has reached a state of satiety, however, he will eat only those foods which are particularly pleasing to him and with which he has had pleasant experiences in the past Thus, because of hunger, one may eat a wholesome meal which is fully adequate for his needs and then, because of appetite, add to it a dessert which is entirely unnecessary so far as caloric requirements are concerned

Neural Control of Food Intake

CENTRAL MECHANISMS

It has long been known that persons suffering from tumors of the hypophysis have a tendency to become obese, the condition is known as Frohlich's syndrome In 1940, Hetherington and Ranson showed that a similar condition could be produced in animals by injury to the hypothalamus in the vicinity of the hypophysis Later, Brobeck and others (1943) showed that the obesity was caused by injury to ventromedial hypothalamic nucleus situated in the tuber cinerium If this area is destroyed in rats, cats, or monkeys, instead of being satisfied with an amount of food appropriate to its caloric requirements, the animal continues to eat as long as it is able to swallow food or as long as food is available, with the result that it becomes excessively obese A little later, Anand and Brobeck (1951) found that injuries to the lateral hypothalamic nuclei, just lateral to those involved in obesity, would cause the animal to stop eating

Voluntary Caloric Intake and Body Weight as Functions of Exercise in Normal Animals

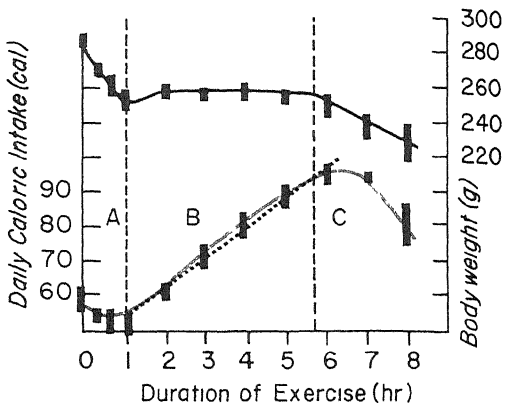

Fig 2 1 The effect of exercise of various durations on caloric intake and body weight of exercised rats Three ranges can be distinguished *A* sedentary *B* proportional response (normal activity) *C* exhaustion (From Mayer (1955) Courtesy of New York Academy of Science)

altogether Animals with such injuries absolutely refused food even though they starved to death If an animal with a medial hypothalamic injury and consequent hyperphagia (habitual overeating) was subjected to an injury to the lateral hypothalamus, it not only recovered from its hyperphagia, but refused absolutely to eat anything From these observations, it was concluded that the nuclei in the lateral area of the hypothalamus contain a "feeding center," and that the medial hypothalamic nuclei contain a "satiety center " Since injury to the medial nuclei was effective only if the lateral nuclei were intact, it was concluded that the medial satiety center acted by inhibiting the lateral feeding center

It is interesting to note that the areas of the hypothalamus involved in the control of food intake have a much higher concentration of high energy phosphate compounds (adenosine triphosphate, creatine phosphate) in fasted animals than in animals recently fed, the increase in these compounds implies increased activity of these areas in hungry animals (Larsson, 1954) The medial hypothalamic areas, which are believed to inhibit the feeding centers in the lateral hypothalamus, exhibit increased electrical activity when drugs which reduce or abolish appetite, such as amphetamine, are given It is believed that the increased electrical activity indicates stimulation of the medial nuclei and that these then inhibit the action of the feeding centers It has been shown that electrical stimu-

lation of the lateral hypothalamic nuclei by means of implanted electrodes produces hyperphagia in rats, cats, mice, monkeys, goats, and sheep During the period of stimulation, the animals exhibit a compulsive desire to eat, and if food is available will eat as much as it is possible for them to swallow (Larsson, 1954)

The neural organization of the feeding centers in the rat have been investigated by Morgane (1961) He devised a clever experiment which required the animal to cross an electrical grill and press a lever to obtain food After electrodes were implanted in various parts of the hypothalamus, stimulation of the far-lateral hypothalamus not only resulted in a feeding response in sated animals, but also motivated them to cross the electrical grill to obtain food When the mid-lateral hypothalamus was stimulated, a feeding response was obtained, but the animals were not "motivated" to cross the electrical grill Lesions were then placed in the medial fore-brain bundle, and it was found that a feeding response could still be obtained in sated animals by far-lateral hypothalamic stimulation but the animals would not cross the grill to obtain food These results suggest that the medial fore-brain bundle is important in "hunger motivation," since overcoming a barrier to obtain food apparently depends upon the integrity of this bundle When the medial fore-brain bundle was interrupted, basic feeding responses could still be obtained, but the animal would not "work" for his food Morgane concluded that the feeding center in the rat probably is composed of both a basic feeding drive (mid-lateral hypothalamus) and a hunger drive (far-lateral hypothalamus) element, and that only the latter is depressed by the satiety mechanism

Grossman (1960) has used an ingenious method of stimulating areas of the hypothalamus of the rat He implanted a small double cannula into the lateral hypothalamus and was able to study the effects of stimulation of the "feeding area" by crystalline chemicals Adrenergic agents, such as norepinephrine and epinephrine, caused satiated rats to eat, whereas cholinergic agents, such as acetylcholine or carbachol, caused the animals to drink large quantities of water Thus, the feeding mechanism appears to be selectively activated by adrenergic stimulation, while the drinking mechanism responds selectively to cholinergic stimulation

Brobeck (1957) suggested that the areas of the hypothalamus which control food intake do so either by facilitating or inhibiting the reflex mechanisms involved in the acquisition and consumption of food, he called these feeding reflexes He classified these in two ways *1)* according to the sensory mechanism arousing the reflex, and *2)* according to the nature of the response The reflexes are listed in Table 2 1 Probably the list could be extended if the mechanisms involved were better understood The important point is that the hypothalamic centers do not control food intake directly, but do so by making more or less responsive to stimuli the lower brain centers which control the reflexes governing the acquisition, consumption, and assimilation of food

PERIPHERAL MECHANISMS

Consumption of food brings about consequences which induce satiety and stimulate the mechanisms that are inhibitory to the feeding reflexes, starvation, or the absence of food, brings about consequences which excite hunger and stimulate the feeding centers In spite of extensive study, and even more widespread speculation, the peripheral mechanisms which contribute to hunger and satiety are still not fully understood Among the possible operating devices we can recognize gastrointestinal mechanisms and metabolic mechanisms The gastrointestinal mechanisms are mainly of a physical nature whereas the metabolic mechanisms are chemical The physical mechanisms are presumed to act through stimulation of sensory nerve endings, whereas the chemical mechanisms are supposed to act on some hypothetical sensory device, either within the central nervous system or connected with it through afferent nerves, although this is by no means certain

Among the gastrointestinal stimuli which tend to increase food intake and to cause a sen-

TABLE 2 1

Classification of feeding reflexes on a basis of initial sensory stimulus (left side) or behavior pattern induced (right side)

Sensory Basis	Behavior Basis
Visual reflexes	Reflexes of attention
Olfactory reflexes	Reflexes of approach
Auditory reflexes	Reflexes of examination
Tactile reflexes	Reflexes of incorporation
Gustatory reflexes	Reflexes of rejection
Enteroceptive reflexes	

Brobeck, 1957

sation of hunger are the so-called hunger contractions of the stomach and intestine (Quigley, 1955) The fact that hunger contractions cause a sensation of hunger helps us little in the solution of our problem, for we still do not know what causes the hunger contractions Besides mere emptiness of the stomach and intestine they are probably excited by something in the metabolic category Emptiness is not the whole answer because, although the stomach may be completely empty a few hours after a meal hunger contractions become more intense and more distressing the longer the fast is continued However, they cease at once when food is taken and before any metabolic changes have taken place, therefore, whatever their cause, they can be completely inhibited by the presence of food in the stomach and intestine

It is known that hunger contractions can be induced, or made more intense if already present, by inducing a state of hypoglycemia through administration of insulin (Quigley et al , 1929, 1930) This brings about stimulation of medullary centers, in which increased activity of the vagus centers is a prominent feature If the vagus nerves are cut, insulin hypoglycemia does not stimulate hunger contractions (Quigley and Templeton, 1930), indeed it tends to inhibit them if they are already present The hunger contractions induced by insulin evidently are due directly to an action of low blood sugar on the central nervous system They can be inhibited by administration of glucose intravenously, but the normally occurring changes in blood sugar level are in no way related to the presence or absence of gastric or intestinal hunger contractions (Quigley, 1955, Scott et al , 1938) Hyperglycemia may or may not inhibit hunger contractions, it obviously does not in diabetic subjects In a majority of experiments on normal animals, hyperglycemia induced by injecting glucose intravenously does not inhibit gastric hunger motility It has been shown by Stunkard and Wolff (1956) that, in those instances in which the hunger contractions were not inhibited by intravenous glucose, the injection of glucose did not cause a great rise in the arterial glucose concentration, as compared to the venous glucose concentration The arteriovenous glucose concentration difference is taken as an index of the rate of utilization of glucose by the tissues On the other hand, in those instances in which there was inhibition of hunger contractions, there was an increase in arteriovenous glucose difference Reference will be made to this fact a little later under the heading of "Metabolic Factors "

Undoubtedly gastric hunger contractions contribute to the hunger state but they are by no means solely responsible for it Enough human cases have been studied in which both splanchnic nerves were severed to establish the fact that this operation abolishes all sensation produced by contraction of the stomach during hunger The contractions persist but they are no longer felt However individuals so operated upon do not experience any decrease in their desire for food and they have periods of hunger just as intense as before the splanchnic nerves were severed Cutting the vagus nerves abolishes the hunger contractions altogether for a time, but by no means abolishes the sensation of hunger We may conclude that the hunger sensation arises not only in the stomach and intestine but elsewhere in the body as well, and that the gastrointestinal component is dispensable

Sensations arising in the gastrointestinal tract which diminish or abolish food intake are somewhat better understood The act of eating will, in itself, diminish hunger and appetite For example, if an animal is prepared with an esophagostomy so that food which is eaten passes through the mouth and pharynx and upper esophagus but does not enter the stomach, the animal will eat more food than would a normal animal, but feeding ceases eventually If an animal is given a measured amount of food before its regular mealtime it will reduce the amount of its voluntary food intake proportionately If the prefeeding is carried out through a gastric fistula instead of by mouth the reduction in voluntary food intake is much less pronounced, indicating that the decrease in food intake was not all due to distention of the stomach but partly to the oropharyngeal stimulation of eating

Distention of the stomach alone inhibits hunger and appetite For example, if an animal is given a portion of its food a few minutes before regular feeding time through a gastric fistula, and this practice is continued over a period of time, eventually the animal will come to reduce the size of its subsequent meal by an amount equal to the amount given through the gastric fistula; in other words, the total size of the meal will be maintained constant (Janowitz and Hollander, 1955) This adjustment does not occur immediately and is never very precise, but it does show that gastric distention

with food tends to reduce hunger and appetite Similarly, if the stomach is partly filled with inert materials, the size of the subsequent meal will be reduced Inflation of a balloon in the stomach has the same effect (Janowitz and Grossman, 1949) That these effects are mechanical and not metabolic in nature is shown by the fact that, if the artificial feeding, instead of being given immediately before the regular meal, is given some 4 hr after, and time is allowed for it to be disposed of, the animal will eat a normal amount at the next regular meal, provided the artificial feeding was not too large As much as one-third of the animal's regular food consumption can be given in this manner over a period of time without affecting his voluntary intake (Share et al , 1952) The fact has already been referred to that animals so fed, although receiving 30% or more in excess of their regular food intake, do not necessarily gain weight The effect of gastric distention on hunger and appetite is doubtless due to the presence in the stomach of stretch receptors (Paintal, 1954) situated in the muscular walls and connected to afferent fibers of the vagus nerves, section of the vagi does away with the effects of gastric distention on appetite Indeed, vagotomy may produce a condition of hyperphagia comparable to that caused by lesions of the medial hypothalamic nuclei

The effects of the gastrointestinal stimuli are largely confined to determining the size of an individual meal They do not serve to regulate the overall balance between the energy intake represented by the food and the energy output represented by the total metabolism of the body Presumably, metabolic factors are responsible for this type of regulation, but any discussion of such factors at the present time would be speculation We know certainly only that some metabolic consequences of the assimilation of food are not effective as regulatory factors It has been shown, for example, that changes in blood sugar, at least those that are not associated with changes in arteriovenous glucose difference, have no effect on voluntary food intake, nor do they influence hunger contractions—except those induced by insulin (Quigley and Hallaran, 1932) An increase in the amino acid concentration of the blood caused by intravenous injection of amino acids has no effect upon voluntary food intake in dogs However, the slight increase in temperature which results from the presence of pyrogens in some intravenous solutions does definitely influence appetite, even though the rise in temperature is too small to be recognized clinically as a fever This, and the fact that taking food causes a slight increase in temperature due to the specific dynamic action of the food, has suggested to Brobeck (1957) the possibility that the increase in body temperature caused by the specific dynamic action of the food may be a factor which limits food intake (Fig 2 2)

Mayer (1955) has suggested that food intake is controlled in some way through the metabolism of glucose—the so-called glucostatic hypothesis Recognizing that hunger and appetite are not related to changes in blood sugar level, Mayer contends that they are governed by the utilization of carbohydrate food by the tissues "According to the glucostatic theory the mechanism postulated for the short term regulation of energy intake rests on the concept that somewhere, possibly in the hypothalamic centers shown to be implicated in the regulation of food intake, perhaps peripherally as well, there are glucoreceptors sensitive to blood glucose in the measure that they can utilize it " In other words, when the tissues are utilizing glucose rapidly, thus establishing a high arteriovenous glucose difference, the glucoreceptors are stimulated, and through their central connections suppress hunger and appetite and inhibit food intake On the other hand, when glucose is not available for tissue utilization, and the arteriovenous glucose difference tends toward zero, a state corresponding to tissue hunger exists, this is sensed in some way by the hypothalamic centers, which then facilitate the feeding reflexes

Another theory suggests that the total energy stores of the body are maintained at a certain predetermined level by the balance between

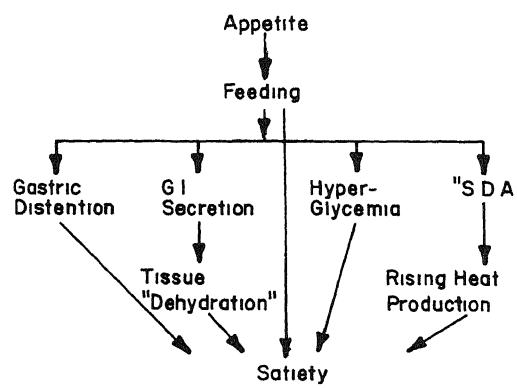

Fig 2 2 Outline of mechanisms taking part in transition from appetite to satiety (From Brobeck, 1957)

hunger and satiety Whatever the mechanism may be, it is evident that metabolic factors are important and quite possibly play a determining role in the regulation of the balance between food intake and energy output in the body

Thirst

The sensation of thirst is referred to the pharynx and is due to the stimulation of sensory nerve endings in this situation Two theories have been advanced to explain the mechanism by which the sensation is aroused

According to one view, thirst is due to the drying of the pharyngeal mucous membrane, the salivary glands being given a role in the regulation of the water balance of the body When the water content of the body falls below a certain level, salivary secretion is depressed The consequent drying of the mucous membrane of the throat then elicits the characteristic sensation If such a view is correct, drying of the pharyngeal mucosa, from whatever cause, should cause thirst Cannon (1929), who provided the principal support for this theory, found, in studies upon himself, that after abstinence from fluids for a time the depression of salivary secretion which resulted was definitely associated with thirst Atropine, which inhibits salivary secretion, also produced the typical sensation, and thirst aroused by the deprivation of water was relieved by the application of cocaine to the mucosa Pilocarpine, or acid substances which stimulate the flow of saliva, also relieve thirst In dogs, however, atropine and pilocarpine have no effect upon the water intake

According to the other view, thirst is a sensation resulting from changes in blood composition, probably due to a rise in its osmotic pressure, which stimulates the afferent nerve endings or perhaps acts upon central nervous structures Thus, Rowntree and his associates (Weir et al , 1922), found that thirst of diabetes insipidus was relieved neither by cocainization of the mucous membrane nor when salivation was induced by pilocarpine The experiments of Gilman (1937) suggest that cellular dehydration, rather than a rise in osmotic pressure, is the prime factor in arousing thirst Elevation of the osmotic pressure of the blood of dogs by the injection of a hypertonic salt solution, and the imbalance thus caused in the osmotic relationship between intra- and extracellular fluids, caused a much greater intake of water than an equivalent rise in osmotic pressure resulting from the administration of urea After the injection of salt, sufficient water was drunk to reduce quickly the osmotic pressure of the blood After injection of urea, to which the cells are readily permeable, and which did not disturb the osmotic relationships the water intake was but little increased and the osmotic pressure of the blood remained elevated In support of the view that a lowered water content of the cells is the true thirst stimulus, Gilman cited an experiment in which anhydremia was induced by the withdrawal of large quantities of extracellular electrolytes (e g , NaCl) without the withdrawal of water In such anhydremic animals, dehydration of the tissue cells does not occur, and although the oral mucous membranes are quite dry, there is no evidence of thirst and water is refused

The two theories are not incompatible, as is indicated by the work of Holmes and Gregerson (1947), who found that, in human subjects, following the intravenous injection of 300 ml of 5% sodium chloride, although there was an increase in plasma volume there was a considerable decrease in salivary secretion associated with the sensation of thirst This proves that the decrease in salivary secretion leading to a sensation of thirst may be caused by an increase in the osmotic pressure of the blood, and suggests that tissue dehydration may induce the sensation of thirst through the reduction in the flow of saliva

The neural mechanisms for the regulation of water intake are similar to those for the regulation of food intake Indeed, they are closely associated and have not as yet been clearly separated Certain types of injuries to the lateral hypothalamus induce not only a cessation of food intake but also cessation of water intake The animals die of dehydration unless given water by stomach tube (Greer, 1955, Morrison and Mayer, 1957) Greer found that stimulation of the dorsomedial nucleus in the cat caused violent drinking activity, thus there are probably centers in the hypothalamus for the regulation of water intake comparable to the feeding centers Like the intake of food, the intake of water is influenced by gastric distention Animals made thirsty by intravenous injection of hypertonic salt solution will usually drink an amount of water over a short period of time approximately equal to the amount necessary to dilute the injected salt to an isotonic concentra-

tion. If the stomach is distended by means of a water-filled balloon, the amount of water that is voluntarily drunk will be diminished and the replacement of the water deficit delayed. The vagi play a part in the regulation of water intake. Vagotomized animals not only eat more food but also drink more water than do normal animals. The food intake and the water intake are increased proportionately by vagotomy; they are decreased by sympathectomy (Towbin, 1955).

Excessive thirst also occurs in lesions of the anterior hypophysis, leading to diabetes insipidus. In this disease there is failure of production of the antidiuretic hormone of the anterior hypophysis, resulting in an excessive loss of water through the kidneys. In this case, thirst is probably secondary to dehydration.

2 / INNERVATION AND VISCERAL SENSATIONS OF THE GASTROINTESTINAL TRACT

The gastrointestinal tract receives an abundant nerve supply via the autonomic nerves In addition, it contains within its walls an elaborate plexus of interconnected ganglia This is usually described as consisting of two plexuses, the *myenteric plexus*, situated between the circular and longitudinal layers of the smooth muscle, and the *submucous plexus*, situated in the submucosa

Extrinsic Nerves

The autonomic nerves are classified as sympathetic and parasympathetic but it is more in keeping with modern thought to consider them as cholinergic or adrenergic, depending upon whether they liberate acetylcholine or an adrenaline-like substance at their final terminations In this sense, most parasympathetics are cholinergic and sympathetics are adrenergic, but there is considerable mixing, since cholinergic fibers have been demonstrated to be in considerable abundance in the sympathetics

The parasympathetic nerve supply to the gastrointestinal smooth muscle comes mainly from the vagus (Fig 2 3), however, the pelvic nerves supply the distal portion of the colon (Fig 2 4) The parasympathetic fibers, whether vagus or pelvic in origin, do not end directly on the smooth muscle cells but end by making synapses with cells in the enteric plexuses Therefore, as pointed out by Carlson et al (1922), they stand in relation to these plexuses as intercalated or internuncial fibers between reflex centers and not as ordinary motor nerve fibers The function of such fibers in the central nervous system, and presumably in this situation also, is to increase or decrease the excitability of the reflex centers and not to initiate muscular activity directly

The sympathetic supply to the stomach and small intestine is by way of the splanchnic nerves. The cecum, appendix, and ascending and transverse colon are supplied by nerves which arise from the superior mesenteric plexus This plexus is a derivative of the aortic plexus through which it also receives vagus fibers from the celiac plexus The lower part of the rectum is supplied by sympathetic fibers which arise from the upper and lower divisions of the hypogastric plexus The preganglionic sympathetic fibers end in the celiac, superior or inferior mesenteric, or aortic ganglia The fibers that reach the intestine, therefore, are postganglionic They probably have no functional relation to the enteric plexuses, even though they traverse the enteric ganglia and are distributed along with the postganglionic enteric plexus fibers Most of them are concerned with the vasomotor supply of the numerous blood vessels in the intestine but some go to the intestinal smooth muscle in the muscularis mucosae (Kuntz, 1953)

FUNCTION OF EXTRINSIC NERVES

The gastrointestinal tract is capable of carrying on its major functions after all the extrinsic nerves have been severed This automaticity may be attributed partly to the local nervous mechanism and partly to the properties of the smooth muscle Probably, the essentially rhythmic functions, such as gastric antral peristalsis and segmentic contractions of the small and large intestine, are dependent upon the properties of the smooth muscle, whereas the more highly coordinated functions, such as forward peristalsis in the small intestine and mass movements in the colon, are dependent upon the functional integrity of the myenteric plexus Both the neurogenic and myogenic functions are regulated through central nervous system reflexes by way of the autonomic nerves.

The tone and peristaltic activity of the stomach are usually increased on stimulation of the vagus nerves The statement that the vagus

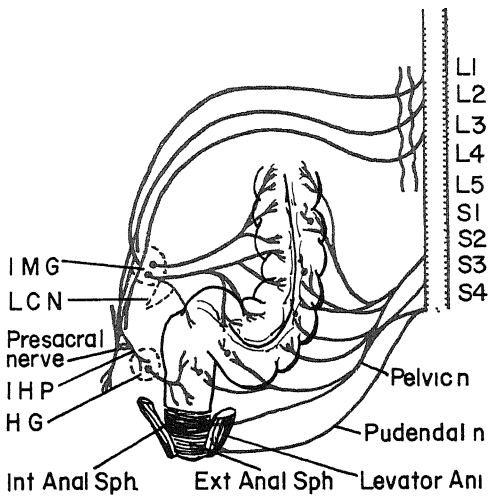

Fig 2 4 Diagram of the innervation of the distal colon

increases the activity of the muscle in the gastric wall while inhibiting the sphincters has been proved to be erroneous, when motor effects are observed in the muscle of the pyloric portion, for example, the pyloric sphincter responds in the same sense, thus the idea of a reciprocal innervation of the sphincters and the other muscle of the stomach is not borne out by the experimental facts

The effect on the stomach of stimulating the splanchnic nerves is usually described as inhibitory but it is far from being invariably so In simple acute experiments on anesthetized animals, increased motor activity is seen about as frequently as inhibition when the splanchnic nerves are stimulated Carlson and his associates (1922) pointed out that motor responses are more likely to be obtained when the muscle is in a state of relaxation, whereas inhibitory effects occur when the muscle is in a state of high tonus or vigorous activity This rule applies to both vagus and sympathetic stimulation, nevertheless, with the muscle in a medium state of tonus, the vagi will more often produce excitatory effects while the splanchnics produce inhibitory effects The reason for the preponderance of sympathetic motor effects in recently anesthetized, operated animals is that the stomach, in such circumstances, is always in a state of very low tone

In the small intestine, the parasympathetic nerves are nearly always excitatory and the sympathetics nearly always inhibitory (Fig 2 5), however, the excitatory vagus effects, as mentioned previously, are usually preceded by a brief inhibition In the upper portion of the small intestine, motor effects from stimulation of the sympathetic nerves are by no means uncommon The tonus rule holds here also, motor effects are more apt to be observed in the relaxed intestine

In the large intestine, stimulation of the parasympathetic innervation is reported to cause mainly increased activity, whereas stimulation of the sympathetic nerves gives results that are even more confusing than those obtained in the stomach Some investigators report only inhibitory effects, others report only motor effects, whereas still others report inhibition of the walls of the viscera with contraction of the sphincters

Visceral Reflexes

While studying the effects of electrical stimulation of autonomic nerves, it is well to bear in

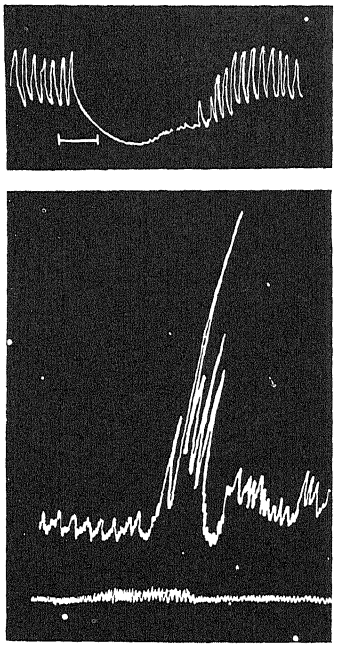

Fig 2 5 Upper inhibitory effect of splanchnic stimulation upon the movements of the small intestine the heavy white line indicates the time during which the stimulus was applied Lower effect upon intestinal motility of stimulating vagus nerves (After Thomas and Wheelon 1922)

mind the fact that nerves were not developed for the purpose of being artificially stimulated Under normal circumstances, the autonomic nerves serve only reflex functions, and when aroused normally through their reflex connections they may produce effects quite different from those seen on electrical stimulation Normal reflex stimulation is selective, exciting only those fibers which will promote the function subserved by the reflex, whereas ordinary electrical stimulation excites all the fibers without regard to their normal function

Certain gastrointestinal reflexes involving the peripheral autonomic nerves have already been mentioned, among these are the receptive relaxation of the stomach, the enterogastric reflex, and the so-called gastrocolic reflex These reflexes chiefly involve the parasympathetic nerves and are concerned with regulation of the normal functioning of the gastrointestinal smooth muscle Other reflexes have been described which occur only under unusual circumstances, and generally involve the functioning of the sympathetic nerve supply One of these is the *intestino-intestinal inhibitory reflex* This consists of reflex inhibition of the whole intestinal tract as a result of distention of some one segment The stomach may also be inhibited, but in this case we are dealing with a mechanism different from the enterogastric reflex previously mentioned The reflex is abolished or greatly diminished when the splanchnic nerves are cut, hence it involves discharge of impulses over the sympathetic nerves It probably belongs in the category of responses to noxious stimuli which, generally throughout the body, tend to cause increased activity of the sympathetic nervous system, and to inhibit gastrointestinal motility Other examples of reflex responses to noxious stimuli are inhibition of the intestine due to irritation of the peritonium, distention of the gall bladder and bile ducts, overfilling of the bladder, or forcible stretching of the anal sphincters All of these stimuli produce inhibition of the gastrointestinal smooth muscle through activation of adrenergic mechanisms, mainly the sympathetic nerves

Visceral Sensations

The abdominal and thoracic viscera are insensitive to the several types of stimuli which readily arouse sensations in the skin and more superficial tissues of the body The effects of the different varieties of stimulus, *thermal*, *chemical*, *tactile*, and *pain*, have been investigated by a large number of observers

TOUCH

The sensation of touch disappears at the lower end of the pharynx This was shown by Hurst (1911), who used an esophageal tube with a slit on one side through which the mucosa of the esophagus could be stimulated Carlson and Braafladt (1915), by means of a test-tube brush passed into the stomach, were unable to elicit the sensation of touch from the gastric mucosa The rectum possesses no tactile sensibility but the anal canal is sensitive

THERMAL SENSIBILITY

The esophagus is sensitive to extremes of heat and cold The sensations of temperature that are felt when hot or cold materials enter the stomach have been thought by some to originate in the lower end of the esophagus, by others to arise in the skin of the epigastrium, either through thermal conduction or by reflex changes in the cutaneous blood vessels. Carlson and his associates have shown, however, that the gastric mucosa is sensitive to extreme tem-

perature changes, i e , protophathic thermal sensibility (below 10° C or above 45° C) It is the lower end of the esophagus, however, which is responsible for the greater part of the thermal sensation that is experienced when excessively hot or cold materials are swallowed This is due to the greater sensitivity of the esophageal mucosa, as well as to the fact that the material may be retained for an appreciable length of time above the cardia The colon is insensitive to temperature changes, but even comparatively slight differences in temperature can be detected in the anal canal

CHEMICALS

Chemicals, with the exception of alcohol, cause no sensation whatever when introduced into the stomach or intestinal canal The mucosa is completely insensitive to acids, the introduction into the healthy stomach of a solution of 0 5% hydrochloric acid causes no pain or sensation of any kind Alcohol stimulates the mucosa of the esophagus and stomach and causes a sensation of warmth Peppermint and various condiments free from alcohol arouse no sensation The pelvic colon and rectum show a similar sensitivity to alcohol but are insensitive to other chemicals The anal canal is extremely sensitive, especially to alcohol and glycerine which cause a burning sensation

Pain

Sensations of pain cannot be elicited from the viscera by procedures that evoke pain in the skin The intestine or the liver, the stomach or the heart may be cut, burned, or pinched without arousing any immediate sensation In the second stage of a colostomy operation, for example, the colon can be opened without pain being experienced by the patient Harvey (1628, see 1962 ed) remarked upon the absence of sensation in the exposed heart of Viscount Montgomery Harvey records, "I carried the young man to the King (Charles I) that His Majesty might with his own eyes behold this wonderful case, that, in a man alive and well, he might, without detriment to the individual, observe the movement of the heart, and with his proper hand even touch the ventricles as they contracted And His Most Excellent Majesty, as well as myself, acknowledged that the heart was without the sense of touch, for the youth never knew when we touched his heart "

The insensibility of the alimentary tract to ordinary forms of stimulation commences in the middle third of the esophagus and extends as far as the commencement of the anal canal How can these observations be reconciled with the well-known fact that pain is one of the commonest manifestations of visceral disease?

The whole subject of pain arising in, or referred from, the viscera is still highly controversial No final answer can be given The most that can be attempted is a summary of some of the more significant experimental results and clinical observations, and the opinions of those who have especially interested themselves in the subject

REFERRED PAIN

When a viscus is diseased, pain or tenderness is frequently felt in the tissues approximately overlying it (abdominal or chest wall) or in some part quite remote from it For example, pain is felt in the neck or shoulder (Fig 2 6) in conditions affecting the diaphragm, between the scapulas in gastric disease, in the region of the umbilicus in appendicitis, in the testis in renal colic and in the sternal region, or down the left arm in angina pectoris Esophageal pain is frequently confused with that of cardiac origin, as it not only characteristically occurs substernally, but may extend into the neck, jaw, and even into the arms When traction is made upon a coronary artery of a dog, the animal whines and indicates the location of the pain by limping on the left forepaw In dextrocardia, anginal pain is felt in the right arm Other examples are the pain in the perineum and tip of the penis caused by a stone in the region of the neck of the bladder, and the pain in the groin due to a stone in the ureter

A given spinal segment supplies a visceral area with autonomic nerve fibers (afferent and

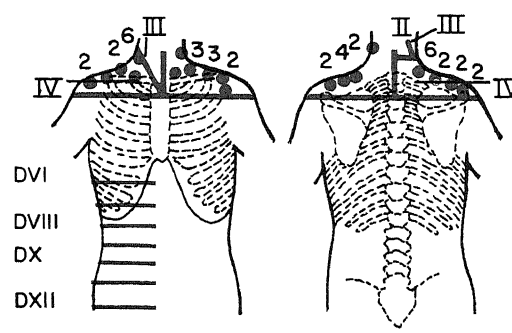

Fig 2 6 Location of maximum points of referred neck pain from diaphragm irritation in 23 cases They are all situated in the region supplied by the third and fourth spinal segments (After Capps and Coleman 1932)

efferent) and also a well-delineated area of the skin (dermatone) with somatic nerves The two types of structure linked in this way through the afferent nerves and the central nervous system may be some distance apart (e g , diaphragm and shoulder) or be more closely related (e g , area of abdominal wall and an underlying abdominal viscus) Mackenzie (1918) believed the afferent autonomic impulses arising in a diseased organ, although of themselves incapable of arousing any sensation, would, upon entering the spinal cord, set up an "irritable focus" with the result that cells accustomed to receive impulses from the corresponding somatic area were excited Thus, the impulses from the viscera spread, or "irradiated," on to cells of the corresponding somatic center New impulses originating in these cells traveled along the usual paths to higher perceptive centers (thalamus) which projected or referred the sensation to the somatic area, e g , skin or muscle, from which it was accustomed to receive impulses In this way, *spontaneous pain* in superficial structures remote from the diseased site was accounted for

Tenderness to touch, pressure, or light pinching of the skin (hyperesthesia and hyperalgesia) was ascribed to the impulses (which ordinarily would be below the threshold for pain) arriving in the segment rendered hyperexcitable as a result of impulses received from the diseased organ In the case of the abdominal viscera, Mackenzie claimed that the area of tenderness in the abdominal wall remained fixed, although the position of the diseased organ changed, thus indicating the referred nature of the pain He explained the rigidity (hypertonus) of muscles overlying a diseased organ (the right rectus abdominis in acute appendicitis, for example) upon a similar basis Afferent impulses of normal intensity arising in the muscle proprioceptors upon arriving at the spinal centers, which had been rendered hyperexcitable by the receipt of abnormal visceral impulses, resulted in a reflex increase in tonus of the corresponding muscles (see Fig 2 7)

Table 2 2 gives the segmental areas to which pain is referred in disease of various viscera

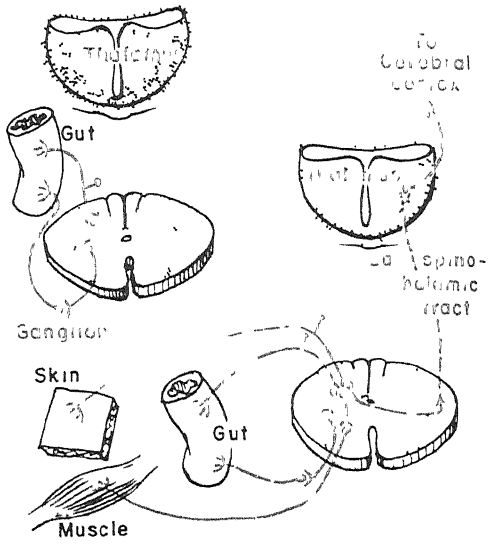

Fig 2 7 Diagram to illustrate Mackenzie's theory of referred pain (1920) A representing normal conditions a visceral reflex is shown B illustrates a visceromotor and a viscerosensory reflux Impulses from a viscus are conceived as setting up an irritable focus in the cord which through the involvement of neighboring neurons increases the tone of muscles innervated by the same segment and causes a discharge of impulses over the pathway for pain The sensation is then projected in consciousness to the periphery as indicated by the dotted line

VISCERAL PAIN

The pains of dysmenorrhea or childbirth, for example, or the pain of intestinal colic or an overdistended bladder, or the substernal pain of coronary occlusion, although diffuse, seem to arise within the organ itself, even when referred as well to a somatic structure, such as muscle or skin Kinsella (1948) observed that, in conscious patients, pressure with the fingers upon an inflamed appendix caused pain centered in the viscus, a healthy appendix is insensitive He and others have also shown that a chronic duodenal ulcer is also tender to direct contact In transsection of the cord at the third thoracic vertebra in a patient (reported upon by Kinsella, 1948), in whom there was complete paralysis and anesthesia of the abdominal wall, intestinal pain was experienced which obviously could not be caused by reference to somatic nerves Impulses in such cases must reach the central nervous system along intact visceral afferents They apparently travel by sympathetic fibers which enter the cord above the level of the transsection It is unlikely that they are transmitted by the vagus.

Pain in a normal viscus may also result from disease in a distant organ through a visceromotor reflex For example, painful contractions of the small intestine may accompany disease of the appendix A distinction should be drawn between pain of this nature and referred pain

Table 2 2
Spinal segments to which visceral pain is referred

Viscus	Spinal Segments
Lungs	1–7 dorsal, mostly 2–5 dorsal
Heart	3–5 cervical, 1–8 dorsal, predominantly on left side, sometimes bilateral
Esophagus	Mainly 5 dorsal, also 6, 7 and 8 dorsal
Breast	4 and 5 dorsal
Stomach	7, 8 and 9 dorsal, usually bilateral
Intestine	9–12 dorsal, bilateral or on left side only
Liver	8–10 dorsal on right side
Gall Bladder	Mostly 8 and 9 dorsal, also 5–7
Kidney	Mostly 10 dorsal, also 11 and 12 dorsal and 1 lumbar
Ureter	11 and 12 dorsal and 1 lumbar
Testis	10 dorsal
Epididymis	11 and 12 dorsal
Bladder	11 and 12 dorsal and 1 lumbar, also 3 and 4 sacral
Prostate	10 and 11 dorsal, also 1–3 and 5 sacral
Ovary	10 dorsal
Fallopian tubes	11 and 12 dorsal
Uterine cervix	11 and 12 dorsal and 1–4 sacral
Uterine body	10 dorsal to 1 lumbar

The Adequate Stimulus for True Visceral Pain. The existence of true visceral pain is not incompatible with the statement made above, that the viscera are insensitive to the ordinary types of stimulus From his investigations, Hurst (1911) concluded that the only adequate stimulus for visceral pain fibers is tension Distension of a hollow viscus, e g , stomach, intestine, gall bladder, etc , gives rise to pain, as a result of the stretch stimulus applied to the nerve terminals in its wall The pain is roughly localized to the viscus itself, or referred Under certain circumstances, chemical substances produced in an ischemic organ, as in angina pectoris or intermittent claudication, may stimulate nerve fibers subserving pain

Although the question is by no means settled, it appears that *contraction* of the muscular wall of a hollow viscus such as the intestine does not cause pain unless the movement of the bowel makes traction upon the mesentery Pain arises, however, if the contraction causes distention of a neighboring portion of the wall, as may result when the contraction wave approaches a mechanical obstruction, a length of bowel in spasm, or a sphincter which fails to relax (*achalasia*) Poulton (1928), for example, found that when a balloon was inserted into the lower part of the human esophagus, the approach of a peristaltic wave toward the obstruction caused pain, but during its passage over the esophageal wall in contact with the balloon, no sensation was felt Poulton ascribes the absence of pain during the passage of the contraction wave to the reduction in the diameter of the tube and the consequent release from stretch of the nerve endings lying between the muscle fibers Pain was also relieved if the esophageal muscle relaxed to accommodate the balloon, that is, adjusted the length of its fibers to the distending force

As further evidence for the effectiveness of distention in causing pain, the following observations may be cited In animals, when an intestinal loop exposed under local anesthesia is stimulated to powerful contraction, there is no evidence of pain, whereas even moderate distention of the loop (as by inflating it with a balloon) is manifestly painful Distention of the human appendix by the injection of fluids through an appendicostomy opening causes severe pain in the epigastrium or in the region of the umbilicus, and when the duodenum is distended by the injection of material through a duodenal tube, pain is felt on the right side The pain impulses undoubtedly reach the central nervous system through the splanchnic nerves Bentley and Smithwick (1940) distended the duodenum of patients whose splanchnics had been divided on one or both sides After unilateral denervation, distention caused pain on the unoperated side only, no pain whatever was felt after bilateral splanchnic section

Nausea

Nausea usually precedes the act of vomiting but may occur alone On the other hand, vomiting may occur without nausea, as in certain cerebral conditions The sensation is felt in the back of the throat or pit of the stomach, and in its milder degrees is merely a "sinking" sensation in the epigastrium It is frequently associated with vasomotor disturbances and sweating Increased tension upon the walls of the stomach or duodenum is a potent cause of the sensation, and Poulton (1928) has shown that it is also induced by distention of the lower part of the esophagus During the passage

of a peristaltic wave which relieves the tension upon the nerve fibers in the esophageal walls, the sensation is relieved. Barclay (1933) showed, by radioscopy in the human subject, that nauseous odors caused the lower border of the stomach to descend an inch or two, evidently as a result of sudden relaxation of the abdominal muscles. This movement would tend to stretch the esophagus and gastric walls and so exert tension upon the nerve endings. The stimulus which induces nausea, therefore, is apparently the same as that which causes visceral pain, but of lower intensity. It is likely that the sensations experienced during changes in speed of an elevator are also the result of tension exerted upon the esophagus and gastric walls. Tension is also probably a contributory factor in the production of seasickness, being brought into play by the pitch and roll of the ship.

The relief of nausea and vomiting by the application of counter-irritants to the epigastrium or over the sternum is probably due either to a reflex change in the tone of the gastric walls or to the reflex initiation of peristaltic contractions.

The tension upon the nerve endings in the latter instance is taken up by the muscle fibers. Poulton (1928) observed, for example, that the sensations caused by a balloon in the esophagus were relieved by vigorous friction of the skin over the sternum; contraction of the esophagus in some cases, or adjustment of the postural tone of the esophageal wall in others, were observed to accompany the disappearance of the sensation.

3 / GASTROINTESTINAL HORMONES

Some background information on the range of actions of gastrointestinal hormones is required for a better understanding of the sections which will follow on gastrointestinal secretion and motility

The great explosion of interest in the principal gastrointestinal hormones has followed from their chemical identification, purification, and, finally, synthesis These hormones are *gastrin* (Edkins, 1906), which "primarily" stimulates the gastric secretion of acid, *secretin* (Bayliss and Starling, 1902), which primarily stimulates the pancreatic secretion of bicarbonate and water, *cholecystokinin* (Ivy and Oldberg, 1928), which contracts the gallbladder, and *pancreozymin* (Harper and Raper, 1943), which stimulates the pancreatic secretion of enzymes

When these substances were available in pure form (Table 2 3), it became clear that pancreozymin and cholecystokinin, as had been suspected, are one substance Secondly, pancreatic glucagon, secreted by the alpha cells of the islets of Langerhans, was found to resemble the other gastrointestinal hormones, especially secretin, which it rather closely resembles in portions of its amino acid sequences Thirdly (Table 2 4), the terminal tetrapeptides of gastrin and cholecystokinin-pancreozymin are identical

However, the most striking finding was the fact that each of the three pure gastrointestinal hormones has an effect on each of the four primary or identifying actions by which the hormones were first described Table 2 5 from the work of Grossman (1970) sets this out

Further, as the effects of these four hormones were explored, their targets became more and more numerous Now the list includes *1)* water and electrolyte secretion by stomach, pancreas, liver, and Brunner's glands, *2)* enzyme secretion by stomach and pancreas, *3)* water and electrolyte absorption by ileum and gall bladder, *4)* release of insulin, glucagon, secretin, and gastrin, *5)* smooth muscle of lower esophageal sphincter, stomach, small and large

Table 2 3

Structures of gastrointestinal hormones[a] The structure of secretin and gastrin have been confirmed by total synthesis Synthesis of the active C-terminal heptapeptide amide of cholecystokinin has also been accomplished

bowel, gallbladder, and sphincter of Oddi and uterus, *6*) release of histamine and augmentation of histadine decarboxylase activity in gastric mucosa, *7*) amino acid uptake by gastric mucosa and pancreas, *8*) growth of gastric mucosa and pancreas, *9*) some metabolic actions lipolysis and glycogenolysis, and *10*) cardiovascular actions including inotropic and chronotropic actions on the heart and effects on blood flow in bowel, liver, gastric mucosa, pancreas, and extremities Table 2 6, from the pioneer work of M I Grossman (1970), details the stimulating and inhibiting actions of these four hormones as they affect secretion, absorption, and muscle contraction

To order this complex area of data, Grossman has hypothesized that the target organs contain a receptor complex with two units —one reactive to gastrin and cholecystokinin, and the other to glucagon and secretin—and that the two sites interact

The great unsolved problem is whether the effects on sites of other than the primary or identifying organ have any "physiological" significance, since in some instances, large doses must be employed In many, however, the dose range seems to fall in the "physiological" one

In addition to the interaction of hormone

with hormone so far discussed, interactions between neural effects and hormones on the gut are likewise important, especially *vagal* effects These are of two main kinds, the vagal release of hormones (especially in stimulation of acid secretion) and vagal effects on the action of the hormones on the target cells (especially the gastric glands), but there is no reason not to think that these interactions hold for the remainder of the gut

4 / SALIVARY SECRETION

The Salivary Glands

Only mammals possess true salivary (digestive) glands Oral mucous glands, however, are found in all terrestrial vertebrates There is considerable variation in the number of salivary glands and also in the cellular structure of individual glands In addition, the products of secretion by salivary glands vary not only from species to species, but from one salivary gland to another in the same animal

In man, salivary secretion is provided by three pairs of glands, the *parotid*, *submaxillary*, and *sublingual* glands Also located within the oral and pharyngeal cavities are numerous other smaller glands that contribute to the production of saliva These smaller glands include the lingual mucous glands located along the borders and at the root of the tongue, lingual serous (Ebner's) glands located in the vicinity of the vallate and foliate papillae of the tongue, and numerous small mucous glands in the mucous membrane covering the cheeks, hard and soft palate, and the walls of the pharynx

The production of saliva by the salivary glands provides the first digestive juice that comes in contact with food In addition to containing salivary amylase that initiates starch digestion, the salivary secretions play an important role in oral hygiene, the sensitivity of taste perception, the process of deglutition, and also serve as a medium for the excretion of certain inorganic and organic substances

GENERAL FORM AND LOCATION

The *parotid glands* are the largest of the salivary glands and in the adult weigh from 20 to 30 g each The parotid gland is located at the side of the face below and in front of the ear

This gland is enclosed in a sheath which limits the swelling of the inflamed gland Because of this facial presentation of the gland, relatively small degrees of swelling are often conspicuous, as in mumps As the anteromedial surface of the gland is in intimate contact with the masseter muscle and the ramus of the mandible, movement of these structures when chewing usually aggravates the pain and tenderness of a swollen parotid gland

The *duct system* of the parotid gland originates in the *acini* of the gland Ducts from neighboring acini join to form ducts of larger caliber which unite again to form still larger ducts The fine ducts that drain the acini are known as *intercalated* ducts The intercalated ducts empty into *intralobular* ducts and these into *interlobular* or excretory ducts Thus, by a progressive convergence of the several orders of ducts, the gland's secretion is conducted finally into a single large duct which opens into the oral cavity This general arrangement of the ductal system is similar to the stem branching of a bunch of grapes—the rounded acini at the ends of the finest channels corresponding to the grapes The term *racemose* (Latin for bunch of grapes) has been applied to glands exhibiting such a structure, and *acinus* (Latin for grape) identifies the smallest group of secretory cells of such a gland

The parotid duct (*Stensen's duct*) emerges from the anterior border of the gland near its upper end and runs transversely across the surface of the masseter muscle At the anterior border of the masseter muscle, the parotid duct abruptly turns medialward, pierces the buccal fat pad and the mucosa to open into the oral cavity at a point lateral to the crowns of the second upper molar The parotid duct is approximately 35 to 40 mm long and about 3 mm in diameter The wall of the duct is tough due to the presence of a thick layer of fibrous tissue

The *submaxillary glands* are shaped somewhat like a flattened walnut and weigh 8 to 10 g each They are located in the submaxillary triangle medial to the mandible Like the parotid glands, the submaxillary glands have a racemose structure The duct system is similar to that of the parotid glands and collects in a large, single submaxillary duct known as *Wharton's duct* The submaxillary duct emerges from the deep surface of the gland and runs forward

and inward to reach the floor of the mouth It opens by a small orifice on the summit of a soft papilla known as the *caruncula sublingualis* by the side of the frenulum of the tongue The submaxillary duct is 40 to 50 mm in length and the walls of the duct are relatively thin

The *sublingual glands* are the smallest of the paired salivary glands and weigh from 2 to 3 g each The sublingual glands are elongated in shape and lie immediately under the mucous membrane of the floor of the mouth under the tongue The structure of the sublingual gland is also racemose Instead of being drained by a single, large duct, the sublingual glands are drained by 5 to 15 or more small, short ducts (*ducts of Rivinus*) that arise from the upper border of the gland and open on small papillae along the crest of the *plicae sublingualis* The anterior portion of the gland is often drained by a single, larger duct, also known as *Bartholin's duct*, which opens alongside the submaxillary duct on the sublingual caruncle Unlike the parotid and submaxillary glands, the capsule of the sublingual glands is poorly developed

MICROSCOPIC ANATOMY

The racemose structure of the salivary glands is found on histological section to consist of acini, a tubule system, and excretory ducts The secreting epithelium of the acini is composed of two types of cells, *mucous* and *serous*, that can be differentiated from one another on the basis of nuclear appearance and staining reactions The nucleus of the mucous cell is small, dark-stained, indented and compressed against the lower pole of the cell The serous cell possesses a larger, centrally placed vesicular nucleus Four different types of cells may be distinguished in the lining of the salivary ducts In addition, *myo-epithelial* cells which have been described in detail by Zimmerman (1927) have been demonstrated between the basal membrane of the acini and ducts

Acinar Structure The acini of the salivary glands are composed of cells that are more or less pyramidal in shape The apices of adjacent cells of an acinus converge upon a minute central lumen, the basal aspects of the cells form the periphery of the acinus The central lumen is continuous with that of the excretory duct system

The acini of the parotid gland in *man* consists entirely of serous cells. Parotid secretion collected separately from the other salivary glands has a characteristic watery character or serous secretion In man, submaxillary gland serous and mucous elements are seen in a ratio of about 4 1 More often than not the mucous acini are "capped" by a single layer of flattened serous cells, referred to as serous demilunes (Fig 2 8) The secretion of the serous demilune is believed to reach the lumen of the acinus by means of small canaliculi between the mucous cells The acinar structure of the sublingual glands is similar to the submaxillary gland except that the ratio of serous to mucous elements is about 1 4

The mucous cells have large translucent granules which readily transmit light, so that in thin sections they appear transparent The serous cells have small granules that are more opaque and appear darker in sections than the mucous cells The serous cells secrete a thin, watery fluid containing the starch-splitting enzyme, amylase, also known as *ptyalin*

The myo-epithelial, or basket cells, are flat

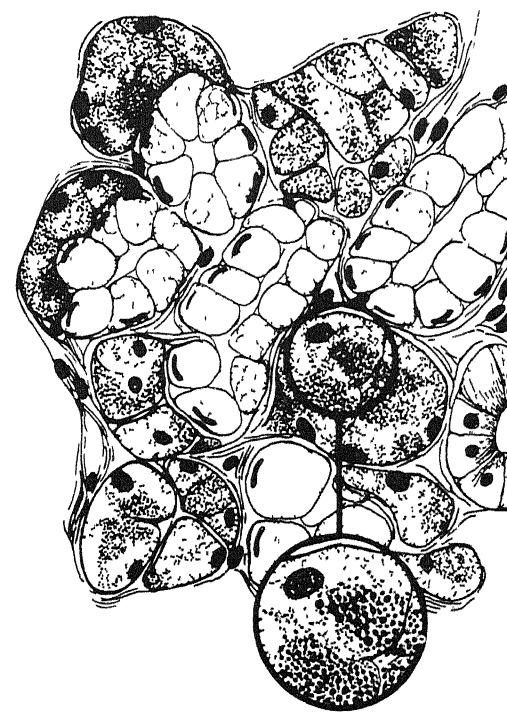

Fig 2 8 Microscopic section of human submaxillary gland showing both mucous and serous groups of cells The mucous cells are lightly stained and appear transparent The serous cells are darker and some appear as demilune cells in the upper left area of the microscopic section The insert is an oil immersion view showing zymogen granules in serous cells (From Stormont 1932)

and somewhat star-shaped with long processes, and, as previously mentioned, lie between the basement membrane and the secretory cells of the acinus They are also found in the intralobular salivary ducts between the basement membrane and the cells lining the lumen The myo-epithelial cells are modified epithelial cells and are thought to have a contractile function, although there is no clear evidence of this The myo-epithelial cells of the salivary glands may serve a function similar to the myo-epithelial cells of the mammary gland In the mammary gland, these cells are well developed and it has been established that their contraction results in the expulsion of preformed milk from the ducts This is observed in the lactating breast and is known as "let down " It has been observed that stimulation of the sympathetic nerve supply to the salivary glands sometimes causes a sudden gush of saliva from the gland This suggests that some previously secreted saliva is being expressed from the ducts by contraction of the myo-epithelial cells

The cytoplasm of both the serous and mucous cells show a glandular structure The fine granules of the serous cells are believed to furnish the enzymes of the secretion and are called zymogen granules The mucinogen granules of the mucous cells provide the mucin that renders the secretion viscous When the glands are in a resting state, the granules accumulate and the fine zymogen granules may load the cytoplasm to such an extent that the nucleus is almost obscured The concentration of secretory granules, mucous as well as serous, is low soon after meals and gradually increases prior to the next meal The *ultrastructure of the serous cells* of the salivary glands has been found to be quite similar to the acinar cells of the pancreas

Nerve fibers have been observed penetrating the basement membrane of a salivary acinus and ending as fine filaments on the basal surface of the acinar cells (Scott and Pease, 1957) The electron microscope reveals the myo-epithelial cell to have a close resemblance to a smooth muscle cell (Porter, 1954) This similarity tends to support the theory that the myo-epithelial cells have a contractile function

Ductal Structure Four different types of cells are found in the salivary ducts In the *intercalary ducts* that lead directly away from the alveoli, the epithelium is *cuboidal* in character These small cuboidal cells are practically filled by a large nucleus The cytoplasm is scanty and rarely are any cytoplasmic granules observed The *intralobular ducts* are lined by *columnar* cells that present a peculiar rod-shaped appearance, resembling in this respect, some of the cells of the renal tubules These cells have a centrally placed nucleus and there is a marked striation of the basal one-third of the cell Electron micrographs reveal that the marked striation observed by the light microscope in the basal third of the columnar cells lining the intralobular ducts is due to the alignment of mitochondria by infoldings of the plasma membrane This arrangement, which greatly increases the surface area of the cell, suggests that it facilitates the transport of materials into or out of the cells The *interlobular* or excretory ducts of the salivary glands are lined by a *two-layered epithelium* composed of a *columnar* superficial layer and a *flattened* deep layer This type of lining of the excretory ducts is continued to near the termination of the duct, where it empties into the mouth At this point, the lining of the duct changes to a layered, *stratified, squamous epithelium* The fact that the cells that line the various portions of the salivary ducts differ in structure suggests that their functions may be different The rod-shaped epithelium of the intralobular ducts is particularly suggestive of a secretory or reabsorptive function

INNERVATION OF THE SALIVARY GLANDS

The salivary glands are supplied with efferent nerves from both the *parasympathetic* and *sympathetic* divisions of the *autonomic nervous system* Functions regulated by the parasympathetic nerve supply are secretion by the acinar cells and vasodilation of the blood vessels Functions regulated by the sympathetic nerve supply include vasoconstriction of the vascular supply, and, presumably, contraction or motor function by the myo-epithelial cells

The origin of the *parasympathetic nerve supply* is in *bulbar centers*, which consist of a group of nerve cells which run forward from the anterior end of the glossopharyngeal nucleus to the sensory nucleus of the facial nerve The anterior (rostral) part is termed the *superior salivary nucleus*, and governs secretion by the submaxillary and sublingual glands, the posterior (caudal) part, called the *inferior salivary nucleus* controls secretion by the parotid gland

The *submaxillary and sublingual glands* receive secretory impulses through the *chorda*

tympani nerve The preganglionic fibers carried by the chorda tympani end in the submandibular ganglion by making synapse with the cell bodies of the neurons of the ganglion The axons arising from the latter constitute the postganglionic fibers which terminate by fine arborizations around the serous cells of the submandibular gland (Figs 2 9 and 2 10)

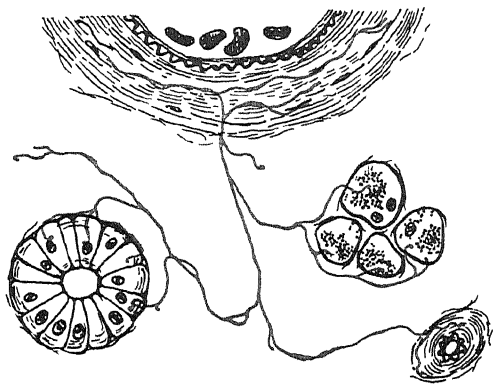

Fig 2 9 Distribution of parasympathetic secretory nerves to cells and blood vessels of submaxillary gland of rabbit (From Stormont 1932)

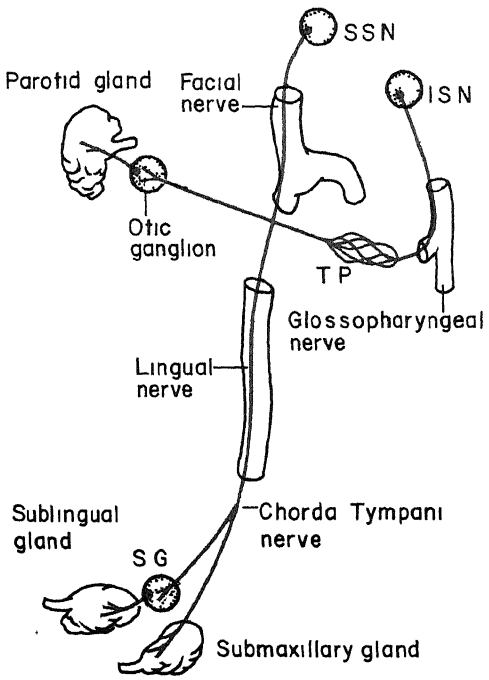

Fig 2 10 Diagram of the parasympathetic nerve supply of the salivary glands S S-N superior salivatory nucleus I-S-N inferior salivatory nucleus S-G submaxillary ganglion T-P tympanic plexus

The parasympathetic or bulbar fibers to the *parotid* gland arise in the medulla from the *inferior salivary nucleus* They pursue the first part of their course in the *glossopharyngeal nerve* The fibers then are conveyed to the *otic ganglion* There they communicate with ganglion cells from which postganglionic fibers arise that innervate the acinar cells

The *sympathetic nerve supply* (preganglionic fibers) to the salivary glands is derived from the lateral horn within the first and second thoracic segments of the spinal cord Axons from the lateral horn cells leave the cord via the ventral roots, enter the paravertebral sympathetic trunk, and continue craniad to the *superior cervical ganglion* where synapse is made with the cell bodies of the second order neuron From the latter, axons arise and follow the external carotid artery to the parotid gland Whether or not these fibers innervate more than vascular musculature is a moot question

Afferent nerve fibers from the salivary glands are found in the *chorda tympani* and the *glossopharyngeal nerves* These fibers carry pain impulses from the salivary glands Claude Bernard (1858) showed that stimulation of the submaxillary gland in a nonanesthetized dog caused evidence of pain Swelling of the gland, as occurs in mumps or when the main salivary duct is obstructed, is also known to be painful

BLOOD SUPPLY AND LYMPHATIC DRAINAGE

Blood flow within the salivary glands, as we shall see later, has an intimate relationship to the process of salivary secretion The arterial supply to the parotid gland is from the *posterior auricular* artery The arteries to the submaxillary gland are derived from the *external maxillary* (facial) and *lingual* arteries, while the arterial supply to the sublingual gland is supplied from the *sublingual* and *submental* arteries In the case of the submaxillary and sublingual glands, the main arterial supply enters the gland at the hilus The parotid gland does not have a well-defined "hilus," and, correspondingly, point of entrance of its arterial supply is subject to variation

Within the gland substance, the arterial supply travels with the interlobular ducts into the lobules Within the lobules, the arteries break up to form a rich capillary plexus about the ducts Consistent with the observation that the ducts perform active transport functions is the fact that the vascularization of the ducts is

much richer than that of the acini Arteriovenous anastomoses similar to the juxtaglomerular vessels in the kidney have been described by Spanner (1937) The function of such arteriovenous anastomoses is not known The capillary plexuses about the alveoli and ducts collect in venules which, in general, accompany the ducts out of the lobules Near the hilus of the gland, Spanner has described large sacculated veins which he suggests serve a reservoir function and tend to back up pressure in the capillary circulation during secretory activity Because of this suggested function, these sacculated, venous structures have been referred to as "throttle" veins Similar veins are found in the penis In studies on the circulation within the salivary glands, Burgen and Seeman (1958) have found that most of the blood perfusing the gland went to capillaries in the duct system and that the flow in these was mainly countercurrent to the flow of the saliva

Lymph spaces are found around the acini which drain into lymphatics that accompany the ducts and vessels Lymphatic drainage from all of the salivary glands is into the superficial and deep cervical glands

Formation of Saliva

The mechanisms of salivary secretion that result in the formation of saliva have been studied extensively but still are only incompletely understood It was thought that the formation of saliva was accomplished by processes similar to those that result in the production of urine by the kidney It was assumed that saliva was an ultrafiltrate of the blood The ultrafiltration theory was disproved by Ludwig (1851) when he showed that the submaxillary gland could secrete against a pressure greater than its arterial blood pressure

It is now recognized that the mechanism of salivary secretion is one that requires energy for the production and secretion of organic substances by the acinar elements and for the "active transport" of inorganic substances across cell membranes against concentration gradients by the duct epithelium

The evidence that salivary secretion is a process that requires energy has been accumulated in a number of ways Northup (1935) has shown that the salivary gland utilized a metabolic process to obtain energy for the work of secretion that is in many ways similar to that of muscle

The *respiratory quotient* (RQ) of slices of maxillary gland suspended in Ringer's solution was found by Deutsch and Raper (1938) to be between 0 6 and 0 8 When they added acetylcholine and eserine to the Ringer's solution, the rate of respiration was increased, but in the absence of glucose, the RQ did not change If glucose was added to the slices during incubation, the RQ increased to 1 0 Epinephrine had an effect similar to that of acetylcholine

Barcroft (1914) found oxygen consumption for the resting submaxillary gland of the dog to be from 22 to 27 μl /g /min In the submaxillary gland of the cat, Stromblad (1957) obtained a value of 20 μl /g /min When the gland is stimulated by injecting acetylcholine or by parasympathetic stimulation, the oxygen consumption increases to 130 to 175 μl /g /min Atropine can block the metabolic effects of acetylcholine Metabolic poisons such as cyanide, iodoacetate and fluoride are also capable of blocking the metabolic effect of acetylcholine

It has also been shown (Hokin and Hokin, 1959) that acetylcholine and epinephrine will increase the incorporation of radioactive phosphorus into the phospholipids of the rabbit parotid and submaxillary and in guinea pig parotid gland slices Atropine and ergotamine are capable of blocking this effect A large proportion of the total respiration of the salivary glands must be attributed to the duct epithelium since these cells possess mitochondria in very high concentration

It is now recognized that the intralobular ducts contribute considerably to the formation of saliva Since saliva is hypotonic to blood serum, this must be accounted for either by the reabsorption of electrolytes in the ducts or by the lack of transfer of electrolytes into the saliva across the cellular membrane To elucidate the role of the salivary ducts in the formation of saliva, Burgen and Emmelin (1961) devised an ingenious method to demonstrate the site of entry of various substances into the saliva by the ductal epithelium The method consisted of rapidly injecting a small amount of an isotope into the arterial blood supply of the salivary gland when the gland is secreting at a steady state The appearance of the isotopic substance in the collected saliva is then determined The amount of isotope used is quite small and thus the secreting gland is exposed to the isotope only briefly After passage through the gland, the isotope is diluted in the animal's blood and body fluids

The appearance time of the isotope in the

saliva is only a matter of seconds and is an indication of the site of its passage across the ductal epithelium to enter the saliva Thus, the more rapid the appearance of the substance in the saliva, the larger the order of duct representing the site of transfer When two or more isotopic substances are injected simultaneously, the same relationship holds, i e , the substance that appears first in the saliva was transported by the ductal epithelium at a point along the duct system that is distal to that at which the other substance was transported Using this technique, the appearance time of water, chloride, bromide, iodide, sulfate, bicarbonate, sodium, potassium, urea, and four amino acids have been determined in parotid saliva of the dog None of the four amino acids, valine, methionine, isoleucine and tyrosine, nor sulfate were detected in any appreciable amounts in the saliva All of the other isotopes appeared after a more of less brief latent period of 2 to 10 sec Following the appearance of the isotopic substance, its concentration rapidly increased to a peak in 5 to 6 sec , then gradually declined during the next 2 to 3 min (Fig 2 11)

Isotopic water appeared first in the saliva, indicating that it was capable of being transported across the ductal epithelium at a more distal site than any of the other substances

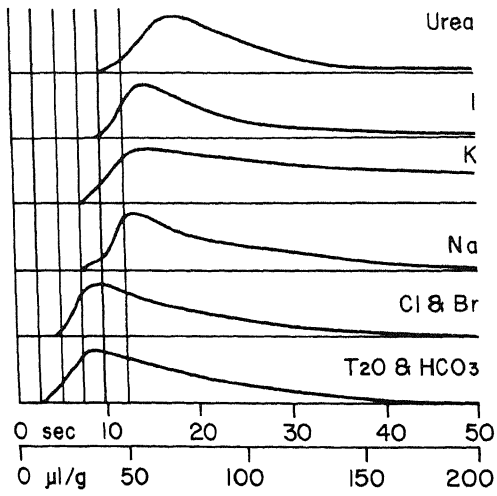

Fig 2 11 Secretion patterns of various isotopic substances after injection into the arterial blood supply of the parotid gland of the dog The appearance of the isotopes was determined in single drops of saliva secreted by the gland Note that tritiated water and bicarbonate appeared first and urea last Except for potassium the outflow curves of all other substances were similar (re-drawn from Burgen and Emmelin 1961)

Bicarbonate was found to enter the saliva at the same point as water and had a similar time concentration pattern Chloride and bromide appeared next, indicating that they entered the saliva through the epithelium of somewhat smaller ducts than those of water and bicarbonate Sodium and potassium ranked third in order of appearance, iodide and urea, fourth It will be noted from Figure 2 11 that the declining slope of the potassium curve after it reaches a peak is quite slow This slow decline of the potassium concentration is taken as evidence that potassium is also secreted into the saliva by the acinar cells

The fact that anions can enter the ducts at a more distal site than cations suggests that anionic exchange may occur at this point If cations are unable to enter the duct at some point, the only explanation of anion entry would be by an anionic exchange mechanism It will be discussed later that there is a reciprocal relationship between bicarbonate and chloride that is controlled by the arterial P_{CO_2} The bicarbonate-chloride exchange may occur in the more distal part of the salivary ducts

Composition of Saliva

The composition of saliva consists mainly of water, inorganic constituents commonly found in the plasma, and certain organic constituents The variability of the composition of saliva is accounted for by the fact that the different salivary glands contribute different constituents and the final composition is adapted to stimuli evoking the secretion In addition, the concentration of many of the common inorganic constituents depends upon flow rate

VOLUME AND FLOW RATE

In man, the amount of saliva secreted in 24 hr amounts to 1000 to 1500 ml (about 1 ml /min) A large proportion of this 24-hr volume is secreted at mealtime, when the secretory rate is highest In the absence of stimulation, as during sleep, the secretory rate is low and may not exceed 0 25 ml /min Schneyer and Levin (1955) have determined that under "resting" conditions the parotids contribute approximately 25%, the submaxillary gland 70%, and the sublinguals 5% In the dog, the maximum secretory rate of the parotid gland is approximately 0 5 ml /g of gland/min , whereas the maximum rate of the submaxillary gland is approximately 1 ml /g of gland/min

Ordinary mixed saliva contains about 99 5% water and 0 5% total solids The specific gravity of mixed saliva is usually between 1 002 and 1 012 The osmolarity of saliva from all of the salivary glands in man is slightly hypotonic to that of plasma Thus, some osmotic work is required for the secretory process The osmolarity of saliva can be increased by dehydration and decreased by subsequent hydration

REACTION

Human mixed saliva is slightly acid in reaction In a large series of normal persons, Starr (1922) found the pH of mixed saliva to vary between 5 75 and 7 05 The pH of saliva is dependent mainly upon the relative concentrations of free and combined CO_2, that is, upon the ratio of $H_2CO_3/NaHCO_3$ Thus, for the true pH value to be obtained, the juice must be collected without loss of CO_2 The older figures in the literature of 7 50 to 8 00 for the pH of saliva are too high, the precaution to prevent loss of CO_2 was not taken The pH of the saliva varies directly with the CO_2 content of the blood This means that when the CO_2 tension in the blood is high, more CO_2 finds its way into the salivary secretion to lower its pH and vice versa Force breathing causes a lessened amount of CO_2 in the saliva and, consequently, a rise in its pH

The *bicarbonates*, and to some extent, the *phosphates*, act as "buffers" in saliva This buffering action is such that the pH of saliva remains relatively constant under all ordinary conditions Even when relatively strong solutions of acid or alkali are introduced into the mount, the reaction, except for such a short period, is not altered

INORGANIC CONSTITUENTS

Bicarbonate concentrate in saliva increases with salivary flow At low rates of secretion, the bicarbonate concentration may be from 5 to 10 mEq /liter With increased rates of secretion, the bicarbonate concentration *exceeds* that of the serum In human parotid saliva, the bicarbonate concentration may go as high as 60 mEq /liter Sublingual saliva has a low bicarbonate concentration Salivary bicarbonate is derived from both gland metabolism and the transfer of bicarbonate from the plasma to the saliva

With changes in bicarbonate concentration, there is a reciprocal change in the chloride concentration and the total anionic concentration is not markedly altered Thus, with an increased arterial P_{CO_2}, bicarbonate enters the saliva and exchanges for chloride The site of this anionic exchange is probably in the more distal parts of the striated salivary ducts

Phosphate concentration in saliva is about twice that of plasma and relatively independent of flow rate Approximately 80% of the phosphate is present as inorganic phosphate The organic phosphate in saliva is acid-soluble and partially split by phosphates

Chloride concentration of saliva from different glands may show considerable variation In general, there is nearly a linear relationship between the chloride concentration and flow rate (see Fig 2 12) At all flow rates, however, the salivary chloride concentration is *below* that of plasma and may vary between 5 and 70 mEq /liter An exception to this general observation is sublingual saliva from the cat, which has a higher chloride concentration than that of plasma Sublingual saliva of man has a higher chloride concentration than parotid or submaxillary saliva

In patients with salt depletion, there is usually little change in the salivary chloride Thus, the salivary chloride concentrations tends to be independent of plasma chloride concentration

Salivary secretion of *bromide* is similar to that of chloride However, the salivary/plasma ratio tends to be slightly higher Little is known about the secretion of *fluoride* by the salivary glands except that it is secreted in the saliva at a lower concentration than the other halides McClure (1941) has reported that the salivary

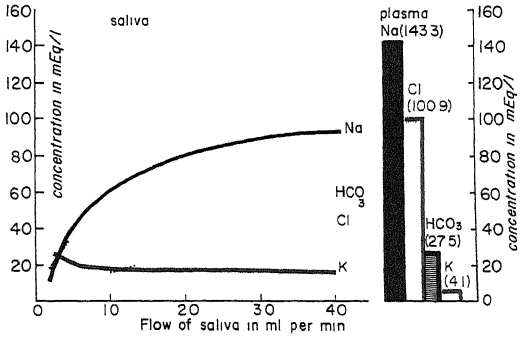

Fig 2 12 Relationship between concentrations of sodium potassium chloride, and bicarbonate in human parotid saliva and rate of salivary flow Plasma concentrations of the ions are also shown (From Thaysen et al 1954)

concentration of fluoride in children is from 0 006 to 0 015 mEq /liter Because of the relationship of fluorides to dental caries, more information is needed on the salivary secretion of fluoride

Sodium concentration in saliva is highly dependent upon the rate of saliva flow At low flow rates, the concentration may be less than 5 mEq /liter, whereas at high flow rates, it may exceed 100 mEq /liter Thus, it is impossible to give a "normal" sodium concentration for saliva Resting saliva in normal children contains from 2 to 15 mEq /liter of sodium In children with cystic fibrosis of the pancreas, the sodium concentration is increased and reaches levels from 20 to 45 mEq /liter

Potassium concentration of saliva is relatively high and exceeds that of the blood plasma All of the main salivary glands of man secrete potassium at a concentration higher than that of plasma Ordinary mixed saliva usually contains 8 to 20 mEq /liter of potassium which is 1 5 to 4 times the concentration in plasma Values as high as 50 to 60 mEq /liter have been found in the submaxillary and sublingual saliva of rats The potassium concentration of saliva resulting from sympathetic stimulation is about twice that obtained with parasympathetic stimulation

The concentration of *calcium* in human parotid saliva, like sodium, increases with flow rate At high flow rates, a concentration of 3 to 4 mEq /liter may be found

ORGANIC CONSTITUENTS

Salivary proteins account for the physical characteristics of saliva Parotid saliva has a low viscosity and is watery in character, whereas submaxillary saliva usually is viscous and sticky due to its mucoprotein content With increasing flow rates, the concentration of protein increases However, with prolonged stimulation, the quantity of protein secreted per unit of time progressively decreases This suggests that protein production by the salivary glands is relatively slow compared with the rate of protein secretion Stimulation of the sympathetic nerves to the submaxillary gland of the cat or dog produces a saliva rich in proteins The concentration and character of the proteins differ from that obtained by parasympathetic stimulation

The proteins are extremely complex in nature and the older classification into albumins and mucins is inadequate Electrophoretic, ultracentrifugation and immunological methods have been used in attempts at identification and classification of salivary proteins The electrophoretic pattern of salivary proteins differs greatly from that of serum In human parotid saliva, the main electrophoretic peak is *amylase* In submaxillary saliva, the major component is a *mucoprotein* of low mobility

Free amino acids are found in saliva Their concentrations are usually 10 to 20% of the plasma levels When plasma levels of free amino acids are raised, the concentration of the amino acids increase in saliva *Urea, uric acid* and *creatinine* are also found in saliva

Amylase is the main digestive enzyme of parotid saliva in man Amylase is also found in the saliva of apes, rabbit, guinea pig, rat and mouse Very little amylase is found in parotid and submaxillary saliva of the dog, cat, cow, horse, sheep, and goat Apparently, starch digestion by salivary amylase is not too important in some animals Amylase can be crystallized from saliva by successive acetone and ammonium sulfate precipitation The optimum pH of amylase is 6 9 to 7 1 and requires chloride ions for its activation The Ca^{++} ion is also required for the activation of amylase Each mole of amylase contains 1 gram atom of calcium, which, if removed, inactivates the amylase

On acrylamide electrophoresis, crystalline salivary amylase has been demonstrated to consist of a number of isoamylases There is usually a major amylolytic band and up to five minor amylolytic bands The number of isoamylases in parotid saliva may vary from three to six in different individuals (Hall, Gulig, Hightower, 1969, Boettcher and de la Lande, 1969) The isoamylases have a molecular weight of approximately 50,000

Lysozyme is an interesting enzymatic substance found in saliva This enzyme, which appears to be a mucoprotein, has the ability of lysing certain bacteria Lysozyme is bacteriolytic for organisms belonging to the genera *Bacillus, Micrococcus, Staphylococcus, Streptococcus, Proteus,* and *Brucella*

Two additional organic constituents of saliva that are of interest are *kallikrein* and the specific *blood group substances* When saliva is injected intravenously into an animal, it produces a fall in blood pressure for a brief period The substance responsible for this has been

found to be due to kallikrein, an enzyme that acts on plasma protein to produce a vasodilator polypeptide This polypeptide is known as *kallidin* or *bradykinin* It has been suggested that the vasodilation in the salivary gland during secretory activity is due to kallikrein release The soluble specific blood group substances found in saliva have the same characteristics as the agglutinogen on the erythrocyte These substances can be demonstrated by the direct precipitin reaction with type specific sera In man, the A, B, O and Le^a substances have been demonstrated The concentration of the blood group substances in saliva is from 10 to 20 mg /liter It appears that most of the blood group substances come from the mucous cells of the submaxillary gland whereas little is produced by the parotid

Glucose is normally absent from saliva and even in patients with diabetes, none or only small amounts are found

Control of Salivary Secretions

Saliva is secreted continuously, but the rate of secretion may vary greatly due to the influence of conditions that are capable of stimulating or inhibiting the process of secretion The *continuous secretion* of saliva in the absence of any known stimulating factors is called "spontaneous" or "resting" secretion The continuous or spontaneous secretion of saliva is important in keeping the mucous membrane of the mouth and the pharynx moist at all times Examples of spontaneous or continuous salivary secretion in animals include the parotid gland of the sheep and ox and the sublingual gland of the cat The mechanism of spontaneous secretion is not known but it has been suggested that it is due to the constant release of minute amounts of acetylcholine within the gland However, atropine has no effect on this type of secretion

During mastication of food the rate of salivary secretion is greatly increased The character of the secretion is adapted in some degree to the type of food undergoing mastication During sleep the rate of salivary secretion is low and accounts for the dry mouth many experience on waking up in the morning Sexual excitement in many animals is associated with an increase in salivary flow

There are two main ways of controlling secretion of the digestive glands one through the nervous system and the other by means of hormones In the case of the salivary glands, it is believed that the control is exclusively through the nervous system At any rate, all efforts to date to find a salivary hormone have failed

REFLEX SECRETION OF SALIVA

The secretion of saliva is brought about reflexly in two ways either through the stimulation of the nerves of the mouth by the presence therein of food or other substances, or by the stimulation of some organ of special sense other than that of taste The former type of reflex is termed *unconditioned* or *inherent*, the latter, *conditioned* or *acquired* A reflex of one type does not, of course, exclude the other and, as a matter of fact, both are called into play together under ordinary circumstances

In addition to the unconditioned salivary reflex brought about by materials placed in the mouth, the salivary glands can be excited readily by the artificial stimulation of afferent nerve supplying structures in the mouth The conditioned salivary reflex depends upon afferent impulses arising from outside the oral cavity

The Unconditioned Salivary Reflex. Materials placed in the mouth call forth, after a short latent period (2 to 3 sec), a secretion of saliva which varies in *quantity* and *quality* with the physical and chemical nature of the substance introduced The effect which sensations of taste produce upon the secretion of saliva are well known Among edible substances, those, generally speaking, which are the most palatable or arouse the sensation of taste with the greatest intensity are the most potent salivary stimulants Materials, especially acids, which are entirely inedible will, if unpleasant to the taste, cause profuse salivation In these instances, the secretions depend mainly upon the stimulation of the taste fibers, and the stimulus is chemical in nature Materials such as dry sand, inedible powders (whether soluble or insoluble) or any other material which is capable of stimulating in a purely physical way will evoke a secretion. The mere movements of the jaws and of the tongue over the mucosa of the mouth will have such an effect A secretion occurs when any substance is chewed, whether or not it is edible or possesses taste The manipulations of the dentist, the contact of his instruments with the oral mucosa, or the grinding of a tooth are familiar and effective salivatory stimuli The salivary glands thus can

be readily excited by the artificial stimulation of afferent nerves supplying structures in the mouth

The reflexes are brought about through the salivary centers The *efferent* limbs of the reflex arcs, including the secretory fibers of the chorda tympani and the tympanic branch of the glossopharyngeal nerves The *afferent* pathways are represented in the trunks of the chorda tympani, the pharyngeal branches of the vagus and glossopharyngeal nerves, and the lingual, buccal, and palatine branches of the trigeminal nerve

The Conditioned or Acquired Reflex. The secretion which flows into the empty mouth when "the mouth waters" is a conditioned reflex The stimulus which initiates such a reflex is not applied to the nerves of the mouth, but is received by one or other of the organs of special sense, particularly those of sight and smell A conditioned reflex may also be elicited through the sense of hearing, or through sensory impressions arising from stimuli applied to the skin In brief, a conditioned reflex is one in which the cerebral centers play an essential part, and in which training and experience are the basis for the development of the reflex process

ADAPTABILITY OF THE SALIVARY REFLEX

It has been mentioned previously that saliva varies in both quantity and quality with the physical and chemical nature of the substance stimulating the secretion This remarkable adaptability or purposeful character of the salivary reflex was observed by Pavlov (1910) and later confirmed by Babkin (1950) The physical and chemical qualities of the juice, to some extent, are conditioned by the agent evoking salivation For instance, if clean pebbles are placed in a dog's mouth, they are expelled—merely allowed to drop out of their own weight Little or no secretion occurs, since none is required, but if the stones are crushed and given as a powder, a profuse water salivation follows to rid and cleanse the mouth of the useless material The juice, in this instance, is poor in organic material and resembles that obtained upon electrical stimulation of the chorda tympani nerve or of the parasympathetic fibers to the parotid Strong acid produces an abundant saliva which, according to Pavlov, is relatively rich in proteins, this exerts a buffer action which reduces or annuls the injurious effect of the acid The salivary response provides a lubricant which is curiously appropriate in volume and viscosity for the food to be swallowed A chunk of meat, given to a dog, is very quickly coated with a viscous mucin-rich saliva and swallowed If the meat is first dried and powdered, or if a dried biscuit is fed to the animal, an abundant watery saliva is produced such as is characteristic of parotid saliva

PARALYTIC SALIVARY SECRETION

Claude Bernard observed in 1864 that if he cut the chorda tympani nerve in a dog or a cat, in about 24 hr the submaxillary gland began to produce a scanty secretion of thin, turbid saliva, the turbidity was due to the presence of leukocytes The secretion increased until the 7th or 8th day, at which time it reached a plateau and began to diminish about the 3rd week It stopped some 6 weeks after the nerve was cut During this time the gland increased in size, and no secretion could be obtained on stimulation of the mouth Stimulation of the sympathetic, however, produced a flow of saliva Division of the sympathetic nerve or extirpation of the cervical ganglion did not evoke a paralytic secretion Rawlinson (1935) repeated these observations in Babkin's laboratory and found, on examination of the gland, that there was evidence of secretory activity during the paralytic secretion in the serous cells Moreover, these cells were more excitable than normal on stimulation by adrenalin or on electrical stimulation of the sympathetic nerves Evidently, cutting the chorda tympani causes some alteration in the gland acini which greatly increases the excitability of the sympathetic nerve endings on the serous or demilune cells Emmelin (1952) points out that only under conditions where a pronounced supersensitivity has been established by denervation and an increase in release of epinephrine occurs does paralytic secretion exist Removal of the adrenal glands from the animal or the injection of sympatholytic agents such as dihydroergotamine abolishes paralytic secretion Thus it appears that paralytic secretion is due to epinephrine secreted by the animal's suprarenal glands, and that the degree of response will depend upon the level of sensitivity of the denervated salivary gland Atropine has no effect on paralytic secretion

Salivary Response to Electrical Stimuli

The importance of neural mechanisms in the control of salivary secretion has long been recognized, thus, experimentation by applying electrical stimulation to the parasympathetic and sympathetic nerves supplying the salivary glands has contributed greatly to our knowledge of salivary secretion Histological and electrical changes can be produced in the acinar cells by electrical stimulation In addition, stimulation of the salivary nerves may affect structures other than the secreting cells and thus modify secretion For instance, marked vascular changes within the gland can result from electrical stimulation In addition, electrical stimuli can presumably cause contraction of the myo-epithelial cells and produce a temporary acceleration of the flow of saliva being secreted

Electrical stimulation of the nerves to the salivary gland produces different results in different species of animals Stimulation of the parasympathetic nerves usually produces an abundant flow of quite watery saliva regardless of the gland or species studied Stimulation of the sympathetic secretory fibers to the submaxillary or sublingual glands, although causing an abundant secretion in the cat, causes only a scanty and very viscid secretion in the dog

PARASYMPATHETIC STIMULATION

Stimulation of the parasympathetic nerve supply to the salivary glands produces a prompt and abundant flow of watery saliva from the gland Vascular vasodilation within the gland also occurs The secretory effect of parasympathetic stimulation was discovered by Ludwig (1851) when he observed a flow of saliva from the submaxillary gland on stimulation of the chorda tympani nerve The vasodilator effect, associated with chorda tympani stimulation, was described by Claude Bernard in 1858 Most workers today consider the vasodilation as secondary to the process of secretion and due to the release of vasodilator agents from the activated secretory cells

The marked secretory effect that can be obtained on parasympathetic stimulation is illustrated by the fact that a salivary gland can secrete an amount of saliva equal to its own weight in just a few minutes With repetitive parasympathetic stimulation, the rate of salivary secretion within certain limits is proportional to the rate of stimuli being applied In the cat, the maximal secretory response from the submaxillary gland is obtained with a rate of 10 to 12 stimuli/sec When the maximal rate of secretion has been attained by parasympathetic stimulation, this rate cannot be exceeded by the addition of other stimuli as epinephrine or acetylcholine or even by stimulation of the sympathetic nerve supply to the gland

Lundberg (1955) has estimated that each acinar cell is supplied with from 5 to 10 parasympathetic fibers By histochemical techniques, Snell and Garrett (1956) have demonstrated true cholinesterase in the fine network of neural fibers around the acinar cells

SYMPATHETIC STIMULATION

Stimulation of the sympathetic nerve supply to the salivary glands produces a much smaller and more variable response than stimulation of the parasympathetic In the cat, sympathetic stimulation usually produces an increase in secretion from the submaxillary gland and little effect is noted upon the parotid gland In the rabbit, on the other hand, the response from sympathetic stimulation is more marked from the parotid gland than the submaxillary gland As early as 1851, Ludwig observed a flow of saliva from a submaxillary gland on stimulation of the cervical sympathetic trunk Claude Bernard in 1858 called attention to the fact that marked vasoconstriction also occurred with stimulation of the cervical sympathetic trunk

The marked vasoconstriction that occurs on sympathetic stimulation is capable in itself of altering salivary secretion With marked vasoconstriction, the blood supply to the gland may be restricted to such an extent that secretion may be inhibited

ELECTRICAL PHENOMENA ASSOCIATED WITH SALIVARY SECRETION

Stimulation of the autonomic nerves to the salivary glands causes characteristic changes in the electrical potentials that may be observed by placing electrodes in various positions on or within the gland, and connecting them to a suitable recording device With one electrode on the hilum and another on the outer surface of the submaxillary gland, stimulation of either the sympathetic or parasympathetic nerves causes the hilum of the gland to become elec-

tropositive to the outer surface after a comparatively long latent period The latent period is 0 2 to 0 3 sec with the parasympathetic, and somewhat longer when the sympathetic is stimulated Following parasympathetic stimulation, the hilum positivity rapidly declines and may change to a negative potential, there is another sharp rise in hilum positivity when the current is turned off The potential caused by sympathetic stimulation is more consistently hilum-positive

Since the submaxillary gland is composed of several different types of cells, each of which may have its own electrical characteristics, it is doubtful what significance should be ascribed to the external secretory potential More precise information may be obtained from the use of micro-electrodes with the tip placed in the interior of a single cell With these, Lundberg (1957) has obtained three types of response representing presumably three types of cells mucous cells, serous cells, and duct cells In all cases, the interior of the cell was electro-negative to the external medium In the case of the mucous cells, stimulation of either the parasympathetic or sympathetic caused a sustained increase in internal negativity or "hyperpolarization" of the cell membrane This followed a time course roughly parallel to that already described for the external secretory potential When the micro-electrode was in what was believed to be a serous cell, the parasympathetic caused hypopolarization, but the sympathetic caused a decrease in the internal negativity of the cell (apparent depolarization) With the electrode in what was thought to be a cell of a salivary duct both sympathetic and parasympathetic nerves caused apparent depolarization

In the sublingual gland, micro-electrodes picked up currents corresponding to those obtained from acinar cells of the submaxillary, but the external secretory potential was of a polarity opposite to that of the submaxillary gland, that is, the hilus became electronegative This difference was believed to be due to differences in the cellular composition of the two glands and not to any difference in the electrical response of corresponding individual cells

These electrical phenomena are remarkable in several respects Evidently they are not analogous to the familiar action potentials of nerve and muscle. They appear not to be concerned with the excitatory process (which must be quite different in gland cells and in muscle cells) but are concerned with the functional work of the cell Lundberg (1958) has presented good evidence that the hyperpolarization, associated with secretory activity, is caused by an active transport of chloride ions through the outer cell membrane which is triggered by the release of a neurohormone at the autonomic nerve endings The apparent depolarization, when it occurs, is not a self propagating disturbance of the cell membrane of the sort we are accustomed to associate with depolarization, but is probably due to the sustained activity of an ion transport mechanism in the duct cells opposite to that causing hyperpolarization in the acinar cells

As a corollary to these observations, Lundberg (1958) has suggested that secretion of water and salt by the acinar cells is accomplished through the activity of an active chloride ion transport mechanism in the outer cell membrane which "pumps" chloride ions into the cell from the surrounding interstitial fluid Electrical forces cause sodium to accompany chloride, and osmotic forces take in water As a result of the increased hydrostatic pressure within the cell, the salt and water escape through the inner membrane (where there may also be ion pumps) into the lumen of the acinus He has suggested further that the rodded epithelial cells of the ducts actively absorb sodium from the secretion Sodium absorption at this point would account for the apparent depolarization of these cells (decreased internal negativity) and also for the fact that saliva may be hypotonic with respect to the blood

Functions of Saliva

Saliva has many functions, but its main functions are to aid in digestion and to provide a protective secretion in the mouth that keeps the mucous membranes moist and aids in oral hygiene Saliva is not essential to life, but its absence results in a number of inconveniences The salivary glands, by secreting saliva, aid in the recognition and monitoring of thirst and body water needs

PREPARATION OF FOOD FOR SWALLOWING

Lubrication is perhaps the most important function of saliva When food is introduced

into the mouth, salivary secretion is increased The saliva thus provided serves to moisten the food and the mucous membrane and greatly facilitates chewing and swallowing

SOLVENT AND CLEANSING ACTION

Taste is chemically mediated, therefore, as a prerequisite to stimulation of the taste buds, any substance must be dissolved It follows that deprivation of saliva would greatly limit taste sensibility It has been mentioned previously that saliva contains little or no glucose and that the concentration of sodium is considerably below that of plasma This is probably significant in the perception of the taste of sweet or salty substances

The constant flow of saliva exerts a very necessary cleansing effect on the mouth and teeth, which are rinsed and kept comparatively free from food residues, shed epithelial cells, foreign particles, etc In this way, saliva inhibits the growth of bacteria by removing the material that may serve as culture media In addition, lysozyme in saliva serves a protective function through its ability to lyse certain bacteria One has but to consider the foul condition of the mouth in certain fevers when salivary secretion is suppressed to realize its importance in oral hygiene When salivation is suppressed, decomposing organic materials swarming with bacteria (sordes), tend to coat the teeth and lips and must be removed by artificial means The moistening of the mucous membranes of the mouth and lips by saliva also aids in articulation When the supply of saliva is insufficient, public speakers must sip water frequently in order to counteract the desiccating effect of evaporation from the mouth

DIGESTIVE FUNCTIONS

The principle substrates in the diet that amylase acts on are starch and glycogen On complete digestion, amylase reduces starch to approximately 88% maltose and 12% glucose The site of action of amylase is at the α,1-4, glycosidic linkage of starch or other oligosaccharides

Little digestion of dietary carbohydrates occurs in the mouth, pharynx and esophagus It has been shown that amylase activity continues in the stomach and that 60 to 70% of a starch or potato meal will be digested in the stomach before the meal is emptied into the duodenum Pancreatic amylase continues the digestion of oligosaccharides in the small bowel

EXCRETORY FUNCTION

Many substances, both organic and inorganic, are excreted in the saliva Mercury, potassium iodide and lead, when introduced into the body, are excreted in part in the saliva Severe inflammation of the oral mucous membrane may develop as a result of the excessive excretion of mercury via the saliva After entering the mouth via the saliva of persons with lead poisoning, lead sulfide is deposited in the gums and appears as a blue line Sulfur derived from organic materials is deposited in the tartar on the lingual side of the teeth near the gum line This explains why discoloration of the gums does not occur where teeth are absent In patients with chronic nephritis, the saliva contains a high percentage of urea Alkaloids as morphine, and antibiotics as penicillin, streptomycin, and aureomycin are also excreted in saliva

Several types of microorganisms, some intensely virulent (e g , the viruses of rabies and poliomyelitis) are excreted in the saliva The latter disease has been reproduced in monkeys by injecting the saliva of an infected person In this connection, it may be added that mumps, which is usually looked upon as a specific inflammation of the parotid gland, is in reality a systemic disease since other organs, including the ovary or testicle, breast, pancreas, and meninges, are often also inflamed The parotid may become inflamed secondarily as a result of passage of the infectious agent through the gland into the saliva

In spite of their versatility in regard to excretory functions, this role of the salivary glands is not an indispensable one The kidney represents the major organ of excretion Doubtless all the excretory functions of the body could be carried on effectively in the absence of the excretory function of salivary glands

Effects of Chemicals and Drugs upon Salivary Secretion

Many chemicals and drugs are capable of affecting salivary secretion Drugs that mimic sympathetic or parasympathetic nerve stimulation result in an increase in salivary secretion *Sympathomimetic* agents that stimulate salivary secretion include epinephrine, norepinephrine, synephrine and amphetamine *Parasympathomimetic* agents causing salivary secretion include acetylcholine, methancholine (mecholyl) and pilocarpine Cholinesterase in-

hibitors known as *anticholinesterases* provoke salivary secretion

Sympatholytic and *parasympatholytic* drugs, which block the effects of epinephrine and acetylcholine respectively, produce inhibition of salivary secretion Ergot, dibenamine and dehydroergotamine are examples of sympatholytic agents that inhibit secretion Parasympatholytic or *anticholinergic* agents such as atropine, scopolamine, and methylscopolamine produce a marked suppression of salivary secretion Many anticholinergic agents used therapeutically (e g , in the treatment of duodenal ulcer) inhibit salivary secretion and produce dryness of the mouth as a disturbing side effect

The salivary secretion caused by various surgical anesthetics such as ether, chloroform, and cyclopropane is reflex in origin due to the anesthetic coming in contact with the buccal mucosa Because excessive salivary secretion can be troublesome to the anesthetist, atropine and scopolamine have long been used as a premedication to anesthesia to suppress salivary secretion When deep anesthesia has been induced excessive secretion stops due to central inhibition

Disturbances of Salivary Secretion

Temporary suppression of salivary secretions due to emotional states such as anxiety or fear, the presence of fever, or as a result of dehydration are not uncommon Suppression of salivary secretion may also result from obstruction of the salivary ducts due to calculi formation In patients with Bell's palsy, in which there is a peripheral paralysis of the facial nerve, secretion of the salivary glands on the paralyzed side is decreased

Permanent suppression of salivary secretion (*xerostomia* or *aptyalism*) is rare and may be associated with congenital hypoplasia or absence of the salivary glands Steggerda (1941) has reported an interesting case of a university student in whom the orifices of the ducts of the salivary glands were not demonstrable The chronic dryness of the subject's mouth was not necessarily related to thirst The student had learned to take a few swallows of water approximately every hour to relieve his uncomfortable xerostomia When he became "actually thirsty" he would drink about 250 ml of water This occurred approximately four times a day He found that it was necessary to take small sips of water frequently during his meals to facilitate mastication and swallowing The water intake of this subject was studied for a number of days and found not to be different from that of four students who served as controls

Hyposalivation may also result from surgical procedures or x-ray therapy in areas where the principal salivary glands are located In xerostomia, the patient complains of difficulty in masticating and swallowing food Articulate speech is also difficult unless the subject takes frequent sips of water In such patients, there is also an increase in dental caries

Hypersalivation, or *sialorrhea*, is sometimes observed during pregnancy The cause of the excessive salivation is not known It may be particularly troublesome because the patient may secrete as much as 3 to 4 liters of saliva per day Neoplasms of the mouth or tongue, or even a carious tooth, may result in hypersalivation due to reflex stimulation of the salivary glands due to local irritation Excessive salivation is not uncommon in diseases of the esophagus, stomach and pancreas Neoplasms of the esophagus, or even esophageal spasm, may result in reflex stimulation of salivary secretion (esophago-salivary reflex) This reflex may be elicited readily in a normal person by the passage of a stomach tube or an esophageal sound Patients with gastric or duodenal ulcer and pancreatitis may also have excessive salivary secretion

Various neurological disorders, such as the parkinsonian syndrome, are associated with excessive salivation The psychotic state of schizophrenia may also be associated with excessive salivation

An interesting disorder of salivary secretion is known as the *chorda tympani syndrome* This syndrome results from a surgical or traumatic severance of the chorda tympani nerve The regenerating chorda nerve fibers become misdirected and grow into nerves innervating sweat glands in the submental region When the subject eats, or when salivary secretion is otherwise stimulated reflexly, sweating occurs in the submental area on the affected side Both the salivary glands and the sweat glands are innervated by cholinergic fibers In the chorda tympani syndrome, impulses intended for the salivary glands are transmitted to the sweat glands and they respond by secreting sweat.

5 / GASTRIC SECRETION

The stomach has the amazing capacity to secrete hydrochloric acid at a concentration of 160 mEq /liter, the proteolytic enzyme pepsin, the intrinsic factor needed for vitamin B-12 absorption by the ileum, the polypeptide hormone gastrin which stimulates the parietal cell to secrete the highly acid juice already listed, as well as a variety of mucoid substances including blood group substances

Structure of the Gastric Mucosa

The surface epithelium of the gastric mucosa consists of a single layer of tall columnar cells that secrete mucus The mucous membrane of the stomach is separated from the outer muscular gastric wall by the *muscularis mucosae* and a supporting stroma of connecting tissue The surface of the gastric mucosa is marked by slight linear depressions into small polygonal areas called *areae gastricae*, giving the surface a mammillated appearance, the areas measure from 1 to 6 mm in diameter The surface is constantly covered by a thick layer of tough, tenacious mucus secreted by the surface epithelial cells The layer of mucus varies in thickness from 0 5 to 2 5 mm Beneath the surface layer of epithelium are located various types of tubular glands which vary in structure and in composition of their secretion in different parts of the stomach When the mucus is removed, the *gastric foveolae* may be seen with the aid of a hand lens The gastric foveolae are separated from one another by a distance of approximately 0 1 mm , thus, there are 90 to 100/mm ^{2} Opening into the bottom of each foveola are three to seven individual gastric glands The lining of the gastric pit is a continuation of the tall columnar surface epithelium

The gastric mucosa can be divided into several areas, each of which contains a particular type of gland The *cardiac area* is the zone, 1 to 4 cm wide, that guards the esophageal orifice The *fundic area* is the largest area of the stomach, accounting for 60 to 80% of total mucosal surface, interposed between the cardiac and the *pyloric* areas The lower limit of the fundic area is marked by the incisura angularis on the lesser curvature of the stomach, and a line extending diagonally toward the pylorus to the greater curvature The junction of the pyloric and fundic area is not sharply demarcated and is frequently referred to as the *transitional zone* The distal part of the pyloric zone extends to the pylorus which communicates with the first part of the duodenum The pyloric area is about 15% of the total gastric mucosal area On the lesser curvature, where the mucous membrane is more firmly attached to the muscular wall of the stomach, the rugae form parallel longitudinal folds and this area is sometimes referred to as the *Magenstrasse*

The gastric glands are tubular in structure and extend from the bottom of the gastric foveolae to the muscularis mucosae where they terminate in a blind bulbar end known as the *fundus* of the gland The main tubular portion of the gland is known as the *body* The *neck* of the gland connects the body to the *isthmus* which communicates with the gastric crypt The total number of gastric glands has been estimated at 35 million

Each area of the gastric mucosa is characterized by its glandular structure The *cardiac glands* tend to be short and tortuous and are made up mostly of mucous cells, although a few pepsinogen cells are also present Similar glands, minus the pepsinogen cells, are found in the esophagus The *fundic glands* tend to be straight, slender structures with narrow lumen Three types of cells make up the fundic glands *mucous* cells, *pepsinogen* or *chief* cells, and *parietal* or oxyntic cells The mucous cells may be further divided into isthmus cells and neck cells Although the isthmus cells are of the mucous type, they probably secrete very little mucus The cells of the neck are true mucous-secreting cells but they secrete a different type of mucus from that of the surface epithelial cells The mucus of the neck cells is soluble, and constitutes a part of the soluble mucus of gastric juice An important characteristic of the isthmus and neck cells is their frequent mitoses It is believed that these cells may develop into pepsinogen cells and thus replace chief cells

In the neck region are also a great many par-

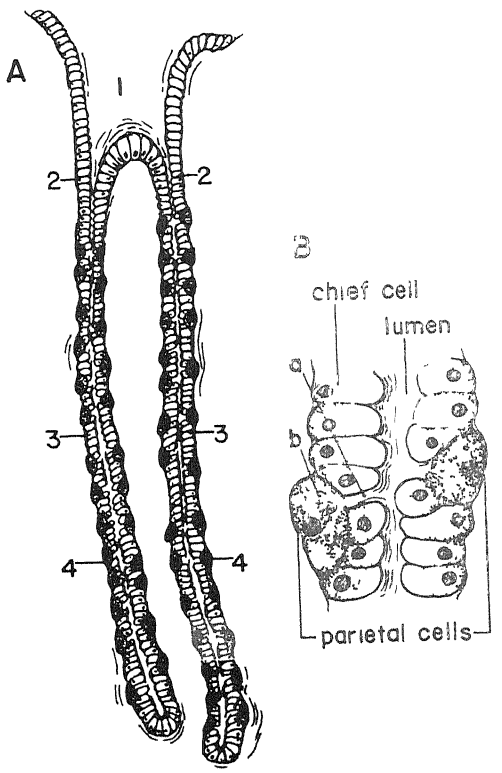

Fig 2 13 *A* gland from the fundus of the stomach *1* crypt or foveola on the mucous surface connected to the neck (*2*) by the isthmus *2* neck of gland containing mucin-secreting cells *3* chief cells *4* parietal cells *B* enlarged drawing showing (a) intercellular and (b) intracellular canaliculi

ietal cells These cells do not form a part of the gland wall but appear to lie outside, giving the gland a nodular appearance (Fig 2 13) The parietal cells secrete the hydrochloric acid and most of the water of the gastric juice and, because of this, they are also known as the "oxyntic" or acid-secreting cells Although separated from the lumen of the tubules by the chief, or pepsinogen cells, the parietal cells transmit their secretion into the lumen through delicate canaliculi lying between the chief cells These canaliculi are extensions of a system of exquisitely fine canals which lie within the protoplasm of the parietal cells. Numerous transparent, smooth-surfaced vesicles are seen in the protoplasm of the cells during rest Depletion of this vesicular material occurs during activity The distribution of parietal cells in the human stomach is shown in Figure 2 14

The body of the gland which makes up the remainder of the tubule is composed principally of pepsinogen cells called *chief cells* Parietal cells are also present, but in diminishing numbers, as the fundus of the tubule is approached In addition to *pepsinogen*, the chief cells probably produce *renin* (in the calf), which coagulates milk, and is believed to be produced only in young animals, and a special gelatin-splitting enzyme known as *gelatinase* (in the pig), which liquifies gelatin at a rate about 400 times that of pepsin It is not known whether each of these enzymes is produced by a different type of chief cell or whether they are produced by the same cell Since the chief cells appear to be morphologically identical, there is no anatomical evidence for assuming that they differ from one another in their secretory products No mitoses are seen in the chief cells

Another type of cell occasionally found in the fundic glands is the argentaffin cell The granules contained in their protoplasm are easily impregnated with silver and this characteristic gives the cells their name The exact function of argentaffin cells in the gastric mucosa is not known

The *pyloric glands* are located in the pyloric area but they also extend into the transitional zone separating the pyloric area from the fundic area of the stomach The pyloric glands tend to be somewhat shorter and are more tortuous than the fundic glands The foveolae in the pyloric region tend to be deep These glands are lined exclusively by mucous-secreting cells that resemble those of the cardiac

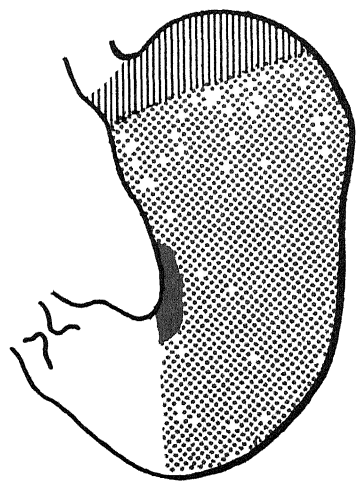

Fig 2 14 Diagram showing the distribution of the parietal (acid-secreting) cells in the human stomach In the black area the proportion of parietal cells is maximal and is taken as 100% in the brown area on lesser curvature the percentage of parietal cells is 75% in the shaded area at the fundus, 50% and in the white area 0 to 1% (After Berger 1934)

glands An occasional argentaffin cell may be noted in the fundus of the pyloric glands Gastrin has recently been found to be contained in or on abundant granules packing the cytoplasm of differentiated cells interspersed in the antral glands These cells appear endocrine-like, and do not take the silver stains

The electron microscope has provided additional information on the structure of the gastric mucosa The presence of intracellular canaliculi in the parietal cells is a constant finding At the free or luminal surface of the parietal cell, as in the case of certain other active transport cells, there is a striated border The intracellular canaliculus simply represents an invagination of this striated border The presence of a very high concentration of mitochondria also is consistent with the cell's role in transport of ions against a concentration gradient (Fig 2 15)

Studies correlating structural change with gastric secretion (Sedar and Friedman, 1961,

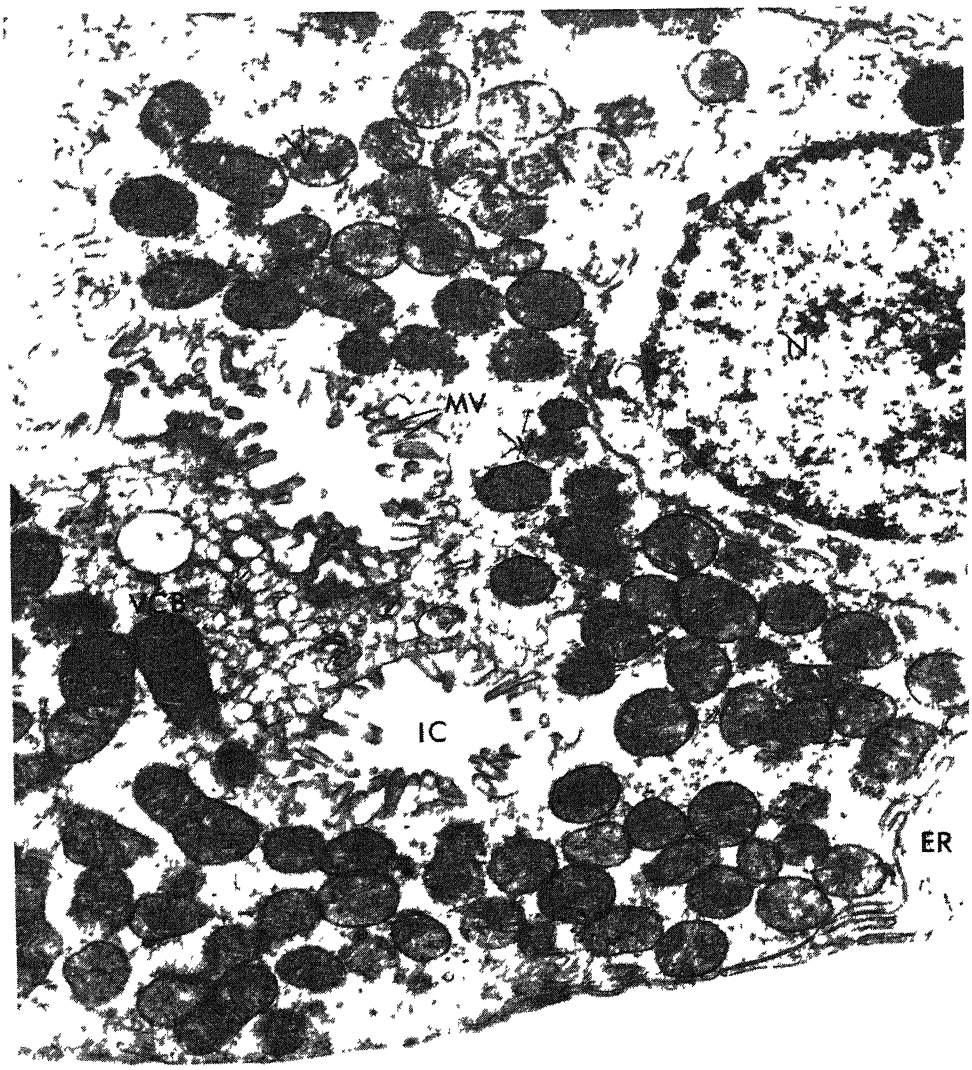

Fig 2 15 Electromicrograph of part of a nonsecreting human parietal cell The specimen was obtained by biopsy Secretion was suppressed by administering 0 5 mg of atropine sulfate The gastric juice contained no free acid and had a pH of 6 6 at the time of biopsy The intracellular canal system (IC) is evident demonstrating patent lumen with projecting microvilli (MV) Throughout the cytoplasm are many small vesicular structures (V) whose content appears less dense than that of surrounding cytoplasm Note the large vacuole containing body (VCB) Nucleus (N) and some endoplasmic reticulum (ER) of adjacent chief cells are also included in electromicrograph (Approx × 22 800) From Rohrer et al 1965)

Sedar, 1962, Rohrer et al , 1965) have demonstrated that during gastric secretion stimulated by histamine, insulin hypoglycemia, or vagal stimulation, definite and characteristic changes occur within the parietal cell (Fig 2 16) The microvilli lining the walls of the canaliculi are markedly increased, to the point that the lumen of the canaliculus is almost occluded by these protoplasmic projections The increased number of microvilli provides a tremendous increase in the surface area of the wall of the canaliculus, which is presumed to be the site of movement of hydrochloric acid and water from the cell into the canaliculus During secretion of hydrochloric acid, the smooth-surfaced vesicles, which are randomly distributed in the cytoplasmic matrix in the resting cell, become concentrated adjacent to intracellular canaliculi With continued secretion of hydrochloric acid, these smooth-surfaced elements decrease in number In some instances it has been possible to observe these vesicles communicating with areas of the canalicular wall between adjacent microvilli

Fig 2 16 Part of parietal cell from same subject as in Figure 2 15 Biopsy was taken after maxima histamine stimulation when gastric juice contained 104 mEq /liter HCl and had pH of 1 Intracellular canaliculus (IC) appears very complex and lumen is filled with microvilli (compare with Figure 2 15) Vesicular components (V) appear decreased in number and are oriented about intracellular canal In cytoplasm are mitochondria (M) a few scattered tubular elements (TE), ribonucleoprotein granules (RNP), and two dense bodies (DB) An infolded cell membrane (CM) is noted on right (From Rohrer et al 1965)

Innervation of the Gastric Glands

The gastric mucosa is innervated by both the sympathetic and parasympathetic divisions of the autonomic nervous system The *efferent sympathetic supply* arises from neurons located in the latter horn of the 5th to 10th thoracic segments of spinal cord The *preganglionic fibers* emerge from the cord in the anterior spinal nerve roots and pass to the ganglia of the thoracic sympathetic chain Here, some form synapses but most continue in the thoracic splanchnic nerves to the celiac plexus and form synapses with the ganglia within the celiac plexus From the celiac ganglia, the *postganglionic fibers* accompany the arterial vascular supply of the stomach *Afferent visceral fibers* from the stomach travel the same course just outlined, in reverse, to the ganglion cells in the posterior spinal nerve roots The afferents do not synapse in, or arise from, the sympathetic ganglia

The *efferent parasympathetic supply* to the gastric mucosa originates in the dorsal vagal nucleus in the floor of the fourth ventricle The *preganglionic fibers* reach the stomach via the right and left vagus nerves The left vagus supplies preganglionic fibers to the anterior surface, and the right vagus to the posterior surface of the stomach In addition, both vagi send branches to the celiac plexus The parasympathetic preganglionic fibers accompany the vascular supply and the sympathetic fibers into the muscular layers of the wall of the stomach, to form synapses with the ganglion cells of the myenteric plexus of Auerbach and the submucosus plexus of Meissner The *postganglionic fibers* supplying the mucosa are thus very short, whereas the preganglionic fibers are quite long *Afferent parasympathetic fibers* are found in the vagus The neurons of these fibers are located mainly in the *ganglion nodosum* The central processes of these afferent neurons terminate in the dorsal nucleus of the vagus, completing the reflex arc

The vagi are the important secretory nerves to the stomach The cephalic or psychic phase of gastric secretion is mediated via the vagi An intact vagal innervation is also important in the release of *gastrin* from the gastric antrum Stimulation of the vagus nerve causes the secretion of strongly acidic gastric juice rich in pepsin This effect is mediated through acetylcholine (Fig 2 17) Atropine, which blocks postganglionic parasympathetic stimulation,

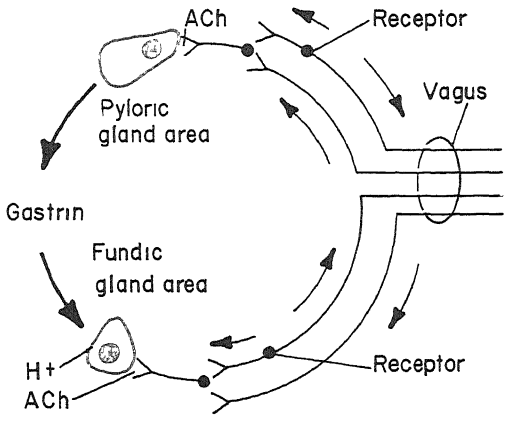

Fig 2 17 Diagrammatic representation of the intramural and vagal innervation of gastric mucosa (From Grossman 1963)

inhibits gastric secretion stimulated via the vagi It should be emphasized that the vagi contain thousands of afferent fibers which probably mediate reflexes originating in the gastrointestinal tract

Stimulation of the sympathetic nerve supply to the mucosa causes the secretion, mainly from the pyloric glands, of an alkaline mucoid juice which is very low in peptic activity The sympathetic response is unaffected by atropine, but is annulled by ergotamine (which paralyzes motor and secretory sympathetic fibers) Vineberg's results (1931) indicate that the vagus controls the secretion of mucin by the mucous neck cells and the surface epithelium of the gastric mucosa The influence exerted by the sympathetic upon the peptic and oxyntic cells of the gastric body is not definitely known According to some, its effect upon these elements is inhibitory

Origin and Composition of Gastric Juice

Gastric juice is the composite product of secretion by the surface epithelium and the various gastric glands The composition of gastric juice varies, depending upon the individual contributions of the various secreting structures The major constituents of gastric juice are water, hydrochloric acid, and other electrolytes as sodium, potassium, calcium, phosphate, bicarbonate, and sulfate The major organic constituents include various enzymes, at least two types of mucus, the *intrinsic factor* of Castle, and blood group substances

It has been estimated that the volume of gastric juice secreted by man in a 24-hr period amounts to 1200 to 1500 ml The amount will vary, depending upon the diet and other stimuli provoking gastric secretion When gastric juice is collected for a 12-hr period during the night, by means of a nasogastric tube with constant suction, the average volume obtained is about 400 ml Fasting human gastric juice collected from healthy young adults has an acidity of 40 to 60 mEq /liter, a pH of 0 9 to 1 2, and a specific gravity of 1 002 to 1 004 Under histamine, 1 ml of mucosa in man can produce 1 mEq of HCl/hr

HYDROCHLORIC ACID AND GASTRIC ELECTROLYTES

The chief problem is to account for the variation in acidity and electrolyte composition of gastric juice based on the main facts parietal cells secrete water and HCl, with a maximal concentration about 160 mEq /liter The main anion is chloride, and when the acidity is low, the other cation is sodium Na^+ and K^+ are always present At times, HCO_3^- up to 25 mN can be detected It is convenient to think of gastric juice as a mixture of parietal and nonparietal secretions

The composition of pure parietal secretion can be arrived at only by computation, inasmuch as no means is available for collecting pure parietal secretion that is not contaminated, at least to some extent, with secretions from nonparietal cells Figure 2 18 illustrates the computed ionic composition of parietal and nonparietal secretions of the gastric glands It is further believed that the composition of parietal secretion remains constant, and is independent of rate of secretion, nature of stimulus, or strength of stimulus The concentration of hydrochloric acid in gastric juice collected from man or a dog may vary from 0 to 150 mEq or more/liter Other things being equal, the concentration of acid increases with increasing rates of secretion, up to a maximum of about 150 mEq /liter The chloride ions that accompany the hydrogen ions into the gastric juice to form HCl are not passively carried along by the hydrogen ions Two important observations that indicate that the chloride ion of the HCl in gastric juice is secreted by an active, energy-consuming mechanism are *1)* chloride ion is transported against a concentration gradient, from a plasma concentration of about 110

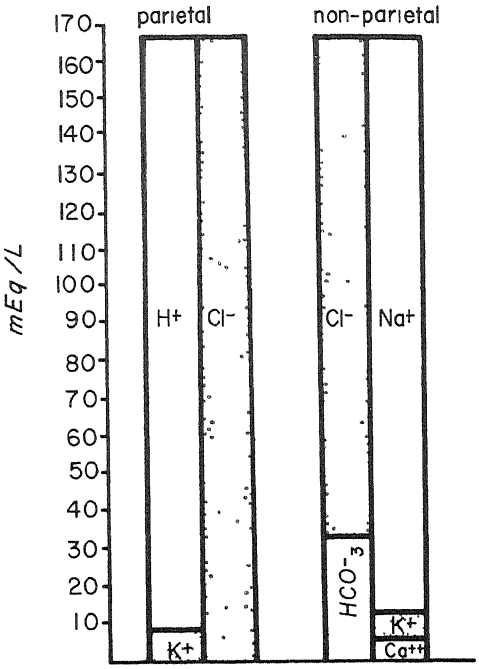

Fig 2 18 Computed ionic concentration of the principal ions in the parietal and nonparietal secretions of the gastric gland (Redrawn from Ivy et al 1950)

mEq /liter, to a concentration in gastric juice up to 166 mEq /liter, and 2) chloride ion is transported against an electrochemical gradient (the luminal surface of the gastric mucosa is negative to the serosal surface with a potential difference of 30 to 50 mV) The chloride ion of HCl is considered to be secreted by a "chloride pump "

It is interesting that the mechanism (chloride pump) for transporting chloride ions into the gastric juice is also capable of transporting *bromide* and *iodide* ions Hydrobromic acid may be recovered from the gastric juice of patients who have taken bromide salts When radioactive iodine, ^{131}I, is administered intravenously to a patient, radioactivity rapidly appears in the gastric juice

A small part of the chloride of gastric juice is balanced against metallic cations, principally sodium This constitutes the so-called *neutral chloride* The concentration of other negative ions in the juice is negligible, thus the osmotic activity of gastric juice is primarily due to the acid, plus the neutral chloride Since gastric juice is practically isotonic with blood, the ionic concentration of total chloride in the gastric juice differs but little from that of the total base of the blood

In highly acid gastric juice, the neutral chloride is present only in small amounts, but in a less acid secretion it may constitute a major portion of the total chloride When it is present in large quantities, its source becomes a matter of considerable interest The source of neutral chloride has been a matter of widespread discussion and controversy but current thinking tends to the view that it is secreted by the nonparietal cells (mucous cells of the surface epithelium and chief cells of the gastric glands), along with sodium, calcium, potassium, and the organic materials secreted by these cells, and that a certain, perhaps smaller, amount enters the gastric contents by diffusion from the interstitial fluid In impure gastric juice, a large part of the neutral chloride may represent swallowed saliva and regurgitated duodenal contents

GASTRIC ENZYMES

Pepsin. The principal proteolytic substance in gastric juice is pepsin, from the chief cells of the fundic glands The zymogen in the cytoplasm of these cells is inactive and referred to as *pepsinogen* Pepsinogen is relatively resistant to heat and alkali and can withstand short exposures to temperatures of 70° C or a pH of 11 without loss of activity The enzyme becomes active only in acid media At a pH below 6, pepsinogen is transformed into pepsin by an autocatalytic reaction The optimum pH for peptic activity is about 2 0 At a pH of 5 0, the action of pepsin is almost abolished Pepsin digests protein by attacking those peptide linkages in which the amino groups are attached to aromatic amino acids The products consist mainly of proteoses and peptones and relatively few amino acids and polypeptides Pepsin is constantly present in acid gastric juice and probably is secreted continuously During interdigestive periods, it is stored in the chief cells of the fundic glands, evidence by the accumulation of zymogen granules Details of the synthesis of pepsinogen from amino acids by the chief cells, or the mechanism of release of pepsinogen from the cells during secretion are not known Samloff and Townes (1969) have demonstrated the existence of seven electrophoretically distinct pepsinogens in human gastric mucosa Five are limited to the fundus and body, two are in the antrum and proximal duodenum This pattern is under genetic control, with some families lacking one specific pepsinogen The major stimulus to pepsin secretion is vagal impulses Gastric secretion induced by sham feeding, electrical stimulation of the vagus nerves, or insulin hypoglycemia results in a gastric juice containing high peptic activity Pilocarpine and acetylcholine are potent stimuli of pepsin secretion Now, however, we know that gastrin itself can stimulate pepsin secretion, independent of vagal stimulation Histamine produces a gastric juice of low pepsin concentration, but does stimulate pepsin in man

Most stimuli of gastric secretion produce a juice that is initially high in peptic activity Gastric secretion in response to a meal will show the highest concentration of pepsin in the 1st hr As the volume of gastric juice increases, the concentration of pepsin falls During the later stages of digestion, when the volume of gastric juice diminishes, the concentration of pepsin increases Since pepsin is a preformed secretory product and cannot be elaborated as rapidly as it is secreted, depletion of cell stores of pepsinogen occurs during the initial period of gastric secretion Prolonged stimulation of gastric secretion, however, does not result in disappearance of peptic activity from gastric juice

Proteolytic activity in blood serum and urine, presumably due to the presence of pepsinogen, has been demonstrated Apparently, a small amount of pepsinogen leaks into the blood Pepsinogen can withstand the slightly alkaline pH of blood and its molecular size (42,500) would permit it to be filtered by the renal glomerulus The name *uropepsin* has been given to the protease in urine

Rennin. This enzyme is the milk-curdling ferment Rennin has been isolated from the gastric secretions of the calf The optimum pH for the action of rennin is between 6 0 and 6 5 The presence of calcium ions are necessary for the action of rennin on milk Gastric rennin, when added to milk kept at body temperature, causes a change in the soluble *casein*, splitting it into a *proteose-like* substance (whey protein) which remains in solution, and *paracasein* The latter is soluble alone but upon combination with calcium forms an insoluble compound, *calcium paracasein*, which precipitates as a curd The protein (paracasein) of the curd subsequently undergoes peptic digestion in the usual manner The softer and more finely flocculent the character of the curd that is formed,

the more readily is it attacked by the proteolytic ferments

Rennin is not found in the gastric juice of man either infants or adults The clotting and digestion of milk in man is by pepsin With an optimum pH of 6 0 to 6 5 rennin would be inactive at the usual pH of the gastric contents of the normal adult

Lipase A gastric lipase has been found in gastric juice The enzyme is a tributerase and may be similar to plasma lipase which is also a tributerase The optimum pH for the action of gastric lipase is between 4 0 and 5 0 and is inactive at a pH of 2 5 The origin of lipase found in gastric juice in the rat is the fundic glands When compared to pancreatic lipase, gastric lipase is a weak fat-splitting enzyme

Other Gastric Enzymes. A number of less important digestive enzymes have been detected in gastric juice Their presence in gastric juice in minute amounts suggests that they are of doubtful digestive significance

Lysozyme (pH optimum 5 3) is a carbohydrate-splitting enzyme In gastric juice from normal individuals, it is found in small amounts Its cellular origin is unknown The lysozyme content of gastric juice has been found to be increased in patients with gastric ulcer This increase in lysozyme concentration is probably secondary to the inflammatory reaction produced by the ulcer

Urease can be isolated from the gastric mucosa and gastric juice Urease is found also in bacteria contaminating the gastric mucosa The hydrolysis of urea by urease to produce ammonia probably plays a negligible role in gastric secretion

Carbonic anhydrase is found in gastric juice in small amounts and its presence is thought to be due to disintegration of desquamated surface epithelial cells In addition to being present in the surface epithelial cells, carbonic anhydrase is found in high concentrations in the parietal cells, where it plays an important role in the process of HCl formation

GASTRIC MUCUS

Two types of gastric mucus occur in gastric juice *Visible* mucus is secreted by the surface epithelial cells of the gastric mucosa and is thick, viscous, and even jelly-like It forms a transparent coating over the surface of the gastric mucosa 2 to 3 mm in thickness Mucus secretion from the surface epithelium is stimulated by various chemicals applied to the surface of the gastric mucosa e g alcohol, ether, clove oil and phenol red In addition, tactile stimuli such as rubbing the mucosa with a brush, or even roughage in the diet, cause secretion of mucus by the surface epithelial cells

Soluble, or transparent, mucus is secreted by the cells of the pyloric and cardiac glands, and also by the mucous neck cells of the fundic glands It is therefore a constituent of pure gastric juice (dissolved mucin) Vagal stimulation evokes a secretion of mucin from the mucin secreting cells of the tubules Mucin is a complex of glycoproteins Secretion collected from pouches from the pyloric part of the stomach of dogs is mucoid, viscous, tenacious, and transparent, with a pH of 7 0 to 7 5 It coats the interior of the stomach and serves to protect the mucosa from the action of the gastric juice, but has little acid-reducing power Mucin does inhibit peptic activity This antipeptic action of mucin is due to its constituent, mucoitin-sulfuric acid, the main monomer of goblet cell mucus By virtue of its high viscosity, mucin effectively lubricates and protects the gastric mucosa from mechanical injury

Brunschwig and associates (1939) demonstrated the presence of a *gastric secretory inhibitor* that they isolated from the gastric juice of patients with pernicious anemia Blackburn and Code (1948) also demonstrated the presence of a gastric secretory inhibitor in human gastric juice and determined that the active material was in the mucin fraction of the juice The exact nature of this gastric secretory inhibitor is not known, but this inhibitor called *gastrone* has been partially purified and consists of a mucus-like substance with a molecular weight over 100,000 containing much carbohydrate, and a nondialyzable glycopolypeptide or glycoprotein with a molecular weight between 10,000 and 400,000

Mechanism of Hydrochloric Acid Secretion

The precise manner in which the gastric mucosa secretes hydrochloric acid is still unknown However, the following facts taken together point in a general way to the processes which must be involved in the secretion

1) It is generally agreed that the acid is formed by the parietal cells of the gastric glands (Davies, 1951) It is not believed to be produced in the protoplasm of these cells but to

appear first in the secretory canaliculi which communicate with the lumen of the gland

2) The acid, as secreted by the parietal cell, has a uniform concentration of approximately 0 17 M The theory of the constancy of the concentration of hydrochloric acid as secreted by the parietal cells was first put forward by Pavlov (1910) and has since been supported by many investigators, including Hollander and Cowgill (1931) This theory is mainly based on the observation that the nearer one approaches to a pure parietal secretion, the nearer the concentration of hydrochloric acid approaches 0 17 M The acidity, when plotted against the neutral chloride, gives a straight line expressing the inverse relationship between them When extrapolated, this line comes to a point representing a zero value for neutral chloride and an acidity of around 170 mEq /liter Since neutral chloride and acid chloride are inversely related, the total chloride tends to remain relatively constant However, since some of the nonparietal secretion contains relatively little chloride, the total chloride increases somewhat with increasing rate of parietal secretion and, therefore, with increasing total acidity (Figs 2 19 and 2 20)

A somewhat different opinion was expressed by Fisher and Hunt (1950), who made a study of the extensive data of Ihre (1938) on gastric secretion in human subjects They concluded that the most probable concentration of hydrochloric acid in human parietal secretion is 160 mEq /liter, and that the secretion contains, in addition, 10 mEq /liter of neutral chloride

3) The secretion of hydrochloric acid involves expenditure of energy, that is to say, no simple chemical reaction which could proceed spontaneously can explain the formation of hydrochloric acid by the gastric glands One estimate is that the secretion of 1 g -molecular equivalent of hydrochloric acid requires expenditures of 10,000 gram calories of energy

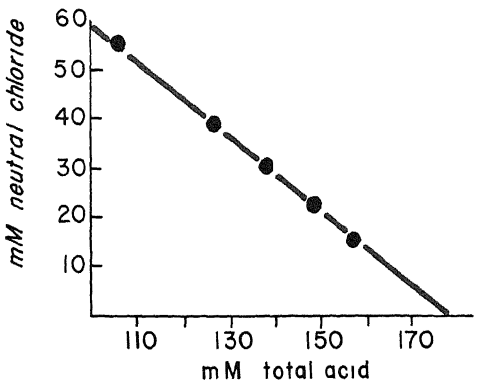

Fig 2 19 Neutral chloride as a function of acidity (After Hollander 1932a)

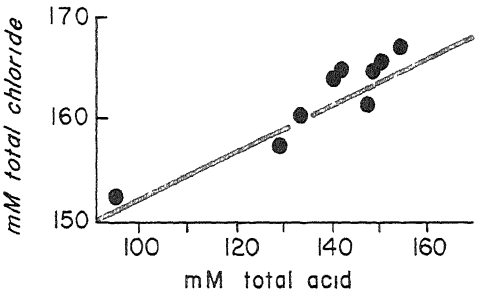

Fig 2 20 Total chloride as a function of acidity (After Hollander 1932b)

4) The energy is derived from oxidation, probably of glucose, and requires the activity of the enzymes ordinarily active in such oxidation

5) For every hydrogen ion produced, a bicarbonate ion is released into the interstitial fluid and ultimately into the blood This requires a continuous supply of carbon dioxide The carbon dioxide may be derived from the metabolism of the parietal cell itself if the secretory rate is low, but at higher rates of secretion the metabolic carbon dioxide has to be supplemented with carbon dioxide from the circulating blood The need for carbon dioxide arises from the fact that, whatever the reacting system may be, removal of hydrogen ion results in accumulation of an excess of hydroxyl ions, if these were not neutralized, the resulting alkalinity would soon destroy the secreting cells The fact that secretion of hydrochloric acid into the gastric juice results in secretion of an equivalent amount of bicarbonate into the blood explains the so-called alkaline tide seen in the urine during digestion (Bence Jones, 1850)

6) Carbonic anhydrase is present in high concentration in the parietal cells (Davenport, 1939), and participates in the overall process, though probably not directly in secretion of hydrogen ions Its apparent function is to aid in the hydration of carbon dioxide and to produce the carbonic acid that is utilized in neutralizing the hydroxyl ions produced during secretion Secretion of hydrochloric acid is greatly depressed and in some subjects, totally inhibited, by the administration of large doses of Diamox, which is an inhibitor of carbonic anhydrase (Janowitz et al , 1957) Although excised frog

gastric mucosa will secrete in the absence of carbon dioxide, the tissue is destroyed by the alkalinity resulting from the loss of hydrogen ions (Davies and Longmuir, 1948) In the living animals, at least in mammals, some mechanism apparently exists to prevent secretion under these circumstances, and this protects the secreting tissue from self-destruction

7) The overall reaction can be summarized by the equation

$$CO_2 + H_2O + NaCl \rightleftharpoons HCl + NaHCO_3$$

This equation is not intended to describe the chemical reactions in detail, but merely to indicate the beginning and end products and their quantitative relationships It indicates that the ultimate source of the hydrogen ions is water, the ultimate source of the chloride ions is the salt of the blood, for each mole of hydrochloric acid produced, a mole of sodium bicarbonate has to be formed The intermediate steps, the source or sources of energy, and the enzymes and substrates concerned in the intermediate reactions, all of which constitute the real problem of the secretion of hydrochloric acid, are not even suggested The fact that the reactions of this equation would ordinarily progress to the left is a simple qualitative proof that energy is required for the secretion of hydrochloric acid

8) Rehm (1950) and his co-workers have shown that there is a maintained electrical potential difference across the gastric mucosa, the secretory surface being negative in an external circuit to the nutrient surface When the two sides of the mucosa are connected electrically, a continuous current can be maintained representing about 10% of the metabolic energy This electrical potential decreases with the onset of acid secretion The rate of acid secretion can be increased or decreased by passing an electric current, from a battery through the mucosa so as to increase or decrease, respectively, the potential difference across the tissue Experiments with metabolic inhibitors show that most of the pathways of aerobic metabolism, and the related phosphorylations, are required to maintain the potential difference and acid secretion The facts prompted Rehm to propose a theory of acid secretion in which it is assumed that electrical energy is utilized in the separation of hydrogen ions during the secretion of hydrochloric acid It seems more likely that here, as elsewhere, the potential difference is the result of, rather than the cause of, the activity

As to the intermediate steps between carbon dioxide and water at one end of the reaction, and hydrogen ions and bicarbonate at the other end, Davies (1951), after reviewing the history of research in this field from Claude Bernard's time until 1951, had this to say "The available evidence shows that two related mechanisms of acid secretion are possible In mechanism 1, the metabolic-hydrogen atoms from glucose and water, which are transported by the dehydrogenases, become oxidized to hydrogen ions at the cytochrome level, and the electrons react with oxygen and water to form, first hydroxyl ions, and then bicarbonate ions by further reactions with carbon dioxide This process uses the oxidation reduction energy from the level of atmospheric oxygen to that of the cytochromes In mechanism 2, phosphate bond energy, generated by reactions at lower oxidation reduction levels is utilized to concentrate hydrogen ions, formed by ionization from water, in an electron cycle mechanism in which hydrogen ions are reduced to covalent hydrogen atoms, transported by a carrier system and oxidized to hydrogen ions at high concentration as a result of coupled phosphorylation Kinetic and thermodynamic considerations show that the hydrogen carrier and electron transport systems could be oxaloacetate-malate and cytochrome b, or perhaps fumerate-succinate and cytochrome c Both mechanisms require a spatial array of enzymes in the paracanalicular zone of the oxyntic cells, and in both cases, chloride ions move in the opposite direction to, and as a result of, the movements of the electrons carried by the cytochromes "

Davenport (1957) wrote 6 years later, "I suspect that the secretory process is a cyclic oxidation and reduction A carrier molecule within the cell combines with high energy phosphate The product is oxidized and the energy contained within it is dissipated in transporting the newly released proton" (hydrogen ion) "against a concentration gradient into the gastric juice Then the carrier is reduced by substrate and is ready to re-enter the cycle Two minor problems remain For each proton secreted an electron must be taken up by oxygen, and the pH of the cell must be kept down by intracellular neutralization using the carbon dioxide mechanism . " "Carbonic anhydrase which occupies a peripheral position is involved, an

enzyme behaving like succinoxidase is there, and it is likely that some sulfhydryl compound is essential" Davenport, like Davies, recognized the need for assuming appropriate orientation of the various components involved in the reaction Davenport's concept is illustrated in Figures 2 21 and 2 22

Davies (1951) considered that "the rate of transport of water by oxyntic cells is so enormous that it could not be handled molecule by molecule by any known enzyme systems The water must be moved in bulk, and probably flow osmotically as a result of the secretion of the hydrogen and chloride ions by the oxyntic cells"

Once H^+ ions have been secreted, the gastric mucosa serves to contain them and offers a barrier to the diffusion of H^+ out of the lumen, and to the diffusion of Na^+ ions into the lumen from the interstitial fluid This "mucosal barrier," as Davenport has named it, is greatest in the fundus, less restrictive in the antrum, and least in the duodenum

Control of Gastric Secretion

Gastric secretion is controlled by both neural and humoral mechanisms The parasympathetic (vagus) innervation provides the pathways for secretory stimuli to the gastric mucosa Sympathetic pathways control gastric secretion indirectly, due to their control over vasomotor mechanisms and blood flow to the mucosa

A number of humoral mechanisms also are involved in the control of gastric secretion Examples include the release of *gastrin* from the gastric antrum which *stimulates* gastric secretion, and the release of *enterogastrone* from the mucosa of the upper small bowel which *inhibit* gastric secretions The last characterized is a substance which inhibits acid secretion but stimulates pepsin output

It is convenient, when discussing the gastric secretory response to a meal, to divide the total response into different phases *cephalic*, *gastric*, and *intestinal* phases, named according to the area where the stimuli arise The volume of gastric secretion resulting from these different phases in the dog is illustrated in Figure 2 23 In man, gastric secretion tends to be continuous For this reason, a fourth phase of gastric secretion, the *interdigestive* phase, is recognized An estimate of the volume of gastric secretion of the various phases in man is shown in Table 2 7

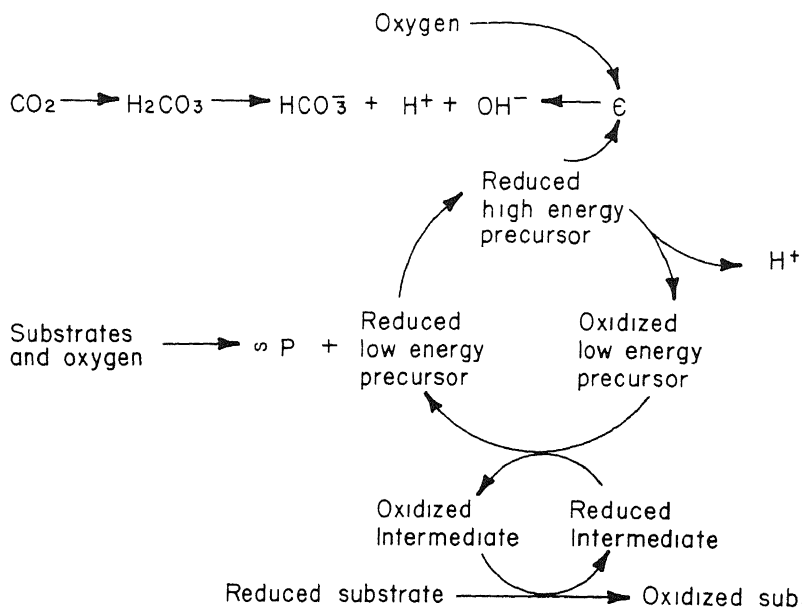

Fig 2 21 Schema of a possible mechanism of gastric acid secretion showing the four essential parts *a* generation of high energy phosphate bounds from substrate and oxygen *b* cyclic oxidation and reduction generating hydrogen ions *c* removal of electrons to oxygen and *d* intracellular neutralization by carbon dioxide (From Davenport 1957 Courtesy of University of Wisconsin Press)

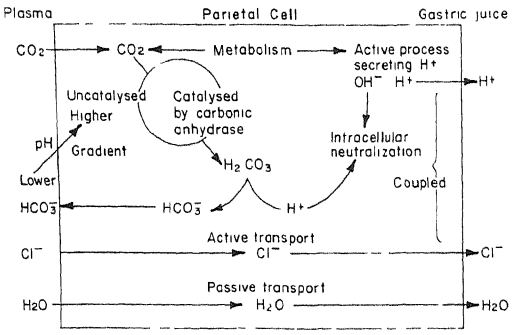

Fig 2 22 Diagram illustrating the role of carbon dioxide in intracellular neutralization during secretion of acid by the gastric mucosa (Redrawn from Davenport 1962)

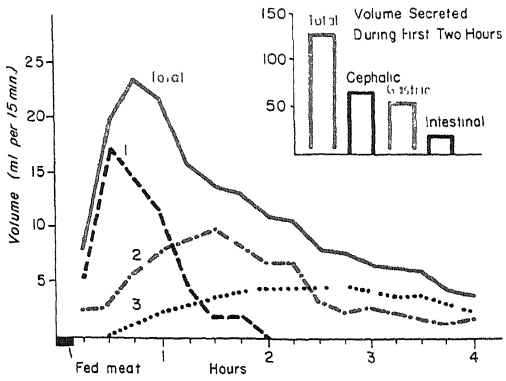

Fig 2 23 Reconstructed curves to show the approximate distribution between the several phases of gastric secretion in the dog after a meal of 300 g of meat *1* cephalic or initial reflex phase *2* gastric or pyloric phase and *3* intestinal phase (Redrawn from Thomas and Friedman 1951)

Table 2 7

Volume of different phases of gastric secretion in man

Period or Phase	Amount (ml)
Interdigestive	30–60 ml /hr
Cephalic	50–150 ml /20 min
Gastric	225–350 ml /5 hr
Intestinal	200–300 ml /5 hr

From Ivy et al, 1950, p 32

CEPHALIC PHASE OF GASTRIC SECRETION

Upon eating a meal, gastric secretion is initiated prior to the food arriving in the stomach by afferent impulses arising in the head (thus the term cephalic) which converge on the vagus nucleus, and efferent stimuli are sent to the gastric mucosa via the vagi The cephalic, or *initial reflex phase*, of gastric secretion results from the sight, smell, or taste of food, or from the act of eating and is prevented by section of the vagus nerves If the secretion results from the sight or smell of food without food making actual contact with the mouth, it is referred to as *psychic* secretion The fact that there can be an abundant secretion of gastric juice, even though there is no food in the stomach, is readily demonstrated by means of sham feeding This phase is mediated by the vagus nerves by two mechanisms *1*) direct cholinergic stimulation of the oxyntic (parietal) cells, and 2) cholinergic release of gastrin from the pyloric gland area, and mechanism 1 probably requires the presence of a small amount of gastrin itself

Janowitz and his colleagues (1950) made some interesting observations in a female subject who had a complete stenosis of the esophagus following a lye stricture and had to have a gastrostomy for feeding purposes They studied the effects of various types of meals on the cephalic phase of gastric secretion and found that an unappetizing meal consisting of cereal gruel evoked essentially no response, whereas a meal selected by the subject evoked a high secretory response The routine hospital ward diet evoked an intermediate response (Fig 2 24) The latent period of the cephalic phase response was less than 5 min The duration of the response ranged from 30 to 120 min following cessation of sham feeding and varied with the type of meal

GASTRIC PHASE

The entry of food into the stomach initiates gastric secretion by the distention from the bulk of the meal, and chemical factors in the partially digested meal alcohols, peptides, and amino acids (especially glycine, β-alanine, serine, (and lysine)

Both distention and chemical factors operate via the same two mechanisms cited for the cephalic phase *1*) direct cholinergic stimulation of oxyntic cells, and 2) cholinergic release of gastrin from the pyloric gland area cells In both, "long" (vago-vagal) or "short" local reflexes within the stomach are probably operative Figure 2 17 diagrams this

Gastrin. The most important advance in our contemporary knowledge of gastric secretion has been the purification, and structural analysis of gastrin by Gregory and Tracy (1964) This linear peptide with 17 amino acid residues occurs in two forms without (Gastrin I) and

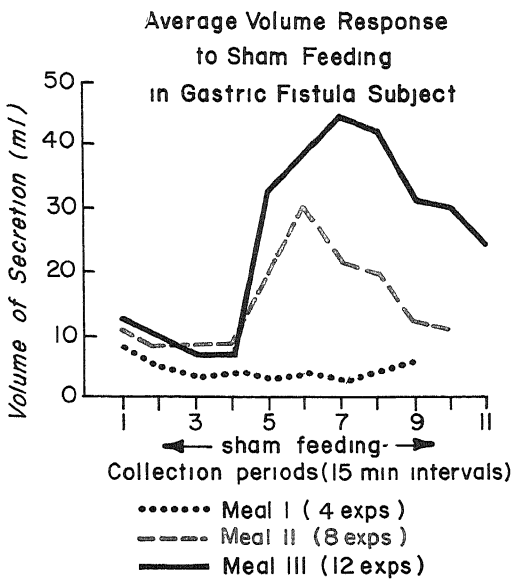

Fig 2 24 Volume response to sham feeding of different types of meals to a patient with a gastric fistula Meal I consisted of cereal gruel meal II was a routine hospital ward diet and meal III consisted of foods selected by the subject (Redrawn from Janowitz et al 1950)

with (Gastrin II) sulfate esterified on the phenolic hydroxyl group of the tyrosyl residue at position 12 Activity resides in the terminal tetrapeptide In the antrum and in the blood, gastrin exists also in a larger form than the 17 amino acid gastrin characterized by Gregory This later "big gastrin" appears to have the same physiological actions as the better known "little gastrin" Gastrin is present in small amounts, outside the antrum, and in the duodenum and probably in the pancreas

The action of gastrin on the acid-secreting cell is influenced by other gastrointestinal hormones and neural impulses Cholecystokinin and secretin inhibit gastrin stimulated acid secretion, the former probably by competitive inhibition, the latter by noncompetitive inhibition Cutting the vagus nerves greatly decrease the secretion of acid in response to gastrin

The release of gastrin from the pyloric gland area is markedly *inhibited* by acid bathing this area of the stomach A pH of 2 or less is required and can counteract the stimulatory effects both of vagal stimuli and of local distention and chemical factors

Interestingly enough, gastrin can be released by rapid increases in the concentration of serum calcium

These considerations help to elucidate the rationale for use of the operations of vagotomy, on the one hand, and of subtotal gastric resection on the other If the nervous and hormonal mechanisms of stimulation were independent of each other, we should expect that cutting the vagus nerves would influence only the initial reflex phase of gastric secretion and leave the gastric phase in full effect In reality, however, all phases of gastric secretion are profoundly depressed by vagotomy, and in some patients permanent achlorhydria has been reported Likewise, resection of the antrum, or subtotal gastric resection, theoretically should affect only the gastric phase Experience indicates, however, that the cephalic phase too is influenced profoundly

INTESTINAL PHASE

It has long been observed that the presence of certain food substances in the small intestine also stimulates gastric secretion This so-called intestinal phase has been extensively investigated The latent period of the intestinal phase is 2 to 3 hr but once secretion is initiated, it may last for 8 to 10 hr The following substances have been observed to excite gastric secretion when placed in the small intestine water, extractive substances of meat, products of protein digestion, (for example, peptone and amino acids), milk, alcohol, histamine, saponin, epinephrine, 0 1 N hydrochloric acid, 10% glycerin solution, and magnesium sulfate The intestinal phase is characterized by less secretory activity than either the cephalic or gastric phases and for this reason, the interpretation of results of studies of the intestinal phase have been more difficult

Experiments on the intestinal phase of gastric secretion have been conducted primarily on animals in the fasting state with the stomach empty Because of the long duration of the intestinal phase of gastric secretion from previous feedings, it is customary to fast the animal (dog) at least 24 hr The results obtained might have been otherwise had the intestinal phase been permitted to follow the cephalic and gastric phases as in the intact situation The known tendency of stimuli of different sorts to act synergistically in the gastrointestinal tract suggests, but does not prove, that the stimuli normally causing an intestinal phase may be much more effective in the presence of the re-

sidual stimuli of the cephalic and gastric phases

The cause of the intestinal phase is unknown, except that it is due to chemical stimuli A completely denervated gastric pouch secretes when food is placed in the intestine, proving that it is secreting in response to some chemical substance circulating in the blood The nature of the stimulus is unknown but may be a hormone, the "intestinal gastrin "

Perhaps one reason for the somewhat erratic behavior of the intestinal phase of gastric secretion is the ease with which inhibition of secretion may be induced by placing certain substances in the intestine The inhibitory effect of acid releasing secretion has already been mentioned, although acid in certain concentrations may stimulate gastric secretion, if the intestinal pH is lowered to 2 5 or below, it acts as an inhibitor

Intestinal (Duodenal) Inhibition of Gastric Secretion. It is appropriate at this point to consider some mechanisms inhibiting gastric secretion which originate in the upper intestinal tract. It has been well established that the presence of acid, fat, and hypertonic solutions in the duodenum released a hormone or hormones which inhibit gastric acid secretion To these hypothetical hormones, the term enterogastrone has been applied ("any hormone released from the intestine which inhibits gastric secretion," Johnson and Grossman, 1970)

While the evidence for an inhibitory action by ingested fats is conclusive, this enterogastrone has not been obtained in pure form It inhibits gastric motility as well The urinary substance(s) derived from this enterogastrone has been named urogastrone and much effort is being directed to its chemical elucidation

The inhibition of acid secretion which follows entry of HCl into the upper gastrointestinal tract is of great interest Part of it can be accounted for by the release of secretin (a known inhibitor of HCl secretion), which follows the presence of acid in the length of the entire duodenum, and appears to be related to the quantity of acid entering the gut Acid may inhibit by other mechanisms since Anderson, working in Uvnas's laboratory, has demonstrated that acidification of the duodenal bulb will inhibit gastrin and sham feeding stimulation of acid secretion without stimulating (secretin mediated) pancreatic secretion

INTERDIGESTIVE PHASE

Even after prolonged fasts, hydrochloric acid is found in the gastric juice of man as well as in that of the dog Both Pavlov and Babkin believed that hydrochloric acid was not secreted in the gastric juice during the interdigestive period When acid was detected in gastric juice of the dog after a prolonged fast, it was thought to result from either swallowing of saliva, regurgitation of duodenal juices, or extraneous stimuli such as the sight or smell of food In man, Heolzel (1926) found variable amounts of hydrochloric acid in gastric juice throughout a fast period of 40 days In both man and dog, the interdigestive secretion of HCl apparently occurs in an intermittent or periodic fashion The causes of such secretion are not known, but mechanisms involved apparently include both humoral and neural stimuli A subcutaneous autotransplanted gastric pouch in a dog, devoid of all original extrinsic nerve and vascular supply, during a fast will secrete acid intermittently This indicates that the stimuli for secretion must be humoral in nature The role of the neural pathways is suggested by the fact that following vagotomy in man, interdigestive secretion of hydrochloric acid is inhibited but not completely abolished With intact vagal innervation, conditioned reflexes in both man and the dog undoubtedly play a part In addition, in man, psychic stimulation is also probably important

The Normal Course of Gastric Secretion

With the discussion of the various phases of gastric secretion as background, we may now consider the sequence of events affecting the secretion of gastric juice following an "average" meal First, there is the sight and smell and the taste of food which, if agreeable, and if the individual has an appetite, will initiate the psychic or cephalic phase of gastric secretion This phase is augmented when the food is actually chewed and swallowed The first juice secreted has powerful digestive action, particularly upon the protein constituents of the food and releases from the food chemical excitants for the second, or chemical, phase of secretion These, along with the mechanical action of such food particles as enter the pyloric antrum, cause the release of gastrin. This augments and prolongs the secretion due to the cephalic phase

and initiates the gastric phase The gastric phase of secretion continues as long as food remains in the stomach As soon as the stomach is empty and the buffering substances present during digestion are no longer available, the pH of the antrum or the duodenum falls to a point at which the inhibitory effect of acid becomes evident, and that period of gastric secretion is brought to an end During the gastric phase of secretion, some chyme enters the small intestine where, after a variable latent period of 1 to 2 hr , it initiates the intestinal phase of gastric secretion This phase probably accounts for less than 20% of the total acid secreted by the stomach In duration, however, the intestinal phase exceeds the other phases, in fact, it may persist for as long as 5 hr Following the completion of the intestinal phase, the interdigestive phase occurs During the interdigestive phase, gastric secretion of minimal amount occurs intermittently

Effects of Some Drugs on Gastric Secretions

SECRETORY STIMULANTS

Histamine is one of the most powerful stimulants of gastric secretion Even endogenous histamine liberated within the body, e g , in dermographism, or even by the immersion of the hand in cold water at a temperature of 10° C, causes a detectable gastric secretory response within 15 min Administration of exogenous histamine is commonly used in gastric analysis Antihistamine agents, such as neoantergen and benadryl, do not inhibit gastric secretion evoked by histamine Histamine is effective when administered subcutaneously in very small doses Even a few 10ths of a milligram (0 2 to 0 3 mg of histamine base) will cause a copious secretion in dogs or man A similar dose given rapidly intravenously has little effect on gastric secretion If given very slowly, over a period of an hour, intravenous histamine is as effective as subcutaneous histamine in stimulating gastric secretion It is thought that histamine acts directly on the parietal cell to stimulate secretion of acid Large amounts of histamine are found in the gastric mucosa, and during active secretion, histamine can be detected in low concentrations in the gastric juice and the urine Histaminase, an enzyme that destroys histamine, is not found in the gastric mucosa

The effects of histamine on gastric secretion have been studied extensively There is a specific dose-response relationship, as illustrated by Code and associates (1949) in Figure 2 25 By increasing the dose of histamine in a step-like manner, the parietal cells can be stimulated to produce a "maximal secretory response " The latter is not equivalent to the *secretory capacity* of the stomach, for it has been shown that through the administration of a parasympathetic drug such as acetyl-β-methylcholine chloride (Mecholyl), and sham feeding, it is possible to stimulate secretion beyond the level achieved by prior histamine administration (Marks et al , 1960) Even so, the maximal secretory response to histamine has been shown to correlate well with the total number of parietal cells in the gastric mucosa Cox (1952) has attempted to calculate the number of parietal cells in the gastric mucosa on the basis of sampling representative fields using human autopsy material Accordingly, the average size of the parietal cell population is 1 18 billion in the adult male and 0 84 billion in the adult female In 15 patients with duodenal ulcer, the average number of parietal cells was 1 8 billion (1 9 billion for 11 males and 1 52 billion for 4 females) In 13 cases of gastric ulcer (sex not stated), the

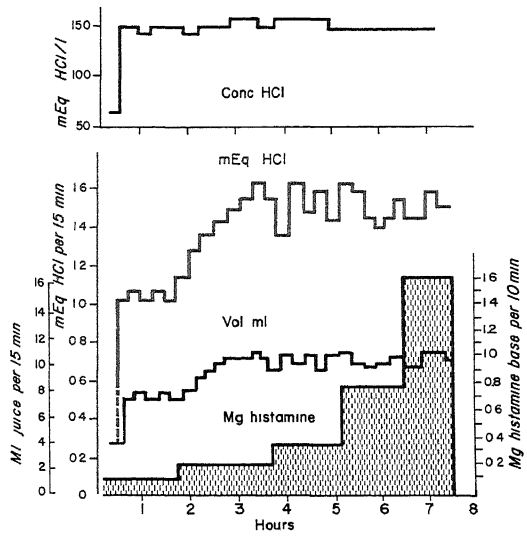

Fig 2 25 Dose-response relationship of a Heidenhain pouch to histamine given subcutaneously every 10 min Note that after a dose of 0 4 mg of histamine base/ 10 min was reached no further increase in gastric secretion occurred even with increasing amounts of histamine administration (Redrawn from Code et al 1949)

average number of parietal cells was 0 8 billion Card and Marks (1960) studied patients before and after partial gastrectomy for duodenal ulcer by measuring the maximal secretory response to histamine and counting the number of parietal cells in the portion of the stomach that was resected When the reduction in secretory response after partial gastrectomy was compared to the estimated number of parietal cells in the resected portion of the stomach, a good correlation was found and indicated that 1 billion parietal cells can secrete, on the average, 25 mEq HCl/hr (Fig 2 26) Marks and his associates (1960) have studied the maximal secretory response to histamine in the dog, and compared this to the "parietal cell mass " A linear relationship was demonstrated These investigators found that, in the dog, 1 billion parietal cells, when responding maximally to histamine, secreted on the average 9 8 mEq HCl/30 min

Histalog, an analog of histamine, (3-β-aminoethylpyrazol) is also a powerful gastric secretory stimulant It is frequently used in place of histamine for gastric analysis, as histalog does not produce the undesirable side effects caused by histamine

Pentagastrin, the commercially available terminal tetrapeptide of gastrin, is a powerful stimulant of gastric secretion and is being widely used as a clinical test substance A dose of 6 μg /kg intramuscularly or subcutaneously produces a peak acid output identical to those produced by a maximum dose of gastrin, histamine, or histalog

Caffein and *alcohol* are strong secretory stimulants The latter has a pronounced secretagogue action causing the secretion of a juice of high acidity and rich in mucin Alcohol exerts its secretory action through the liberation of gastrin

Parasympathomimetic agents as acetylcholine, Mecholyl (acetyl-β-methylchlorine chloride), pilocarpine, and nicotine are secretory stimulants

Insulin, in a dosage sufficient to lower the blood sugar to about 50 mg /100 ml , has an effect on the gastric glands similar to that of stimulation of the vagus nerves, namely, that the output of acid and pepsin is increased By an ill-understood mechanism, vagal stimulation also causes hypoglycemia Hypoglycemia activates sympathetic as well as parasympathetic centers Insulin convulsions are merely a further manifestation of this general excitatory

The Relationship Between the Maximum Acid Output and the Parietal Cell Mass

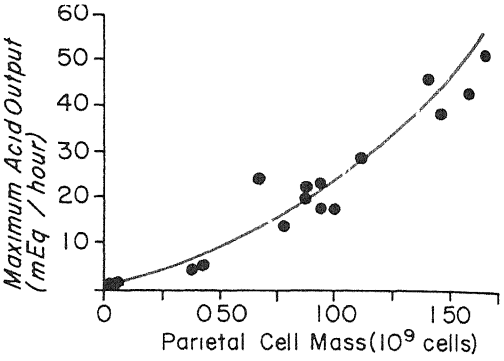

Fig 2 26 The relationship between the maximum acid output and the parietal cell mass calculated for the resected portion of each of 17 human stomachs The figure indicates that one billion parietal cells can produce approximately 25 mEq of HCl/hr (Redrawn from Card and Marks 1960)

effect of hypoglycemia of rapid onset Release of gastrin by the pyloric antrum may be reduced by insulin, as well as by vagal excitation, both of which are associated with hypoglycemia

Our understanding of the action of insulin on gastric secretion is complicated by observations which indicate that the hormone exerts an inhibitory effect in addition to the excitatory influence just described The duration of the inhibitory influence is brief (15 to 30 min) in man, but as long as 1 hr in dogs The inhibitory effect of insulin has been demonstrated during intravenous glucose administration, thus ruling out hypoglycemic mediation Insulin inhibition effectively controls gastric secretion induced by vigorous histamine stimulation

Since the effect of insulin on gastric secretion is dependent upon the integrity of the vagus nerves, the "insulin test" has been used as a means of determining the completeness of therapeutic vagotomy in human subjects (Hollander, 1946) A positive insulin test is proof of the presence of intact vagus fibers but a negative result is less conclusive, since some subjects with intact vagi fail to secrete in response to insulin The test, has, nevertheless, been of great value in the surgical control of duodenal ulcer.

SECRETORY DEPRESSANTS

Belladonna or its alkaloids, *atropine* and *hyoscine*, and *hyoscyamus* or its alkaloid *hyoscyamine*, are secretory depressants These

agents are capable of abolishing the cephalic phase of gastric secretion through their action on the vagus nerves Atropine reduces but does not suppress secretion due to histamine, alcohol, or caffeine Atropine has recently been shown not to inhibit the release of gastrin in response to feeding in man

Certain *synthetic anticholinergic agents* which inhibit gastric secretion with minimal side effects are available These agents are commonly used in the control of gastric acidity in patients with duodenal ulcer Many of these agents have a greater inhibitory action than atropine on gastric secretion and motility, and have less effect on other peripheral structures than atropine does, so that their use for regulation of gastric secretion becomes feasible In general, these parasympatholytic drugs can be divided into *tertiary* and *quaternary* amines The tertiary amines produce few side effects but usually are not too potent as secretory inhibitors The quaternary amines, on the other hand, are potent secretory inhibitors, and when given in adequate therapeutic doses, effectively suppress gastric secretion Such agents are particularly valuable in controlling the cephalic and interdigestive phases of gastric secretion Mild side effects as dryness of the mouth, blurring of vision, or slowing of the urinary stream are not uncommon, however

Effect of Emotional States on Gastric Secretion

In general, irrespective of the nature of the emotion, whether it be fear, anger, or frustration, the effect on gastric secretion is one of inhibition Beaumont (see 1929 republication) observed, in Alexis St Martin, that anger and fear caused suppression of gastric secretion In his book, *Bodily Changes in Pain, Hunger, Fear and Rage*, Walter B Cannon (1915) focused attention on the inhibitory effects of intense emotions That certain types of emotional disturbances stimulate gastric function, in fact increase secretion of hydrochloric acid, was first demonstrated by Wolf and Wolff (1943) in studies on their modern Alexis St Martin, Tom Little When exposed to sudden fear or pain, Tom's stomach became pale and ceased to secrete hydrochloric acid in accordance with the concept popularized by Cannon, however, when a situation developed which caused prolonged resentment or deep seated chronic anger, the opposite effects were observed, the gastric mucosa became congested and the secretion of hydrochloric acid was increased The weight of evidence indicates that chronic anxiety, anger, resentment, and fear, if sufficiently prolonged, tend to produce effects on gastric function characteristic of increased activity of the parasympathetic division of the autonomic system, including increased secretion of hydrochloric acid by the stomach

The central mechanism for these effects is situated partly in the hypothalamus This portion of the brain has been shown repeatedly to be a center for the coordination of impulses involved in emotional expression (Bard, 1928, 1929, Fulton and Ingraham, 1929)

It has long been known that stimulation of the posterior portion of the hypothalamus brings about visceral responses characteristic of the activity of the sympathetic division of the autonomic nervous system Evidence that the vagi, or other parasympathetic nerves, could be activated from the hypothalamus has not been so abundant, but it is becoming increasingly apparent that parasympathetic effects can be obtained from various regions of the hypothalamus by appropriate stimulating techniques (Strom and Uvnäs, 1950)

Measurement of Gastric Acidity

The words "free acid," "combined acid," and "total acid" were coined at a time when we had little understanding of the nature of gastric acidity, and little knowledge of ionization and the nature of buffers These terms were based on the concept that a certain fraction of the hydrochloric acid existed free in solution, a certain other fraction existed in combination with protein or other acid-absorbing substances, and that these fractions could be distinguished by the use of indicators We realize now that indicators merely tell us when the solution has reached a certain pH It is customary now to measure titratable acidity by titration with 0 1 N NaOH to a fixed end point (pH) colorimetrically or electrometrically, and to measure hydrogen ion activity with a pH meter

"Titratable acidity = hydrogen ion concentration + un-ionized hydrogen concentration" is the current equation instead of the obsolete terms "Total acidity = free acidity + combined acidity "

Much discussion has been devoted to the question of what is the correct end point for titratable acidity Some have suggested pH 7 0

as physiochemical neutrality; others recommend pH of plasma of 7.4.

It is customary to measure the pH of the gastric contents using a glass electrode and pH meter. pH, it will be remembered, is the negative logarithm of the hydrogen ion concentration. The glass electrode measures the hydrogen ion activity, not true concentration, and can be converted to concentration by a correction factor, the activity coefficient. Thus, from the pH value, one can calculate the hydrogen ion concentration in terms of moles per liter. The pH value is particularly useful when the acidity is low (James 1957).

It should be remembered that expression of gastric acidity in terms of free acid and total acid is an expression of the *concentration* of HCl in the gastric contents. Quantitative data of output can be expressed in terms of *milliequivalents* of hydrochloric acid secreted *per unit of time*.

6 / PANCREATIC SECRETION

Structure of the Pancreas

The pancreas is both an endocrine and exocrine gland It develops from two outgrowths (ventral and dorsal) of the primitive gut The ventral pancreatic bud arises with the hepatic diverticulum, and together they grow into the ventral mesentery The dorsal pancreatic bud enters the dorsal mesentery, and, as a result of the rotation of the gut together with its mesenteries as well as growth of the pancreatic anlages themselves, the two portions of the pancreas meet along the left border of the duodenum and soon fuse with one another The duct of the ventral pancreas becomes confluent with that of the dorsal anlage, usually near its origin In keeping with the fact that the proximal portion of this duct was developed in conjunction with the liver bud, the definitive pancreatic duct (of Wirsung) enters the duodenum in close association with the common bile duct That portion of the duct of the dorsal rudiment which lies between the duodenum and the point of anastomosis with the ventral duct is normally retarded in subsequent development and becomes the accessory duct or *duct of Santorini*

The pancreas is a racemose gland, its alveoli resembling those of the salivary gland in their general arrangement and design The pancreas is made up chiefly of groups of cells forming acini which tend to be spherical or ovoid in general, in the closely packed tissue of the pancreas they are actually polygonal Groups of acini form primary lobules, also polygonal in contour, which are imperfectly separated from other primary lobules by incomplete connective tissue septa Numerous adjacent primary lobules form a secondary lobule The secondary lobules are completely surrounded by connective tissue The pancreatic tissue proper is composed of acinar cells, islet cells, and duct cells The acinar cells tend to be pyramidal, with the truncated apex of the pyramid directed toward the lumen They are large with well-developed nuclei and abundant granular cytoplasm The granules (zymogen granules) vary in number and position in the cells depending upon the activity of the gland, but tend to be more abundant in the apical region of the cell which is adjacent to the lumen of the acinus

Cells, corresponding in structure to the cells of the terminal ducts, may be seen in microscopic sections within the acini, these are called *centroacinar cells* and contain abundant mitochondria

INNERVATION OF THE PANCREAS

The pancreas receives its nerve supply from the vagi and splanchnic nerves The extrinsic nerve supply to the pancreas passes through the celiac plexus and reaches the gland by way of the nerve plexus surrounding the arteries, chiefly the superior pancreaticoduodenal artery The vagus fibers end in the intrinsic ganglia of the pancreas From these the parasympathetic path is continued through postganglionic unmyelinated fibers to the acinar cells, islet cells, and the smooth muscles of the ducts The efferent splanchnic fibers, destined to supply the pancreas, all end in the celiac and associated ganglia From there the sympathetic path is continued through unmyelinated, postganglionic fibers which are distributed solely to the pancreatic blood vessels Myelinated visceral afferent fibers from the pancreas are also present in the splanchnic nerves

It is often incorrectly stated that the pancreas receives all, or the greater part, of its vagus nerve supply from the right vagus This error arises from the tendency to overlook the fact that after the vagi merge in the esophageal plexus, the right and left nerves can no longer be distinguished Two or more trunks emerge from the esophageal plexus The trunk that occupies the more posterior position at the level of the diaphragm, although referred to by some anatomists as the right vagus, contains fibers from both the right and left vagi as they occur in the neck When stimulated in the neck, the right and left vagi are equally effective in modifying pancreatic function

Pancreatic Juice

The pancreas secretes a colorless, odorless, alkaline fluid of low viscosity Exceptional specimens having a high concentration of enzymes may be more viscous Pure pancreatic juice collected from dogs without loss of carbon dioxide has a pH between 8 0 and 8 3, and a specific gravity that ranges from 1 007 to 1 042, but usually falls between 1 010 and 1 018

Pancreatic juice is iso-osmotic with the plasma, and its osmolality is independent of rate of flow Induced alterations in the osmotic pressure of the plasma are followed rapidly by corresponding alterations in the juice

ELECTROLYTE COMPOSITION

Sodium concentration in the juice is approximately equal to Na^+ in plasma water, as is K^+ concentration both are independent of the rate of flow (Fig 2 27) Table 2 8 (Janowitz, 1967) records the values for dog pancreatic juice The values for man are similar Calcium concentration is lower (1 7 ± 0 3 mmol /kg H_2O) than in plasma Calcium appears to enter pancreatic juice along with the enzymic components, not with the major electrolyte (HCO_3^-) containing fluid

It is now well established that the bicarbonate and chloride concentrations of pancreatic juice vary in a reciprocal manner, so that the sum of the two expressed in milliequivalents is approximately constant and nearly the same as the total cation of the blood plasma In human pancreatic juice, Janowitz and Dreiling (1962) have found the sum of bicarbonate and chloride concentrations to remain remarkably constant at different secretory rates They reported a value of 154 ± 10 mmoles/kg H_2O

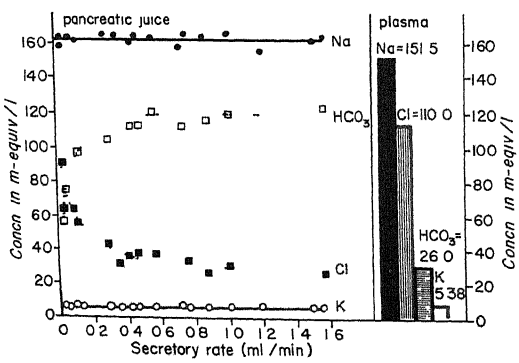

Fig 2 27 Relation between rate of secretion and concentrations of electrolytes (From Bro-Rasmussen et al 1956)

Table 2 8
Electrolytes of dog serum and pancreatic juice

	Serum mmole/kg H_2O	Juice mmole/kg H_2O
Cl	117 8 ± 4 8	
Total CO_2	28 3	154 ± 10
Na^+	153 1 ± 3 2	154 ± 7
K^+	5 1 ± 0 3	4 8 ± 0 9
H_2O	92 4%	98%

From Janowitz (1967) p 926

The bicarbonate concentration increases and the chloride concentration decreases with increasing rates of secretion This relationship holds over a wide range of secretory rates and is such that a straight line results when the logarithm of the bicarbonate concentration in milliequivalents/liter is plotted against the *reciprocal* of the rate of secretion expressed as cubic centimeters of secretion per kilogram of body weight per minute, the slope indicates an inverse relation The maximum bicarbonate concentration in juice collected from different dogs ranges between 135 and 148 mEq /liter and the maximum rate of secretion is about 0 1 ml /kg /min , or about 1 ml /min for a 10-kg dog, higher rates than this are occasionally seen The relationship of bicarbonate concentration to flow rate in pancreatic juice collected from man is illustrated in Figure 2 28 In addition to chloride and bicarbonate, the pancreatic juice contains a small amount of phosphate, but less than that occurring in blood plasma The electrolyte composition of a sample of human pancreatic juice secreted at a relatively high rate is illustrated in Figure 2 29

PROTEIN CONTENT

The protein content of pancreatic juice varies over a wide range, but in an orderly manner with the conditions governing secretion In samples of dog's pancreatic juice collected under different conditions, the protein content varied between 0 1 and 10% Concentrations found in human pancreatic juice collected through fistulas are nearer the lower extreme, ranging from 0 1 to 0 3% The protein in the juice consists mainly of enzymes Using electrophoresis, it has been possible to determine that there are at least 10 distinct proteins in pancreatic juice, with the possibility of still others that fail to separate out in the time during which the electrical field is maintained (Gross-

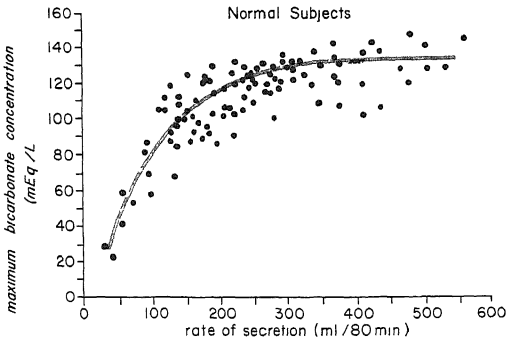

Fig 2 28 Maximum bicarbonate concentration observed at different rates of pancreatic secretion in normal subjects following stimulation of the pancreas with intravenous secretin (Redrawn from Dreiling and Janowitz 1959)

berg, Komarov, and Shay, 1952) This method of separating the proteins of pancreatic juice also separates the enzymatic activity, proteolytic activity is found in one component, lipolytic activity in another, and amylolytic activity in another In man, the following enzyme proteins have been reported amylase, lipase, trypsinogen, chymotrypsinogen, procarboxypeptidase A and B, ribonuclease, deoxyribonuclease, proelastase, and trypsin inhibitor

PANCREATIC ENZYMES

The enzymes of pancreatic juice are capable of digesting all three classes of foodstuff The proteolytic enzymes, as they occur in the pancreatic tissue and freshly secreted pancreatic juice, possess no proteolytic activity and are referred to in that state as *proenzymes* and require activation For trypsin the proenzyme is trypsinogen Kunitz and Northrup (1934) have shown that what was called trypsin or trypsinogen consists of at least two components, for one of which they retain the name *trypsin* and for the other they coined the name *chymotrypsin* The proenzyme of chymotrypsin is known as chymotrypsinogen

Trypsinogen. The molecular weight of *trypsinogen* is approximately 25,000 Trypsinogen is a single polypeptide chain containing 229 amino acid residues (Neurath, 1964) Cleavage of trypsinogen between residues 6 and 7 yields active trypsin. As an enzyme trypsin hydrolyzes native protein, producing proteoses and peptides it accelerates coagulation of the blood, in which it acts as a thrombokinase In its action on proteins, trypsin hydrolyzes only those peptide bonds whose carbonyl group is contributed by an amino acid that has a positively charged side group as arginine or lysins Trypsin cleaves peptide bonds that occupy an internal position in a polypeptide chain and also is referred to as an "endopeptidase" Its optimum pH for casein lies between pH 8 and 9

Trypsinogen is indistinguishable on chemical analysis from trypsin, but has different solubilities and a different crystalline form, and it exhibits no proteolytic activity It changes spontaneously in solution to active trypsin, but the change is accelerated by acid or by exposure to concentrated magnesium sulfate, calcium chloride, active trypsin, or to certain activating enzymes called *kinases* The effectiveness of trypsin in the activation of trypsinogen is of great importance because such autocatalytic reactions progress with great rapidity once they are started and require only minute amounts of activating agents to set them going Spontaneous activation of trypsinogen is suppressed in crude extracts (and doubtless also in living pancreas) by the presence of a trypsin inhibitor Trypsinogen is activated on contact with the intestinal mucosa by an enzyme in the mucosa called *enterokinase* Enterokinase does not appear in the intestinal secretion in the absence

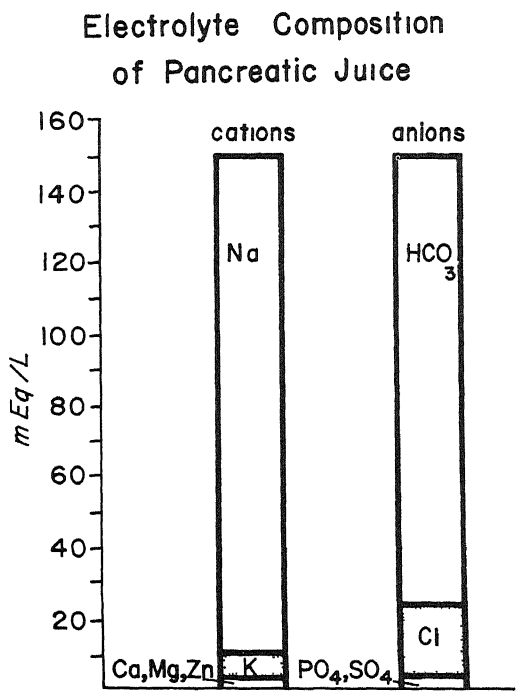

Fig 2 29 Example of the electrolyte composition of human pancreatic juice secreted at a high flow rate of 3 5 ml/min

of pancreatic juice but is present in intestinal mucosal extracts

Chymotrypsinogen Chymotrypsinogen has a molecular weight of approximately 25,700 and, like trypsinogen, is a single polypeptide chain containing 246 amino acid residues, or 17 more than trypsinogen (Neurath, 1964) When cleaved between residues 15 and 16, chymotrypsinogen is converted to the active enzyme chymotrypsin The "active centers" of both trypsin and chymotrypsin are remarkably similar In each enzyme a "histadine region" and a "serine region" have been localized and found to be connected by disulfide bonds (from two half-cystine residues) that lock the histadine and serine residues in a fixed position

Chymotrypsinogen is converted to chymotrypsin by active trypsin only, but indirect activation can be accomplished by enterokinase if trypsinogen is also present If chymotrypsinogen is activated rapidly by fairly large amounts of trypsin, π-chymotrypsin is formed which then changes spontaneously to δ-chymotrypsin, as a result of the π-chymotrypsin acting upon itself If smaller amounts of trypsin are used the major products are α-, β-, and γ-chymotrypsin which appear to have essentially the same molecular weight as chymotrypsinogen and π- and δ-chymotrypsin A sixth type, known as chymotrypsin (and chymotrypsinogen) β, also has been isolated The activity of chymotrypsin is comparable to that of trypsin but it has different specificities, for example, it coagulates milk but not blood Chymotrypsin digests casein somewhat more rapidly than does trypsin, but the digestion is carried much further by a mixture of the two enzymes than by either alone, indicating that the two enzymes attack different linkages in the protein molecule Chymotrypsin acts preferentially on peptide bonds whose carbonyl group is adjacent to an amino acid residue that has a six-carbon ring in its side group, as tyrosine and phenylalanine Like trypsin, chymotrypsin is also an "endopeptidase," and cleaves peptide bonds that occupy an internal position in a polypeptide Chymotrypsin is reversibly inactivated by boiling in acid solution Its optimum activity occurs in the same pH range as that of trypsin

Other Proteolytic Enzymes. The peptides resulting from protein digestion by trypsin and chymotrypsin are further digested by enzymes known as *peptidases* Most of these come from the intestinal mucosa, but two have been identified and isolated from pancreatic juice enzymes known as *carboxypeptidase* A and B, "exopeptidases" which split off the end amino acid containing a free carboxyl group from polypeptides In fresh pancrease, they occur in an inactive form, procarboxypeptidase A and B, and, like chymotrypsinogen, are activated by trypsin

Pancreatic juice also contains *ribonuclease* and *deoxyribonuclease*, which partially hydrolyze the corresponding nucleic acids into mononucleotides The optimum pH for deoxyribonuclease is in the neighborhood of 7 *Elastase* (Balo and Banga, 1949), and more recently, *collagenase* (Houck and Patel, 1962), have also been demonstrated in pancreatic juice

Lipase *Pancreatic lipase* accounts for the ability of the juice to emulsify and hydrolyze fats This enzyme is known principally through its activity and has not been isolated in a pure state or crystallized Pancreatic lipase hydrolyzes fat only in the presence of bile salts or other substances with similar properties, for example, some of the synthetic detergents Bile salts in high concentration inhibit the action of lipase, as do salts of certain heavy metals, e g , copper, iron, and cobalt, it is also inhibited by the halogens, fluorine, iodine, and bromine The pH at which pancreatic lipase exhibits its optimum activity varies with the substrate, but is always on the alkaline side of neutrality Pancreatic lipase hydrolyzes triglycerides to free fatty acids and glycerol

Pancreatic juice also contains two phospholipases *Phospholipase A* splits a fatty acid off lecithin or cephalin to form lysolecithin or lysocephalin *Phospholipase B* is capable of splitting a fatty acid off lysolecithin to form glyceryl-phosphoryl-choline

Amylase. *Pancreatic amylase* is an α-amylase, as is salivary amylase Amylase has been isolated in crystalline form from human pancreas The molecular weight is approximately 45,000 Pancreatic amylase splits an α-1,4-glycosidic bond to hydrolyze starch to maltose The amylolytic activity has an electrophoretic mobility in human serum similar to that of γ globulin Amlyase is excreted in the urine and the amylolytic activity of urine is an excellent indicator of the amount of amylase released from the pancreas into the blood Pancreatic amylase is secreted in active form but becomes inactive if dialyzed against distilled water—

owing to the removal of neutral salts which are thus proved to be essential for the activity of the enzyme The most efficient activating ion is chloride The optimum pH for activity of pancreatic amylase varies between 6 9 and 7 1 The enzyme digests glycogen as well as starch, and under favorable conditions, the end product in both instances is maltose

The importance of the pancreatic enzymes in digestion is evidenced by the fact that when pancreatic juice is excluded from the intestine by pancreatectomy or ligation of the ducts, there is serious impairment of digestion and absorption of the various foodstuffs This is most pronounced in the case of fat and protein, unabsorbed fat particularly appearing in large amounts in the stools The bicarbonate of the juice also serves the neutralize the gastric juice as it enters the intestine and to establish in the intestine a pH more favorable for intestinal digestion than would otherwise be the case

Mechanism of Pancreatic Secretion

It has long been assumed that the inorganic constituents of pancreatic juice are secreted by the same cells that produce the enzymes, namely the acinar cells However, the fact that fluid secretion and enzyme secretion are separately regulated raises a theoretical objection to this view All current theories of stimulation require that cells shall respond to a stimulus with a characteristic type of functional activity regardless of the nature of the stimulus In the other digestive glands, about which we have more information, each component of the secretion that is independently regulated is formed by a different type of cell We must also take account of the clinical observation that in certain types of pancreatic disease, enzyme secretion may be depressed or absent, whereas secretion of fluid and bicarbonate remains normal (Lagerlöff, 1939, Friedman and Snape, 1950) On the other hand, in glands injured by alloxan, fluid secretion may be subnormal, whereas enzymes are secreted normally This latter observation, reported by Grossman and Ivy (1946), contains a hint as to a possible solution of the problem Histological examination of the gland which failed to respond normally to secretin showed no injury to the acinar cells, but the cells of the intralobular ducts appeared abnormal, in particular, they exhibited vacuolization The intralobular duct cells are continuous with the centroacinar cells that line the alveoli and are identical with these cells in their cytological structure It is now thought that cells of this type secrete water and bicarbonate and that the acinar cells secrete the enzymes

Finally, the enzyme carbonic anhydrase has been demonstrated by histochemical methods only in ductular epithelium, and in view of the role of carbonic anhydrase in the secretion of HCO_3, suggests further that this structure is involved in the elaboration of water and electrolytes

In discussing details of the mechanism of pancreatic secretion, the secretion of fluid and electrolytes will be considered separately from the secretion of enzymes The evidence presented above indicates that pancreatic juice like gastric juice, is a mixture of secretory products from different glandular structures that are under the influence of separate regulatory mechanisms

FLUID AND ELECTROLYTE SECRETION

Three hypotheses have been suggested to account for the variation in composition of the electrolytes of pancreatic juice (See Fig 2 30)

1) Admixture concept the pancreatic juice is visualized as a mixture of three fluids neutral chloride at 174 mEq /liter, HCO_3 at 174 mEq /liter, and a third fluid containing enzymes, mucus, and an acid chloride

2) Exchange mechanism the pancreatic juice is formed by the elaboration by the centroa-

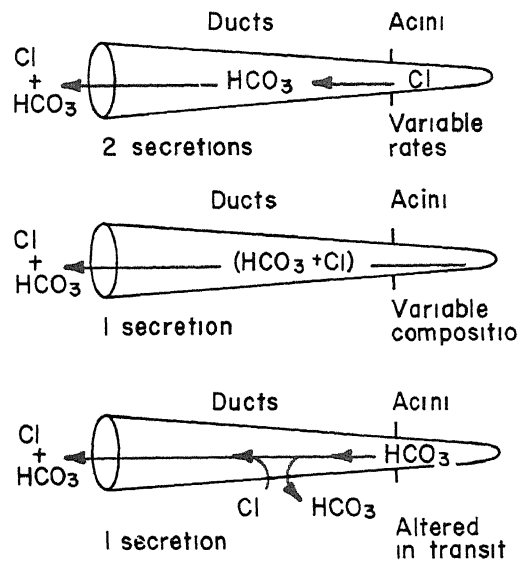

Fig 2 30 Hypothetical mechanisms of pancreatic secretion (From Makhlouf and Blum 1970)

cinar cells of a HCO_3 solution (isotonic with the plasma, 150 to 160 mEq /liter) and exchange of HCO_3 for Cl as the fluid traverses the pancreatic collecting ducts

3) A unicellular concept in which a single source elaborates a juice which the concentration of HCO_3 and Cl vary

The available data do not permit any conclusive choice among these alternatives, although perfusion and stop flow studies indicate that HCO_3 and Cl can exchange passively Micropuncture experiments are difficult to reconcile but some do indicate that HCO_3 is added to the juice along the smallest radicles of the ductular system

The bicarbonate in pancreatic juice is thought to come from both metabolic CO_2 and HCO_3^- from the blood plasma The pancreas contains an abundance of carbonic anhydrase, suggesting that it plays a role in the formation of bicarbonate It has been demonstrated that acetazolamide (Diamox), a potent carbonic anhydrase inhibitor, is capable of inhibiting the secretion of bicarbonate by the pancreas (Dreiling and Janowitz, 1959)

If the concentration of sodium or potassium is increased in the plasma by injecting hypertonic NaCl or KCl, the concentration of these cations is increased in the pancreatic juice to the same degree (Ball, 1930) In addition, if radioactive sodium is administered intravenously, it appears in pancreatic juice within 3 min, and after 15 min the activities of the isotope in pancreatic juice and serum are essentially the same (Montgomery, Sheline and Chaikoff, 1941)

Discussion so far has stressed the role of transport of the anions (HCO_3 and Cl), however, some recent evidence suggests that an active role for sodium transport may also exist The enzyme, adenosine triphosphatase (ATPase), shown to be involved in the active transport of Na in the kidney and elsewhere has been demonstrated in the pancreas, and inhibitors of this (Na, K) ATPase, such as ouabain, inhibit pancreatic secretion of fluid significantly It may be that the secretion of Na and HCO_3 are coupled

SECRETION OF ENZYMES

Secretion of enzymes by the pancreas involves at least three distinct processes *1*) synthesis within the cell of the enzymes or their synthesis within the cell of the enzymes or their precursors, *2*) storage of the enzymes within the cell in the form of zymogen granules, and *3*) discharge of the enzymes from the secretory cells into the ducts

Synthesis is a continuous process, dependent upon the availability of various amino acids that are required for the synthesis of the enzymes The nature of the dietary protein, and in particular its amino acid composition, has a profound effect on the total concentration of enzymes in the pancreas

Interesting light has been shed on the synthesis of enzymes by the studies of Hokin (1951, 1952) and Hokin and Hokin (1956) on pigeon and mouse pancreas in vitro They found that pigeon pancreas slices would synthesize amylase in vitro in glucose solutions, in serum, in amino acid solutions, and in saline Synthesis was most rapid in solutions of amino acids and least rapid in normal saline, it proceeded at an intermediate rate in serum One can see here the effect of an increased concentration of reacting substances (amino acids) on synthesis of protein by the cells of the pancreas Although pancreozymin and parasympathomimetic drugs caused discharge of amylase from the cells into the surrounding medium (secretion), the rate of synthesis of the enzymes was not materially affected Certain amino acids were essential for synthesis but others could be supplied from sources in the medium Those essential for maximum synthesis were tryptophane, arginine, threonine, valine, tyrosine, lysine, leucine, histadine, isoleucine, and phenylalanine

The synthesized material appears as *zymogen granules*, which accumulate in the resting gland until they come to occupy most of the available space within the cells (Hirsch, 1939, Hirsch et al , 1957, Sluiter, 1944) Under the influence of appropriate stimuli the zymogen granules diminish in number and in size, at the same time enzymes appear in the secretion Stimuli such as HCl and secretin, which produce a watery secretion with a low enzyme content, have little effect on the granules, whereas stimuli which call forth secretion rich in enzymes deplete the granules and, if they act over a long period of time, may leave the cells almost free of zymogen granules

According to the observations of Hokin and Hokin (1956) on pancreatic and salivary gland slices in vitro, effective stimuli for secretion of enzymes cause a remarkable increase in the

rate of turnover of phosphorus and its incorporation into the other soluble phospholipids, possibly in the phospholipids of the plasma membrane

Palade, Siekevitz and Caro (1962) have used electron microscopy and autoradiography to study intracellular synthesis, storage, and transport of enzymes Radioactive carbon-labeled leucine was injected into guinea pigs Pancreatic tissue was obtained at different time intervals for examination by electron microscopy and autoradiography Within 3 min , high specific activity was found in the ribonucleic acid (RNA) particles or ribosomes attached to the α-cytomembranes (endoplasmic reticulum) From the ribosomes, α-chymotrypsinogen of high specific activity was obtained by means of column chromotography The labeled enzyme is then transferred into cisternae formed from the α-cytomembranes These structures have been termed "rough-surfaced cisternae," due to the attached ribosomes Just how the enzyme is transferred from the ribosome across the cisternae membrane is not known In the region of the Golgi apparatus, the enzyme content of the rough-surfaced cisternae is transferred to smooth-surfaced vacuoles This occurs about 20 min after the administration of the labeled amino acid It is in the smooth-surfaced vacuoles that the enzyme is concentrated and stored The filled vacuoles are recognized by light microscopy as "zymogen granules" The stage of storage in a "mature" zymogen granule is reached in about 45 min In this form, enzymes can remain in storage for hours until discharged into the acinar lumen The process of discharge of the contents of the zymogen granules is thought to involve a coalescence of the membrane of the zymogen granule with the plasma membrane of the cell The various stages of the process just described are illustrated in Figure 2 31 The pancreatic acinar cell is capable of secreting enzymes at a high rate, even after zymogen granules have been depleted Thus other pathways than via storage in a zymogen granule probably exist for the secretion of pancreatic enzymes

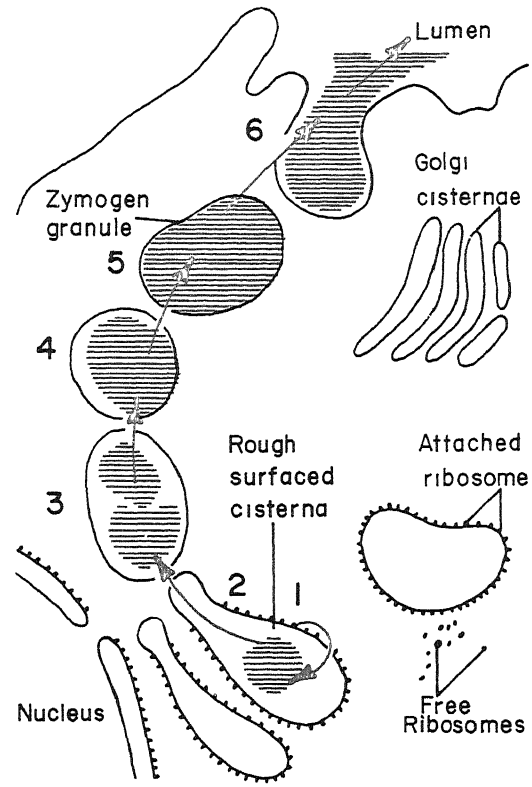

Fig 2 31 Diagram illustrating the various stages of synthesis storage and secretion of pancreatic enzymes by the acinar cell of the guinea pig *1* enzymes are synthesized by the ribosomes and transported into a rough-surfaced cisterna *2* enzymes are transferred from the rough surfaced cisterna into a smooth surfaced vesicle *3* and *4* near the Golgi apparatus enzymes are concentrated within the smooth-surfaced vesicles to become *5* a mature zymogen granule *6* illustrating the secretion' of enzymes into the lumen of the acinus (Redrawn from Palade et al 1962)

Control of Pancreatic Secretion

The pancreas is under the control of both *nervous* and *humoral* mechanisms The nervous control of pancreatic secretion is provided by both the sympathetic and parasympathetic divisions of the autonomic nervous system In addition, there is evidence that a *local cholinergic mechanism*, independent of vagal innervation, may play a role in controlling pancreatic secretion Humoral control of pancreatic secretion is provided by the hormones *secretin*, *pancreozymin*, and *gastrin*

NEUROGENIC CONTROL

The effects of *sympathetic stimulation* on pancreatic secretion are variable Both augmentation and decrease in flow rate have been reported Atropine is said to block the effects of sympathetic stimulation, causing an increase in flow rate, indicating that cholinergic secretory fibers are present in the sympathetic innerva-

tion of the pancreas As in the stomach, sympathetic stimulation can influence pancreatic secretion indirectly, due to changes in blood flow through the organ Sympathetic stimulation may also alter the flow rate due to effects on the pancreatic ducts, since constriction of the ducts would slow the passage of pancreatic juice

Stimulation of the vagus or *parasympathetic* innervation of the pancreas results in the secretion of enzymes but has little or no effect on the secretion of bicarbonate Acetylcholine is the mediator of the vagal effect Vagotomy and atropine markedly depress the secretion of enzymes by the pancreas The effects of vagal stimulation on pancreatic secretion can be demonstrated easily in the experimental animal In a dog with an esophagogastrostomy and pancreatic fistula, sham feeding produces a prompt secretion of enzymes by the pancreas Insulin hypoglycemia, known to produce vagal stimulation, also results in the secretion of enzymes Electrical stimulation of the peripheral segment of the cut vagus produces a similar response Cholinergic drugs, as pilocarpine, stimulate pancreatic secretion of enzymes whereas atropine and anticholinergic agents produce inhibition However, these kinds of stimuli may release gastrin from the antrum or upper gastrointestinal tract as well

The presence of a gastropancreatic reflex has been demonstrated by White, Lundh and Magee (1960) In dogs, these investigators found that distending the fundus of the stomach with a balloon caused an increase in volume and enzyme output in pancreatic juice Vagotomy abolishes the gastropancreatic reflex for a few weeks but then it returns, suggesting that local reflex pathways exist which are independent of vagal innervation

HUMORAL CONTROL

The two hormones, *secretin* and *pancreozymin*, provide for the humoral control of pancreatic secretion Both of these hormones can be extracted from the mucosa of the duodenum and upper small bowel The specific cells in the mucosa that produce secretin and pancreozymin are not known Under normal circumstances, secretin and pancreozymin are released into the blood by appropriate stimuli and carried to the pancreas to produce their effects Dilute hydrochloric acid in the duodenum is a potent stimulus for the release of secretin Peptones or products of protein digestion serve equally well for the release of pancreozymin Secretin acts on the ductule or centroacinar cells to stimulate them to secrete water and bicarbonate while pancreozymin stimulates the acinar cells to secrete enzymes

Secretin The discovery of secretin in 1902 by Bayliss and Starling was an event of great historical significance, inasmuch as secretin was the first chemical substance known to be secreted into the blood and act as a stimulus to an organ at a distance from the site of its formation Recognizing this fact, Bayliss and Starling coined the word *hormone* to characterize this and similar substances Before the discovery of secretin, it was known that acid in the intestine induced secretion of pancreatic juice in animals in which all the nerves to the pancreas and to the intestine had severed While workers in Pavlov's laboratory in St Petersburg were busily searching for the unknown nervous pathways which, they supposed, conveyed impulses to the pancreas after all the known fibers had been cut, Bayliss and Starling in England did the simple experiment of making an acid extract of the mucous membrane of the intestine and injecting it into an animal This caused the pancreas of the injected animal to secrete The excitement in Starling's laboratory can well be imagined A "chemical reflex" had been discovered, something hitherto unknown in physiology They called the new substance *secretin*

In the introductory section the structural formula of the polypeptide secretin with its 27 amino acids has been presented In contrast to gastrin, the entire molecule is required to stimulate the pancreas to secrete a bicarbonate secretion at high rates of flow

Pancreozymin. The crude extract prepared by Bayliss and Starling caused the pancreas to secrete enzymes as well as water and bicarbonates Since purified secretin seemed to stimulate only the output of water and bicarbonate, a search was made by Harper and Raper (1943) for the material in the extracts which stimulated secretion of the enzymes They succeeded in separating a fraction which did not increase the volume of pancreatic juice but did greatly increase the enzyme concentration This substance they called *pancreozymin*

The formula of this 33 amino acid polypeptide has already been presented, which has the same terminal tetrapeptide as gastrin, is iden-

tical with cholecystokinin, and causes the pancreas to release its enzymic content with little fluid

It has long been known that hydrochloric acid in the intestine liberates secretin into the blood, thus causing the pancreas to secrete The flow of pancreatic juice is also increased by distilled water, hydrochloric acid, soaps, and peptones The enzyme concentration is also increased by these same stimuli, thus proving that both secretin and pancreozymin are released by all the ordinary stimuli used to excite pancreatic secretion

INTERACTION OF NERVOUS AND HUMORAL CONTROL MECHANISMS

Although the various nervous and humoral control mechanisms have been discussed as separate or individual factors capable of influencing pancreatic secretion, the student should not be misled in thinking each mechanism acts independently of all others The pancreatic response to a meal indicates that in all likelihood there is a high degree of interdependence between the neural and humoral mechanisms

In a recent review, Preshaw (1967) concluded "mainly from studies with anticholinergic drugs" that cholinergic mechanisms contribute to the action of secretin on pancreatic secretion, but it is uncertain whether this mechanism is independent of the vagus He found little evidence to indicate that the release of pancreozymin involved similar cholinergic mechanisms Recognition that gastrin stimulates pancreatic enzyme secretion reinstates the vagus in this chain Potentiation between neural and hormonal mechanisms of pancreatic secretion have not been established

Tests of Pancreatic Exocrine Function

Pancreatic exocrine insufficiency may be caused by a number of diseases affecting the pancreas Since the pancreas is the principal source of lipase furnished to the upper small bowel for the digestion of fats, an insufficient amount of pancreatic juice and its contained lipase results in maldigestion of fats and causes steatorrhea The gastric juice provides pepsin and secretions from the small bowel (succus entericus) provide proteolytic enzymes so that maldigestion of proteins is not as marked as the defect in fat digestion Amylase provided by the salivary glands and various disaccharidases provided by the small intestines also promote digestion of carbohydrates, even in severe exocrine insufficiency of the pancreas Thus, the principal clinical manifestation of pancreatic exocrine insufficiency is an excess of fat excreted in the feces

FECAL FAT EXCRETION

A commonly used test for the detection of pancreatic exocrine insufficiency is the quantitative measurement of fecal fat excretion Normal individuals on an average diet seldom excrete more than 6 or 7 g of fat in the feces in a 24-hr period Patients with exocrine insufficiency of the pancreas may excrete up to 50 g of fat/24 hr , depending upon the dietary fat intake and the severity of the insufficiency

SECRETIN AND PANCREOZYMIN TESTS OF PANCREATIC FUNCTION

Since secretin and pancreozymin in injectable form have become available, tests of pancreatic function using these hormones as stimuli have been developed Secretin was first available in a form pure enough for use in humans and more experience has accumulated with it The secretin test was introduced by Ågren, Lagerlöff, and Berglund (1936) and has been used extensively in this country and abroad It is wise to test the patients for hypersensitivity to the secretin preparation before conducting the test To perform the test, a double-lumen tube is passed through the patient's nose or mouth, into the stomach for draining gastric juice, and the other into the duodenum for collecting the pancreatic and duodenal secretions It is important that the double-lumen tube be positioned accurately by means of fluoroscopy The gastric and duodenal secretions are collected separately Gastric juice is usually aspirated continuously by a low pressure vacuum pump while the duodenal contents are aspirated periodically Samples are collected during 10 or 20 min intervals After a control period of approximately 30 min , to provide for clearing of the duodenal samples of gastric juice, secretin, in a dose of 1 clinical unit/kg body weight, is given slowly intravenously over a 4- to 5-min period The duodenal contents are then collected in separate 10- to 20-min samples for a period of time,

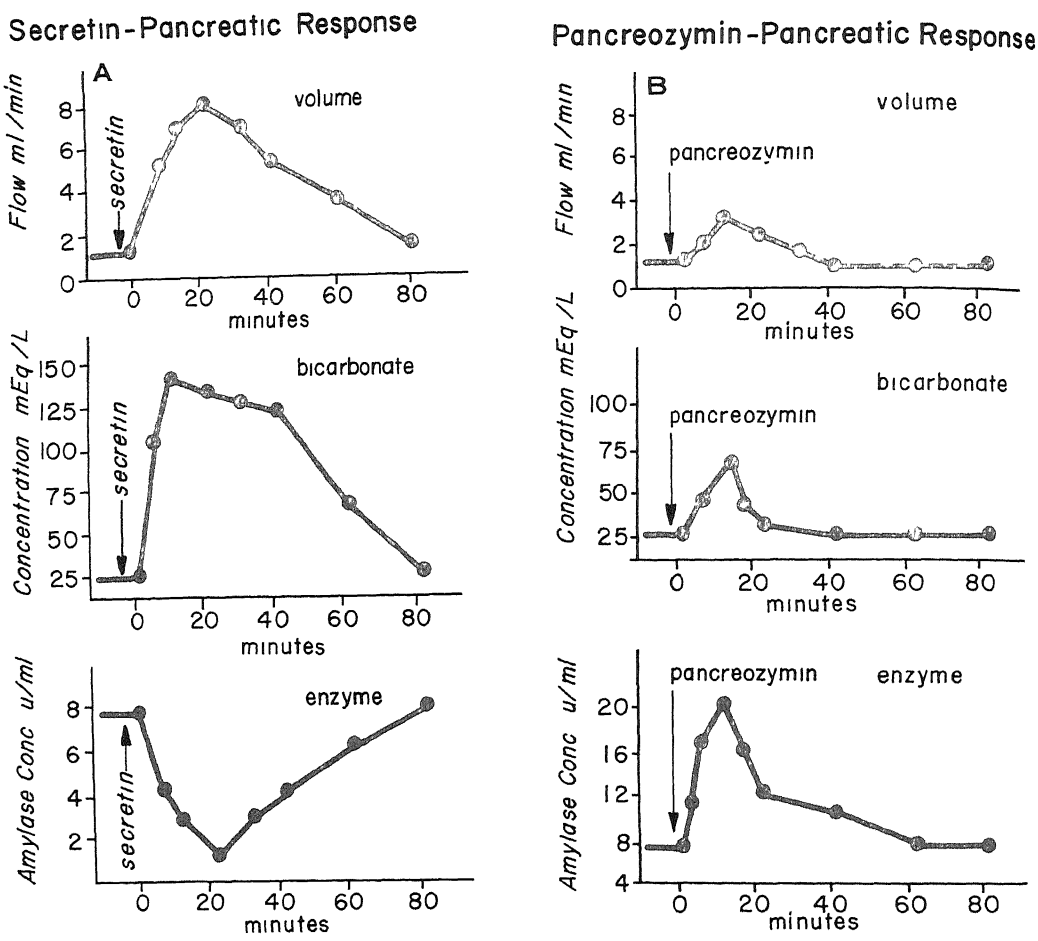

Fig 2 32 Volume bicarbonate and amylase response following the administration of secretin and pancreozymin to a normal subject The hormones were administered intravenously in a dose of 1 unit/kg (Redrawn from Dreiling et al 1964)

usually 30 to 80 min Volume, pH, bicarbonate, and enzyme determinations are made on the samples collected from the duodenum

With normal function, there is a rapid increase in flow rate following secretin injection, with the maximum flow rate usually being reached in 20 min A flow rate of 1 to 2 ml /kg weight/30 min is usually obtained in normal individuals The bicarbonate concentration increases with the flow rate and may go as high as 140 to 150 mEq /liter As the flow rate increases, there is an associated decrease in enzyme concentration In patients with obstruction of the pancreatic ducts due to neoplasm or calculi, there is a reduction in flow rate In diseases of the pancreas associated with destruction of the secreting parenchyma, such as pancreatitis or fibrocystic disease, a reduction in flow rate also is observed In inflammatory diseases of the pancreas, the bicarbonate concentration may be markedly reduced A concentration of 90 mEq /liter is usually taken as the lower limit of normal for bicarbonate

When pancreozymin is used as a stimulus for pancreatic secretion to test pancreatic function, the procedure of the test is the same as that described for the secretin test As a matter of fact, secretin and pancreozymin are frequently used together in testing pancreatic function There is some disagreement as to which hormone should be administered first when they are used together English and European workers have tended to give secretin first, followed by pancreozymin in 30 min (Burton et al , 1960), while workers in the United States seem to prefer the reverse order, giving pan-

creozymin first, followed 10 min. later by secretin (Sun and Shay, 1960). Dreiling and Janowitz (1962) have used both sequences of secretin-pancreozymin and pancreozymin-secretin in testing pancreatic function and have come to the conclusion that the addition of pancreozymin to the standard secretin test technique does not significantly improve the diagnostic accuracy of the procedure.

The separate effects of secretin and pancreozymin on pancreatic secretion of man are illustrated in Figure 2 32.

7 / BILIARY SECRETION

Bile is a mixture of secretory and excretory products consisting of water, bile salts, bile pigments, inorganic salts, and a mixture of lipid material including fats, cholesterol and lecithin. In most animals and man, bile is formed continuously by the liver. In its transport to the intestinal tract, bile first passes along the bile capillaries, then the hepatic and cystic ducts to the gallbladder where it is stored and concentrated. The expulsion of bile from the gallbladder and its passage along the common bile duct into the duodenum is intermittent, related in time to the arrival of food in the intestine, and is quite independent of the formation of bile by the liver.

Hepatic Architecture

Microscopic sections of the normal human liver reveal a rather characteristic arrangement of the hepatic cells. Groups of cells appear to be arranged in a lobular fashion around a *central vein*, with the periphery of the lobule delineated by the presence of *portal triads*. A portal triad consists of a small arteriole of the hepatic artery, a venule derived from the portal vein, and a bile ductule. The central vein of the hepatic lobule drains into the hepatic vein.

It was originally thought that the liver cells were arranged in cords, two cells thick, with a bile capillary embedded in the center of the cord between the cells. It is now realized that liver cells are not arranged in cords as previously supposed, but in the form of *plates* one-cell thick that provide a honeycomb or sponge-like architecture (Elias, 1949, 1953). Throughout the sponge-like structure, the cell plates are tunneled by a communicating system of cavities known as *lacunas*. The lacunas contain the blood sinusoids which have a basement membrane formed of *Kupffer cells*. The very narrow space separating the sinusoidal wall from the liver cell plates is known as *Disse's space*. The sinusoids convey blood from the portal vein and hepatic artery to the hepatic vein.

The *biliary canaliculi* are located within the liver cell plates, and are arranged in a communicating system surrounding the hepatic cells. The liver cell thus forms a narrow wall between the blood stream on the one hand and the bile stream on the other.

The electron microscope has provided new information regarding the relationship of the liver cells to the biliary canaliculi. The bile canaliculus is a space less than 1 μ in diameter between neighboring liver cells. The boundaries of the canaliculus are formed by the plasma membrane of the liver cells, and small finger-like projections or microvilli extend from the liver cells into the lumen of the canaliculus. It will be recalled that this arrangement is characteristic of surfaces across which fluid transfer occurs. In the pericanalicular zone, a membrane system of lamellas and vacuoles is always present. This is the Golgi complex. Free ribosomes, vacuoles, and dark, rounded bodies occur in the pericanalicular zone. It is thought that these structures, as in the pancreatic acinar cell, are related to the secretory functions of the hepatic cells (Schaffner, 1965).

The Composition of Bile

Table 2.9 gives the composition of human liver bile (as parts in 1000). Liver bile has a pH which varies between 8.0 and 8.6. The reaction of human gall bladder bile is neutral or very slightly alkaline, that of the dog (or cat) is definitely acid with a pH between 5.0 and 6.0. The chief biliary components are the *bile salts*, *bile pigments*, *cholesterol*, and *lecithin*. These organic materials make up over 60% of the total biliary solids. As a result of the absorption of water and inorganic salts, gall bladder bile is several times more concentrated in organic solids than liver bile. The biliary constituents may vary independently of one another.

BILE ELECTROLYTES

The electrolyte composition of bile is related to flow rate, in a manner similar to that observed in the pancreas. In turn, flow rate is related to the availability of bile salts. The principal cations in bile are sodium and potassium; the principal anions are bicarbonate and chlo-

ride It has been estimated that 85 to 90% of the bile salts excreted in the bile are reabsorbed and return to the liver for re-excretion

If bile salts are prevented from entering the intestinal tract due to removal through a biliary fistula, biliary flow gradually decreases To overcome this problem, Wheeler and Ramos (1960) infused sodium taurocholate intravenously at a constant rate into dogs which had been prepared with biliary fistulas They were then able to obtain multiple bile samples for measurement of electrolyte concentration without interfering with flow rate They found that the taurocholate concentration of the bile was equal to the difference between the cations (Na^+ and K^+) and the anions (Cl^- and HCO_3^-) This relationship was maintained over a wide range of taurocholate concentrations (40 to 280 mEq /liter)

A characteristic alteration in the bile electrolyte composition was observed with increasing flow rate As the flow rate increased, the taurocholate concentration decreased, indicating that the bile salt was excreted at a constant rate With increase in bile flow, there was a striking increase in bicarbonate concentration and pH, similar to that observed in the pancreas Chloride concentration also increased with increased flow rates The changes observed in chloride and bicarbonate concentration and pH at different flow rates are illustrated in Figure 2 33

The *osmolarity* of the bile samples showed little variation, despite marked differences in electrolyte composition, bile flow, or time of collections In all samples, the osmolarity of the bile was essentially that of plasma The explanation of the apparent discrepancy between varying concentrations of inorganic ions and a relative constant osmolarity is due to the bile salts forming large aggregations or micelles that have low osmotic activity It is the sum of $Na^+ + K^+ + Cl^- + HCO_3^-$ that accounts for the osmolality of both liver and gallbladder bile

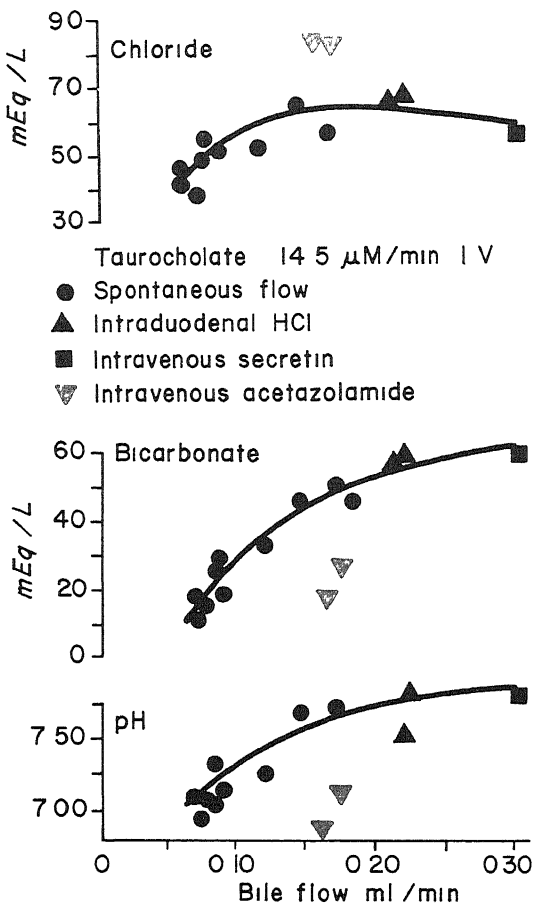

Fig 2 33 Relationship between bile flow and composition Sodium taurocholate was administered by a constant intravenous infusion at a rate of 14 5 micromoles per minute Maximal flow pH and bicarbonate concentration were observed after intravenous secretin or intraduodenal HCl After intravenous acetazolamide the chloride concentration was higher and the bicarbonate concentration lower than at comparable spontaneous lows (Redrawn from Wheeler and Ramos 1960)

Table 2 9
Constituents of human hepatic bile

Substance	Parts/1000
Water	976 22
Solids	23 78
Mucin and pigments	5 00
Bile salts	9 00
Fatty acids from soaps	1 23
Cholesterol	0 63
Lecithin / Fat	0 60
Inorganic salts	7 32

BILE SALTS

The most important secretory products of the liver are the bile acids which appear in the bile as salts of sodium or potassium There are a variety of bile acids to be found in the bile of different species, all of which are formed by conjugation of an amino acid with a bile acid The conjugated bile acid then combines with sodium or potassium to form a bile salt

Bile salts are divided into *primary* and *secondary* types. Primary bile salts are formed by the cells of the liver and secreted into the bile. Secondary bile salts are formed in the intestinal tract as a result of the action of bacteria on the primary bile salts. The secondary bile salts are absorbed by the gut, recirculated to the liver, and then secreted in the bile.

Origin and Formation. In man and other primates, primary bile acids are formed from cholesterol by the action of liver enzymes. In most mammalian species, the main primary bile acids are cholic acid and chenodeoxycholic acid. These primary bile acids are conjugated with the amino acids taurine or glycine.

In the lower part of the small intestine, the primary bile acids are subjected to the action of various intestinal microorganisms which result in the conjugated bile acids being hydrolyzed to free bile acids. Additionally, the 7 α-hydroxyl group is removed from cholic acid and chenodeoxycholic acid yielding deoxycholic acid and lithocholic acid, respectively.

A number of organisms have been identified in the small intestine including *enterococcus*, *lactobacillus*, *bacteroides*, and *clostridium*, which are capable of converting the primary bile acids to secondary bile acids. Figure 2-34 illustrates the major bile salts found in man. Many of the bile acid metabolites resulting from the action of bacteria are not absorbed and some, as lithocholic acid, are absorbed very poorly. Most of the lithocholic acid formed in the intestine becomes tightly bound to intestinal microorganisms and with other bile acid metabolites is excreted in the feces. The main bile acids found in portal blood are cholic acid, chenodeoxycholic acid, deoxycholic acid, and a very small amount of lithocholic acid.

Conjugation of Bile Acids. The conjugation of bile acids with taurine and glycine is catalyzed mainly by the microsomal faction and requires ATP, CoA, and Mg.

The ratio of glycine to taurine conjugates in human bile varies widely due to the fact that the ratio is influenced by diet, hormones, disease, and the types of microorganisms in the small and large bowel.

Control of Bile Acid Formation. The exact mechanisms that control bile acid formation have not been completely defined. Most of our information has been obtained by studying the hepatic metabolism of cholesterol which is the precursor of bile acids. Additional information has been obtained from studies of the rate of bile acid synthesis in animals with biliary fistulas. If bile is continuously drained from a bile fistula, the synthesis of bile acids increases 10 to 15-fold. Infusions of bile acids into the small bowel in such a preparation reduce the rate of bile acid synthesis.

An increase in cholesterol synthesis precedes the increase in bile acid synthesis. Myant and Eder (1961) have found that labeled acetate is

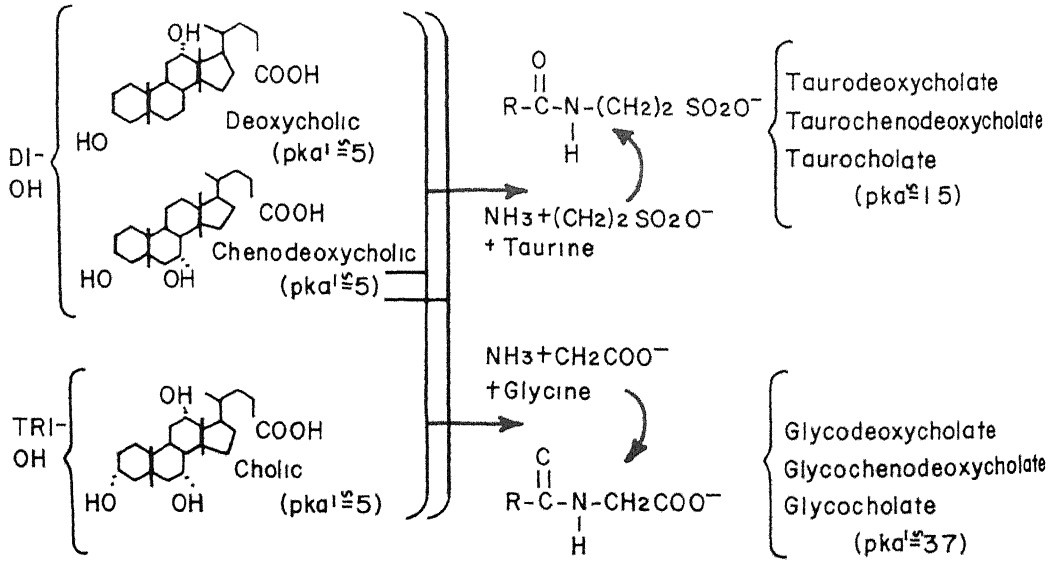

Fig 2-34 Predominant bile salts of human bile. The two primary bile acids—cholic and chenodeoxycholic—and the secondary bile acid—deoxycholic—are conjugated with glycine or taurine in a peptide bond resistant to all digestive enzymes. (From Hofmann, 1968a.)

incorporated into cholesterol at an increased rate in bile fistula rats Beher and associates (1962) have suggested that the synthesis of bile acids is regulated by a "double feedback" mechanism Bile acids inhibit the conversion of cholesterol to bile salts, this leads to an increase in liver cholesterol, and this, in turn, leads to a decreased cholesterol synthesis Bergstrom (1959) has suggested that the site of control of bile acid biosynthesis is the first step in the conversion of cholesterol to bile acids, the 7 α-hydroxylation Recent observations by Danielsson and his associates (1967) support Bergstrom's view for they have found that the rate of 7 α-hydroxylation of cholesterol is several times faster in homogenates from bile fistula rats than in homogenates from control rats, whereas other reactions occur at about the same rate in both control and bile fistula rats

Danielsson (1963) has made an extensive review of the pronounced effect of diet on formation and metabolism of bile acids, including the effects of carbohydrates, steroids, bile acids, vitamins and minerals When the regular diet of man is changed to a synthetic diet, the half-life of bile acids is increased and bile acid production is decreased If indigestible material is added to the diet, bile acid production is increased and the half-life of bile acids is decreased

The state of thyroid activity also influences a rate of synthesis of cholesterol as well as bile acids Hyperthyroid states increase the rate of synthesis of cholesterol as well as that of bile acid production Hypothyroid states are associated with decreased cholesterol synthesis, a prolonged half-life of bile acids and decreased bile acid formation

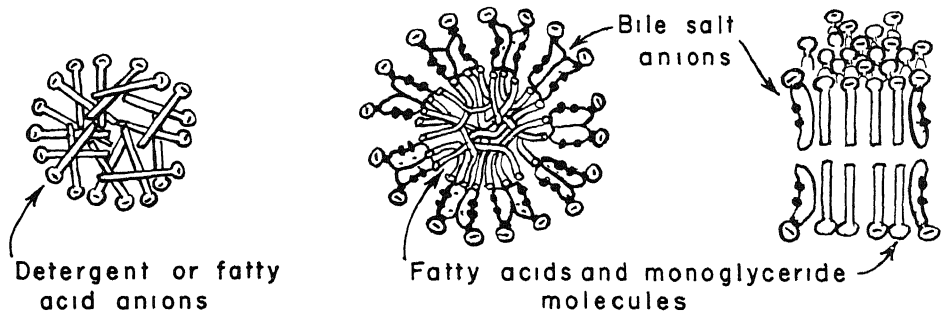
Bile Salts Micelles The formation of bile salts from cholesterol, which is water insoluble, yields a C-24 carboxylic acid which has a steroid nucleus containing hydroxyl groups The bile acids are polar molecules with high aqueous solubility

Bile salts are similar to ionic detergents and are amphipathic molecules which have both hydrophilic and hydrophobic regions It is these water soluble and fat soluble regions of the molecule which account for the characteristic physical properties of bile salts At very low concentrations, bile salts form molecular solutions When the concentration reaches a critical level, however, the amphipathic molecules form molecular aggregations called *micelles* The concentration at which molecular aggregation occurs is called the *critical micellar concentration*

The micelles formed by bile salts are completely different from those formed by ionic detergents The bile salt molecule has a rigid disc-shaped body that is fixed to a small side chain On one side of the molecule are all of the polar hydroxyl groups, and the charged group is at the end of the short side chain Bile salts are more effective in forming micelles in the presence of polar lipid substances as fatty acids and monoglyceride molecules The present concept of the bile salt micelle is illustrated in Figure 2 35

The Enterohepatic Circulation of Bile Salts In the jejunum, the primary function of the bile salts are to solubilize dietary triglycerides by forming a micellar solution of bile salts, fatty acids, and monoglycerides The fatty acid and monoglyceride are rapidly absorbed from the micelle and the bile salts continue down the small bowel where they are absorbed primarily from the terminal ileum

By use of ^{14}C labeled cholic acid, Lindstedt (1957) studied normal subjects and found that



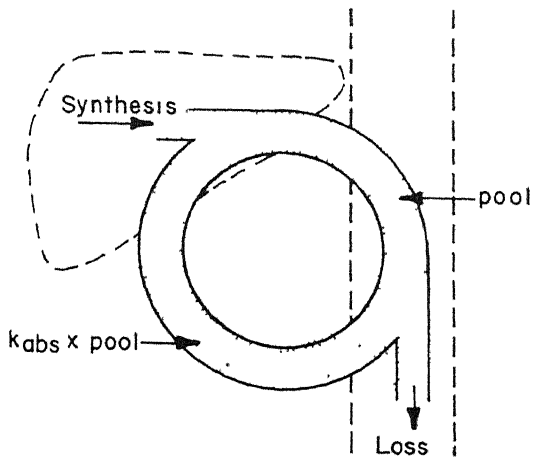


Fig 2 35 The probable molecular arrangement of a typical soap or anionic detergent micelle (*left*) is contrasted to two proposed models for the bile salt-polar lipid micelle (*center* and *right*) A cross section of each micelle is shown the aggregate on the *left* and in the *center* is spherical that on the *right* disc-shaped (From Hofmann 1968a)

the radioactive bile acid was diluted in a large bile acid "pool." The size of this bile acid pool varied from about 3000 to 4000 mg. The half-life of the pool was calculated to be about 3 days. The daily synthesis of bile acids was about 350 mg. Thus the bile acid pool is 6 to 10 times the amount synthesized daily.

In the lower part of the ileum, the primary bile salts, as well as secondary bile salts resulting from microbial action, are absorbed and returned to the liver via the portal blood. They are then resecreted into the bile and delivered back to the small bowel. This secretion, absorption, and resecretion is known as the *enterohepatic circulation* of bile salts. It is estimated that each bile salt molecule participates in 15 to 20 enterohepatic cycles before excretion. Figure 2-36 illustrates the enterohepatic circulation of bile salts.

The bile salt pool remains relatively constant as synthesis is balanced against excretion. Synthesis is under the influence of the amount of bile salts absorbed in the terminal ileum, approximately 80 to 90% of all bile salts secreted in the bile are reabsorbed by the small bowel. In man 20 to 30 g of bile acids are secreted by the liver daily in the bile; however, only 0.5 to 0.7 g of bile acids appear in the feces each day.

$$k_{abs} = \frac{\text{bile acid absorbed/cycle}}{\text{bile acid pool}}$$

Fig. 2-36 Schematic representation of the enterohepatic circulation of bile salts. It is customary, in the manner of Lindstedt (1957), to estimate the size of the bile salt pool by extrapolating the specific activity decay curve for biliary bile acids to zero time. The bile salt pool thus represents the sum of the fraction of the bile salt pool absorbed during the previous cycle (*K* pool) plus that bile acid synthesized by the liver during that particular enterohepatic cycle. If the pool remains constant in size, daily loss is equal to $(1 - K)\,PC$, where C is the number of enterohepatic cycles per day (Hofmann, 1966). Most of the bile salt reabsorption is considered to occur in the ileum where there is an active transport mechanism for bile salts. (From Hofmann, 1968a.)

Excretion of Bile Salts. The main pathway for excretion of bile salts is with the feces. Less than 5% of bile acids excreted appear in the urine. Under normal conditions, bile acids found in feces are a complex mixture of compounds most of which have been formed by microbial action on the primary bile salts rendering them essentially unabsorbable. The complexity of the mixture of fecal bile salts makes their quantitative determination difficult and of little clinical importance.

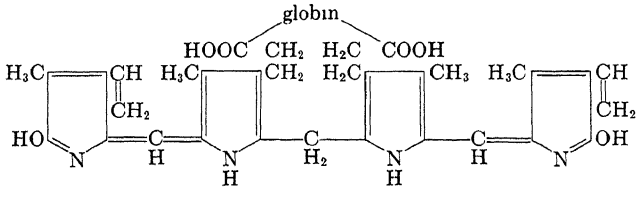
THE BILE PIGMENTS

Bilirubin ($C_{33}H_{36}N_4O_6$) is the chief pigment in human bile and in the bile of the carnivora. Biliverdin ($C_{33}H_{36}N_4O_8$) is an oxidative derivative of bilirubin, and although it is present in only small amounts of human bile, it is the chief pigment of birds' bile. Besides biliverdin, other derivatives of bilirubin are found in the body. *Urobilinogen* is a reduction product of bilirubin, upon oxidation it yields *urobilin*. *Bilifuscin* and *bilifuscin* are formed by the oxidation of biliverdin. The latter two pigments are not found in bile but may be present in gall stones. The pigments constitute from 1.5 to 2.0% of the total solids in liver bile.

Origin of the Bile Pigments. Bile pigments are derived from the free hemoglobin resulting from the destruction of red cells in the body, and in smaller amounts, from other chromoproteins. Approximately 85% of bilirubin is derived from senescent red cells. The red cells have a life span of about 100 to 120 days. Those that perish are disposed of by the reticuloendothelial cells distributed throughout the body. From these cells an average of about 8 g of hemoglobin is released per day, this yields about 300 mg of bile pigments. In order to produce bile pigment from hemoglobin, the hemin portion must be separated from the protein (globin) portion of the hemoglobin molecule. Oxidation scission of the iron-porphyrin follows. This involves opening the tetrapyrrole ring at the alpha position and the "shelling out" of iron. The resulting iron-free pigment is probably biliverdin, which is later reduced to bilirubin. All these reactions are presumed to take place in the reticuloendothelial cells, but

the order in which they occur is not known In particular, it is not known if the splitting of the hemin moiety on the protein portion of the molecule must take place before the porphyrin ring is open

Bilirubin derived from hemoglobin is unconjugated and known as "free bilirubin" It is highly lipid soluble and has limited aqueous solubility Free bilirubin is bound by albumin which greatly increases its solubility in plasma Each mole of human albumin is capable of binding at least 2 moles of bilirubin Other plasma proteins, such as α1- and α2-, and β-globulins, bind bilirubin to a limited extent when plasma bilirubin concentrations exceed 20 to 30 mg /100 ml



The binding of free bilirubin by albumin is of considerable clinical importance Bilirubin encephalopathy or kernicterus which occurs in infants shortly after birth is due to high concentrations of free bilirubin in the plasma The highly lipid soluble unconjugated bilirubin enters the neurons of the basal ganglions, hippocampus, cerebellum and medulla causing necrosis of these nerve cells Adequate available binding sites on albumin prevent this from occurring Anionic drugs as sulfonamides are also bound by albumin and compete with bilirubin for the available binding sites Thus, the administration of sulfonamides to an infant with unconjugated hyperbilirubinemia displaces bilirubin from albumin increasing the risk of kernicterus Free fatty acids produce a similar effect and asphyxia, hypoxia, and other conditions leading to acidosis also increase the risk of kernicterus

The chemical relationship between bilirubinglobin and the various bile pigment derivatives is shown schematically in Diagram 1

Bile pigments may be formed, not only in the liver, but also in the spleen and bone marrow and at various other places in the body This was not generally recognized until the experiments of Whipple and Hooper (1913) and the more conclusive experiments of Mann and his associates (1924) The former attempted to isolate the liver from the general circulation, whereas the latter removed the liver completely In either case, bile pigments continued to be formed, and, since they could not be excreted through the liver, they accumulated in the blood and produced a condition analogous to jaundice Mann and his associates also showed that the blood of the splenic vein of a normal animal has a higher bilirubin concentration than does the blood in the corresponding artery

By use of ^{15}N-labeled glycine, in vivo, the non-hemoglobin origin of bilirubin has been better defined When ^{15}N-labeled glycine is administered, the label appears incorporated in stercobilin within a few days This rapid appearance of the isotope in the intestinal oxidation product of bilirubin has been termed "early labeled bilirubin" When isotopically labeled δ-aminolevulenic acid is administered, the radioactive label is more readily incorporated into early labeled bile pigment than into hemoglobin heme. The principle sites of formation of "early labeled bilirubin" are the liver and bone marrow Most nonhemoglobin heme proteins, such as myoglobin, catalase and cytochromes, are degraded in the liver and these proteins contribute to the early labeled bile pigment

Possible sources of bone marrow origin include the intracorpuscular degradation of hemoglobin during erythrocyte maturation and destruction of newly formed erythrocytes in the bone marrow before they reach the circulation

Diagram 1

In patients with pernicious anemia sickle cell anemia and congenital porphyria the early labeled pigment is responsible for a major portion of the bile pigment excreted Early labeled pigment is also found in patients with disorders of erythropoieses as thalassemia and after hemorrhage

Hepatic Uptake of Bilirubin The unconjugated bilirubin formed in the reticuloendothelial cells is transported to the liver tightly bound to albumin The exact mechanism of uptake of the unconjugated bilirubin by the hepatic cell is unknown However it is known that unconjugated bilirubin in the plasma enters the liver preferentially with respects to other tissues

It has been suggested by Gartner and Arias (1969) that two possibilities exist for the rapid uptake of unconjugated bilirubin One is that the relative specificity of the hepatic cell to remove unconjugated bilirubin from the plasma could reside in the plasma membrane facing the sinusoid Lateral extensions of the membrane in this area may have specific molecular configurations that permit the entrance of the unconjugated bilirubin into the cell This suggestion is based upon the heterogeneity of enzymatic activity in different portions of the hepatic cell plasma membrane and the binding of sulfobromophthalein (BSP) and other organic anions by liver plasma membranes Equal molar amounts of organic anions as taurocholate, unconjugated bilirubin, and fluorescein, which do not compete with BSP uptake when simultaneously injected in vivo, show little or no interference with BSP binding by plasma membranes in vitro Other organic anions, however, as indocyanine green, which compete with BSP for hepatic uptake in vivo, considerably reduces BSP binding by isolated plasma membranes in vitro These findings suggested to Gartner and Arias that the plasma membrane of the liver cell is not molecularly homogenous and that different specific receptor sites for various organic anions may be located in the lateral extensions of the plasma membranes facing the sinusoid

Another possibility is that the unconjugated bilirubin may be dissociated from albumin at the plasma membrane and be transferred to an intracellular protein which acts as an acceptor and facilitates the transfer of bilirubin into the liver cell Recently, two basic albumin proteins designated as Y and Z have been isolated from the cytoplasm of hepatocytes and they account for most of the intracellular binding of bilirubin and BSP Apparently, Y has a greater affinity for bilirubin and BSP than Z Binding on Z does not occur until concentration of bilirubin and BSP on Y reaches a critical level

Conjugation of Bilirubin Within the liver cell bilirubin is conjugated with glycuronic acid forming bilirubin glycuronide (Schmid, 1956, Billing et al 1957) The conjugation of bilirubin is accomplished by a microsomal enzyme glucuronyl transferase which utilizes uridine diphosphoglucuronic acid as a donor The lipid soluble unconjugated bilirubin is thus converted to a conjugated water soluble form Since bilirubin is capable of combining with two molecules of glucuronic acid, either the mono- or diglucuronide may be formed Glucuronyl transferase is also found in skin, ovary, adrenal glands, kidneys, testes, and synovial membrane Conjugation may take place to some extent in these areas, but the greatest activity of this enzyme occurs in the liver where it is associated with the endoplasmic reticulum membrane portion of the parenchymal liver cell It has been suggested that the extrahepatic glucuronyl transferase results in "pigment I" or bilirubin monoglucuronide and then converted to the diglucuronide, "pigment II," in the liver Bilirubin excreted in the bile is essentially bilirubin diglucuronide The existence of the monoglucuronide in bile is doubtful

A number of clinical conditions are now recognized as being due to abnormalities of glucuronyl transferase activity. Several drugs, dyes and steroids may inhibit glucuronyl transferase activity A small percentage of nursing mothers excrete in their breast milk an unusual isomer of pregnanediol, which markedly inhibits the glucuronyl transferase activity of their infant This leads to prolonged benign unconjugated hyperbilirubinemia until about the 12th week of life unless breast feeding is terminated These mothers apparently have an inheritable defect in steroid metabolism that affects the course of hyperbilirubinemia in their neonates

Chronic, nonhemolytic, unconjugated hyperbilirubinemia in man and animal has long been recognized and it is now known that glucuronyl transferase deficiency or absence can account for these conditions The Gunn rat, a mutant Wistar rat, has a congenital absence of glucuronyl transferase These animals have a lifelong, chronic, nonhemolytic, unconjugated

hyperbilirubinemia They are capable, however, of excreting administered conjugated bilirubin Kernicterus frequently develops in these animals

Crigler and Najjar (1952) first described a similar type of nonhemolytic acholuric jaundice developing in infants shortly after birth These infants' jaundice was found to be due to high levels of unconjugated bilirubin in the serum An absence or marked deficiency of glucuronyl transferase in the liver tissue of these infants has been demonstrated Although rare, a congenital absence of the conjugating enzyme, glucuronyl transferase, may be a cause of jaundice in man, as previously shown to be the case in the Gunn rat

In the so-called *physiological jaundice* that develops in most full-term infants between the 2nd and 7th days of life, there is no evidence of hemolysis and the jaundice is of the acholuric type In newborn humans, a deficiency of glucuronyl transferase activity has been demonstrated The activity of the adult liver is not reached until about the 10th day of life These observations suggest that physiological jaundice of the newborn is related to a delay in the development of the glucuronide-conjugating system In premature infants, the deficiency in glucuronyl transferase activity may lead to severe jaundice and kernicterus

Phenobarbital is one of a number of drugs that can increase glucuronyl transferase activity This discovery has led to the treatment with phenobarbital of some patients with the Crigler-Najjar syndrome who have mild unconjugated hyperbilirubinemia In these patients, who have only a deficiency of glucuronyl transferase, there is a dramatic amelioration of jaundice on administration of phenobarbital Phenobarbital has also been administered to women before delivery and it has been shown that this will reduce serum bilirubin concentrations in their infants by approximately 50%

Hepatic Excretion of Bilirubin. Bilirubin must be conjugated with glucuronic acid prior to excretion The mammalian liver has a large reserve in regard to excretory capacity for handling bilirubin However, the process is rate limiting In adult rats, it has been determined that the maximum excretory rate is approximately 60 μg of bilirubin excreted per 100 g /min The high ratio of bile bilirubin to plasma suggests that the process is energy dependent and the excretion of bilirubin is an example of active transport The exact mechanism, however, is not known The microvilli, extending into the biliary canaliculi, and the presence of several phosphatases associated with the plasma membrane, also suggest that the process is an active one

When severe hemolysis occurs in patients with normal liver function, the degree of unconjugated hyperbilirubinemia is slight In the presence of liver disease, however, jaundice may be marked Conjugated hyperbilirubinemia occurs only in the presence of liver disease The capacity of the human liver to handle conjugated bilirubin is not known In the rat, administered conjugated bilirubin is cleared about as rapidly as administered unconjugated bilirubin

The Dubin-Johnson syndrome (1954), which occurs in man, is an example of a defect in the excretion of conjugated bilirubin A similar condition has been found in sheep The liver has a characteristic black color which is due to retention of a pigment, originally thought to be lipofuscin, in lysosomes of the hepatic cells Recent studies suggest that the pigment is a melanin and possibly results from impaired biliary excretion of epinephrine metabolites

In the mutant sheep, with an excretory defect comparable to the Dubin-Johnson syndrome in man, it has been found that the excretion of administered taurocholate is apparently normal This suggests that bile acids and bile pigments are excreted by the liver cell via different pathways

In 1948, Rotor and his colleagues described cases in which there was chronic conjugated hyperbilirubinemia but no abnormal pigment was present in the livers of these patients This condition, thought to be transmitted by an autosomal dominant gene, is also considered as a clinical example of an excretory defect in the excretion of bilirubin, BSP, and other organic anions In both the Dubin-Johnson syndrome and the Rotor syndrome, the excretion of BSP is essentially zero However, hepatic storage of BSP is apparently normal Conjugation of bilirubin with glucuronide apparently proceeds in a normal fashion, but excretion does not occur for some unknown reason

Within the past few years, it has been discovered that various drugs, such as anabolic steroids, estrogens, and oral contraceptive agents, reduce the capacity of the liver to excrete organic anions such as BSP During pregnancy,

some women manifest chemical and morphological signs of cholestasis during the last trimester Additionally, when they take oral contraceptive agents, they may also have mild jaundice It is thought that these patients must have some defect in the excretory mechanism for handling bilirubin and BSP With the further depression of this mechanism by the estrogens of pregnancy or oral contraceptives, they develop cholestasis

Enterohepatic Circulation of Bile Pigments The bilirubin that enters the intestine undergoes reduction by bacteria to form *urobilinogen* (also called *stercobilinogen*) A part of this is excreted in the stools and by exposure to air, is oxidized to *urobilin* Some of the urobilinogen is reabsorbed into the portal circulation and passes to the liver where it is reconverted in part to bilirubin in the bile (Figure 2 37) It is then almost entirely re-excreted both as bilirubin and as urobilinogen Any urobilinogen which escapes into the general circulation and is excreted by the kidney becomes oxidized to *urobilin* after the urine has been voided Normally, however, no urobilin, or mere traces (0 5 to 2 0 mg), appears in the urine Only traces are present in normal blood Bilirubin itself does not normally appear in the urine The urobilinogen normally present in bile merely represents re-excretion of this pigment after its absorption from the intestine When the entire output of bile is collected through a biliary fistula, there is complete disappearance of urobilinogen from the bile after the pigment already present in the intestine has been carried away in the feces When a part of the bile is allowed to enter the intestine, or bile is fed by mouth the derived pigment invariably appears in the fistula bile

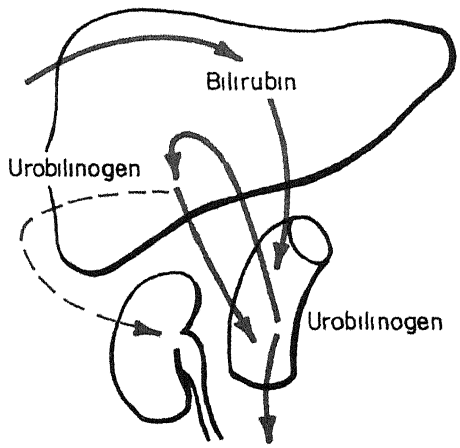

Fig 2 37 Diagram illustrating the formation of urobilinogen from bilirubin in the intestine, its excretion in part in the feces and its absorption in part into the portal blood. Normally, the absorbed pigment except in negligible amounts is practically all re-excreted in the bile The dotted lines indicate its passage into the blood, and its excretion by the kidney in cases of liver damage, excessive blood destruction, or in the early stages of obstructive jaundice

Complete experimental obstruction of the common bile duct, since it prevented the re excretion of the urobilinogen absorbed from the intestine, also resulted in its accumulation in the blood and its excretion in the urine These effects, however, can only occur for a short time after the duct has been obstructed and are due to the absorption of pigment remaining in the intestine from the period prior to obstruction After the pigment has been cleared from the intestine, the urine, although it may contain large amounts of bilirubin, is quite free from the derived pigment Depression of the excretory function of the liver by hepatic poisons or disease causes urobilinogen to appear in the urine When bilirubin formation is increased by hemolytic agents, urobilinogen production is also increased, the liver, even though its function is normal, is unable to re-excrete the excess pigment absorbed from the intestine, and urobilin appears in the urine

The availability of unconjugated and conjugated bilirubin ^{14}C has made it possible to study the enterohepatic circulation of bile pigments in a more precise manner Lester and Schmid (1963a) administered both conjugated and unconjugated bilirubin ^{14}C to rats which had been prepared with an external biliary fistula These investigators found that both of the labeled pigments were absorbed and appeared promptly in the bile The urinary excretion of the isotope was less than 5% of the dose Because essentially all of the labeled pigment re-excreted in the bile was conjugated, it could not be decided whether the unconjugated and conjugated bilirubin had been absorbed intact or had undergone chemical modification during the absorptive process The experiments were repeated in a strain of Wistar-Gunn rats that have a congenital deficiency of hepatic glucuronyl transferase Although they are unable to conjugate bilirubin, they are able to excrete conjugated bilirubin Thus, if conjugated bilirubin was unaltered in the absorptive process, it should be excreted in the bile of the Gunn

rats It was found, after intraduodenal administration of either unconjugated or conjugated bilirubin ^{14}C, that no radioactive pigment appeared in the bile, indicating that conjugated bilirubin had been altered in the absorptive process

The absorption of urobilinogen ^{14}C has also been studied (Lester and Schmid, 1964) In rats, it has been found that significant quantities of intact urobilinogen is absorbed from the intestine and re-excreted predominantly in the bile

In man, Lester and Schmid (1963b) have demonstrated that unconjugated bilirubin is readily absorbed from the intestine but little conjugated bilirubin is absorbed (Figure 2 38) Evidence indicates that conjugated bilirubin remains intact during its transit through the biliary tree and small bowel Conjugation prevents reabsorption of the pigment, thus the enterohepatic circulation of bilirubin is minimal

When bacteria in the terminal ileum and colon reduce bilirubin to urobilinogen, it is not known if the glucuronide ester remains intact during these reductive steps Conjugated forms of urobilinogen have not been isolated, but if they do occur, Lester (1964) indicates that minimal absorption of intact urobilinogen glucuronide would be anticipated

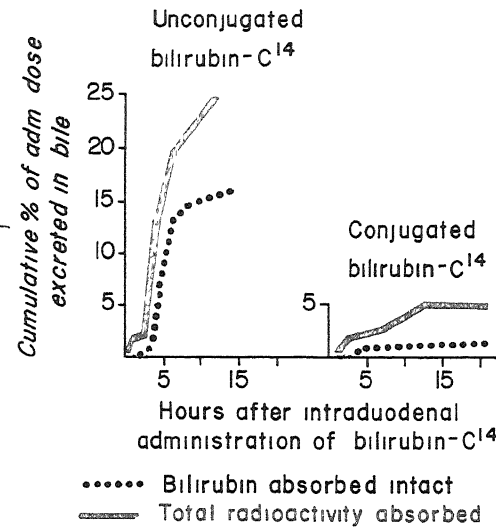

Fig 2 38 Pigment absorption after administration of unconjugated ^{14}C labeled bilirubin and conjugated ^{14}C labeled bilirubin to two human subjects (From Lester and Schmid (1963b))

OTHER CONSTITUENTS OF BILE

Lecithin and Cholesterol. *Lecithin* is present in human liver bile to the extent of from 0 02 to 0 05% The *cholesterol* content is normally from 0 04 to 0 16% The cholesterol is present in the free state, i e , not in the form of esters The percentages of these materials in the bile of the gallbladder are, as a result of the absorption of water and salts through the gallbladder mucosa, much higher than the percentages in liver bile The ratio of the concentration of cholesterol in bile to that of the bile salts is from 1 20 to 1 30 The ability of the bile to hold cholesterol in solution is, in large degree, dependent upon the bile salts If the ratio falls to 1 13, precipitation of cholesterol occurs If bile is dialyzed against water, bile salts are removed and the bile becomes turbid, as a result of cholesterol precipitation

Lecithin and cholesterol are kept in solution by the bile salt micelles In the intestinal tract, the bile cholesterol is mixed with dietary cholesterol and is absorbed principally in the upper small bowel Of the total amount of cholesterol delivered to the small bowel from the bile and the diet, only about 50% is absorbed Most of the unabsorbed cholesterol is converted to coprostanol, a neutral sterol, by microorganisms in the large intestine In germ-free animals, or animals treated with antibiotics, dietary and biliary cholesterol appears in feces in its free form

Bile Proteins. Immunologic techniques have demonstrated the presence of normal plasma proteins in human bile Rawson (1962) has identified albumin and γ-globulin in human bile obtained at autopsy, and from the fistula drainage of patients who had undergone biliary surgery. Russell and Burnett (1963) have used the Ouchterlony gel diffusion technique, immunoelectrophoresis, and gel electrophoresis for the identification of plasma proteins in human bile Samples of bile were obtained from both the gallbladder and common hepatic duct in patients undergoing laparotomy for various reasons Bile samples were obtained from patients with gallstones as well as from patients who had a normal gallbladder and biliary system No differences between normal bile and that obtained from patients with gallstones were found

The presence of plasma proteins in the bile of patients with inflammatory disease of the gallbladder or biliary system on postmortem would

not be too surprising, as one would expect plasma proteins to escape through the mucuous membrane lining the biliary system and gallbladder The presence of plasma proteins in normal bile is not as easily explained However, the liver synthesizes large quantities of albumin and the presence of albumin in normal bile during life might be anticipated. On the other hand, γ-globulin is not formed in the liver Russell and Burnett point out that the hepatic pericellular space (the space of Disse) communicates freely with the liver sinusoids as well as the biliary canaliculi but that molecules with a molecular weight greater than 15,000 are unable to pass from blood to bile Thus, further investigation is needed to determine the pathway by which plasma proteins gain entry into the bile in the absence of disease

Control of Bile Secretion

Bile is secreted continuously and is an excretion as well as a secretion On a normal feeding schedule, more bile is secreted during the daylight hours than during the night More bile is secreted after meals than in the fasting state, and meals are normally eaten in the daytime. If an animal is fed at regular intervals throughout the 24 hr , as much bile is secreted at night as in the daytime The stimulating effect of food on the volume output of bile is due mainly to its protein content Kocour and Ivy (1937) studied a variety of foods for their effect on the output of bile and found that only meat and liver were consistently effective

Before discussing various agents influencing the flow of bile, it is well to define some of the terms that will be used A *cholagogue* is any agent which increases the flow of bile into the intestine The bile may come from the gallbladder, so the word does not necessarily signify an increase in the secretion of bile by the liver A *choleretic* is an agent which increases the output of bile from the liver without necessarily changing its concentration, thus a cholerectic will usually increase the output of bile solids, as well as of the liquid portion of the bile A *hydrocholerectic* causes an increase in the volume of bile without a corresponding increase in the output of bile solids.

The natural bile salts have a powerful cholerectic action on the liver No doubt a great part of the increase in the flow of bile after a meal is the result of the discharge of bile from the gallbladder, which increases the amount of bile salts in the intestine and consequently in the portal blood. Certain oxidized bile acids, notably dehydrocholic acid, act as hydrocholerectics and are sometimes used in therapy to produce an abundant flow of dilute bile

Secretin increases the secretion of bile by the liver although it does not contract the gallbladder Studies by Grossman and his coworkers (1949) indicate that secretin acts as a hydrocholerectic in man The site of action of secretin is thought to be the small bile ducts or ductules Its effect results in increasing the volume of bile by addition of water and markedly increasing the bicarbonate concentration The onset of effect is similar to that of the pancreas Some recent evidence suggests that an electrolyte fraction may be secreted which is dependent on the active transport of Na and is inhibited by inhibition of ATPase

Secretin causes only a moderate increase in bile flow, and none at all if the liver is already secreting vigorously The maximal rate of flow that can be induced by secretin is only about one-tenth the rate that can be attained by the administration of bile acids and this ratio cannot be increased by increasing the dose of secretin These facts suggest that secretin is not a major factor in the regulation of bile secretion.

In addition to humoral and hormonal factors affecting the secretion of bile, the autonomic nervous system may take part in the regulation of bile flow The precise roles the autonomic nervous system play in bile secretion have not been clearly defined

In 1938, Tanturi and Ivy demonstrated that vagus nerve stimulation produced a marked increase in bile flow in dogs More recently, work from Brooks' laboratory (Fritz and Brooks, 1963, Jones *et al* , 1965) has shown that both feeding and insulin hypoglycemia causes a choleresis in dogs However, this can be prevented by vagotomy or anticholinergic drug administration They also demonstrated that the gastric antrum was necessary for the vagal effect on bile flow This suggested that the true effect was probably caused by gastrin Additional evidence by Zaterka and Grossman (1966) also indicate that gastrin has a cholerectic effect Thus, a direct vagal effect on bile flow has not yet been demonstrated

The diagram shown in Figure 2 39, taken from Wheeler, (1968) illustrates some of the factors known to affect bile flow.

Denervating the liver, insofar as this is possible, causes an increase in bile flow, distention of the colon or stimulation of any one of a number of visceral afferent nerves causes inhibition of the flow of bile from the liver It is not known whether the inhibitor effect is due to direct inhibition of the liver cells or to alterations in hepatic blood flow

Mechanism of Bile Secretion

In considering the mechanism of bile secretion, it is convenient to divide the bile constituents into two classes (Brauer, 1958) Class A, which includes water, the inorganic salts, and other highly diffusable constituents, and Class B, which includes the bile pigments, bile acids, and certain foreign substances such as Bromsulphalein, which may be used in liver function tests and appear in the bile

Pure mechanical filtration is ruled out, for bile may be secreted under a pressure which is higher than the pressure of the blood in contact with the liver cells As pointed out by Brauer, in order for a filtration process such as is utilized in the kidney to be effective, it would be necessary for the capillary pressure to exceed the maximum pressure of bile in the bile ducts by an amount at least equal to the colloid osmotic pressure of the blood, this condition is not attained in the liver The flow of bile has been shown to be independent of blood flow or of blood pressure, so long as the oxygen supply is adequate. Another bit of evidence is that cooling the liver greatly reduces the rate of flow of bile For example, in the rat liver, a 10° C reduction in the perfusion temperature between 18° and 38° C reduces bile flow by a factor of 4 Such a change in temperature should have little or no effect on a pure mechanical process. Ether anesthesia also reduces the flow of bile The situation is not so clear with respect to the inorganic salts, and it may be supposed that they are transformed along with the water The

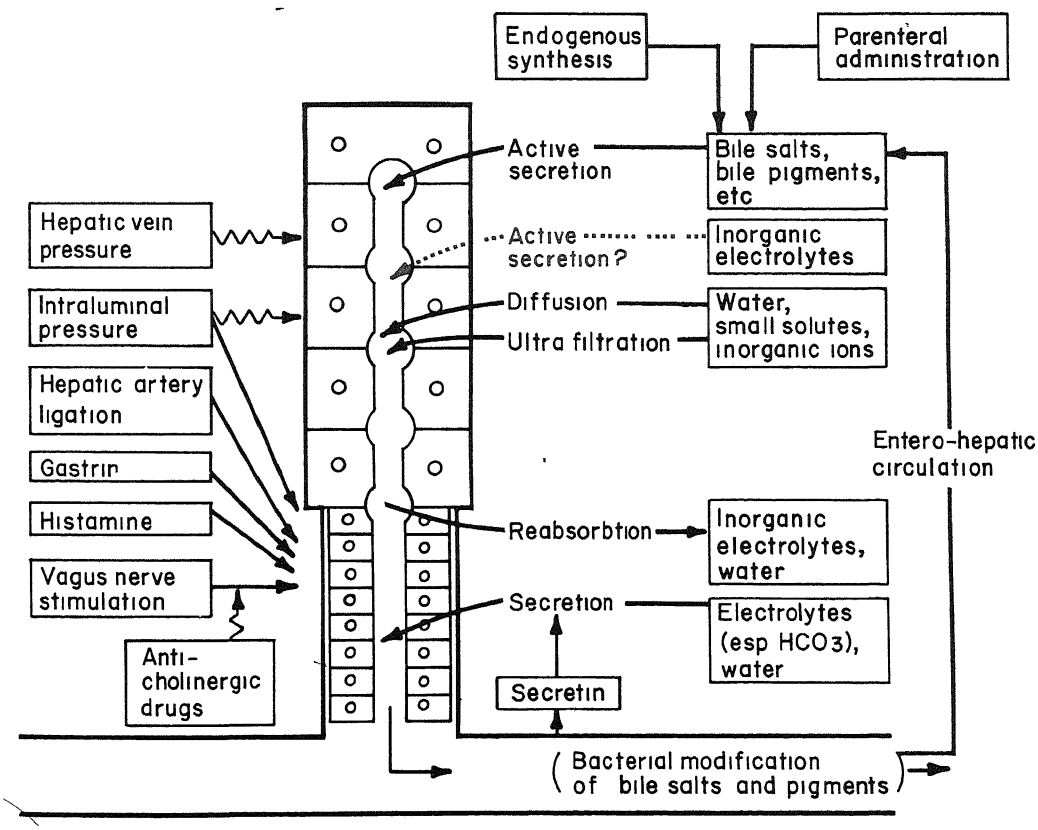

Fig 2 39 Diagrammatic summary of some of the factors known to affect bile flow and electrolyte composition Mechanisms shown on the right are believed to act at canalicular or duct level as shown Locus and mode of action of factors shown on the left is speculative (From Wheeler 1968)

evidence suggests that there is a free interchange of inorganic salts between the blood and the bile as the bile passes through the bile ducts, thus osmotic equilibrium is established between the blood and the bile.

It is interesting to note that, if the concentration of salts in blood plasma is increased so as to make the blood hypertonic, vacuoles appear in the polygonal cells of the liver. This is taken as evidence that these cells are involved in secretion of water into the bile. These hepatic cells secrete the water, as is further evidenced by the fact that in certain forms of toxic hepatitis in which only the polygonal cells are damaged, a sharp reduction in the volume of bile is one of the earliest signs (Brauer, 1958). Bile may be reabsorbed into the blood if the pressure of bile in the bile ducts is elevated above a certain critical level, but at normal pressures reabsorption of bile is negligible.

Organic constituents of the bile are actively secreted. They appear in such concentrations in the bile relative to their concentration in the blood that an active process is inevitable. The liver cells exhibit a certain maximum capacity for secreting various of the bile constituents, comparable to the tubular maximum of the kidney tubules for certain of the constituents of the urine. For example, there is a maximum rate of secretion of Bromsulphalein into the bile beyond which an increase in the dose, or in the rate of infusion in the blood, no longer alters the secretion rate. Similar phenomena have been observed for sodium dehydrocholate, bilirubin, and certain dyes. The same cells are involved in the secretion of different organic compounds, as is indicated by the fact that the secretion of some of these by the liver cells limits the rate of secretion of certain others. For example, if the liver is actively secreting Bromsulphalein, its capacity to secrete bilirubin is limited, and if it is actively secreting bilirubin at a rate near its maximum capacity, it is unable to secrete bile salts at their normal maximal rate. This indicates that there is competition within the individual liver cells among the various substances that are secreted into the bile.

It has been possible to observe, in suitable preparations, the path taken by certain of the substances that are secreted into the bile. For example, fluorescein can be seen to appear first in the parenchymal cells of the liver, then secreted into the bile canaliculi, and then transported down the bile ducts. Similar observations are possible by different methods using radioactive isotopes. Thus it appears that all the constituents of the bile, both organic and inorganic, are normally secreted by the liver cells and by a process which involves the expenditure of energy.

The Gallbladder and Bile Ducts

ANATOMY

The human gallbladder has a capacity of about 50 ml. Its wall is composed of a thin layer of muscle fibers and fibroelastic tissue, with a lining of mucous membrane. The muscle fibers are sparse, and loosely interlaced with one another and with the strands of fibroelastic tissue. The mucosa is surmounted by a layer of columnar epithelium.

The *cystic duct*, through which the bile enters and later leaves the viscus, is tortuous, or S-shaped, and shows spiral folds of mucosa—the *valves of Heister* within its lumen. These so-called valves do not have a valve-like action, for they offer little resistance to the passage of bile in either direction, nor do they seem to prevent a too rapid flow of bile as some have supposed. They develop late in phylogenetic history, apparently being associated with the erect posture and they are found only in primates. The folds are formed in the embryo by the twisting or winding of the duct during development. Their function, as suggested by Keith (1903) and supported by Lichtenstein and Ivy (1937), is to stiffen the wall of the duct and so prevent its kinking.

The *common bile duct*, formed by the union of the hepatic and cystic ducts, passes very obliquely through the muscular wall of the duodenum and joins with the pancreatic duct to form the *ampulla of Vater*.

Though it possesses important functions, the gallbladder is not indispensable, since it can be removed with impunity. After such an operation, however, the larger bile ducts undergo some dilation, which may, in part, compensate for the removal of the viscus. The gallbladder is absent in some animals whose habits and digestive processes are not apparently essentially different from those of animals that possess one. It is absent in the horse, deer, and rat but present in cattle, sheep, dogs, cats, and mice. It is present in fish, amphibia, reptiles, and birds, but is absent from orders lower than these.

Fine Structure of the Gallbladder Mucosa. The mucous membrane of the gallbladder of various animals and man has been studied in detail by light microscopy However, only recently has the fine structure of the gallbladder mucosa of man been studied by electron microscopy The mucous membrane of the gallbladder of man is composed of three distinct types of cells that have been designated "ordinary epithelial cell," "pencil cells," and "basal cells " The most common type of cell is the ordinary epithelial cell, which is arranged as a single layer of tall columnar epithelium The so-called "pencil cell" is rarely seen but appears to be a compressed ordinary epithelial cell Like the ordinary epithelial cell, it extends from the basement membrane to the lumen of the gallbladder The third type of cell, the so-called "basal cell," is scattered randomly throughout the mucous membrane, occupying a position adjacent to the basement membrane The basal cells do not extend to the luminal surface of the mucous membrane

Electron microscopy reveals that the columnar epithelium of the gallbladder has many characteristics of an active absorbing membrane (Evett et al , 1964) The luminal surface of the epithelial cells is composed of a microvillus border The plasma membrane of the microvilli is continuous with that of the intervillus surface and the lateral cell walls of the epithelial cell At the luminal junction of adjacent epithelial cells, the plasma membrane forms "terminal bars" which are thought to prevent intraluminal material from gaining entrance into the intercellular spaces The lateral walls of adjacent cells are interlocked into each other by folds in plasma membranes The basal wall of the ordinary epithelial cell rests on the basement membrane and is straight

The cytoplasm and organelles of the epithelial cells are stratified in a manner similar to that observed in other cells which participate actively in secretory or absorptive functions Just below the microvillus border, there is a small cuticular zone that is clear, due to the absence of mitochondria or granules Immediately beneath this is the subcuticular or dark zone which extends over a third of the cell's height It is in this zone that many mitochondria, vesicles, granules, and a dense endoplasmic reticulum are observed Beneath the subcuticular or dark zone is observed the Golgi apparatus, which appears to be quite similar to that observed in other secreting or absorbing cells The nucleus is large and rounded and occupies the lower third of the cell It possesses no features to distinguish it from nuclei of other cells

The pencil cell, like the ordinary epithelial cell, extends from the basement membrane to the lumen It possesses microvilli and terminal bars, and has a stratification of cytoplasmic organelles similar to that of the ordinary epithelial cell The basal wall of the pencil cells has papillary projections of cytoplasm which extend deep into the basement membrane The function of the pencil cell is unknown

The nucleus and cytoplasm of the basal cells are darker than those of the adjacent ordinary epithelial cells The plasma membrane of the cell is relatively straight The cytoplasm of these cells is more simply organized than is that of the other two cells previously described Small infrequent mitochondria and the endoplasmic reticulum are randomly distributed throughout the cytoplasm Only rarely are Golgi membranes or vesicles observed The function of the basal cell is not known

CONTRACTION OF THE GALLBLADDER AND COMMON BILE DUCT

The gallbladder shows spontaneous *rhythmical contractions* which occur at the rate of 2 to 6/min (in the dog), and also a *tonic contraction* which lasts from 5 to 30 min or more The rhythmical contractions (in the dog) are capable of producing a pressure change of 250 to 300 mm of water, which is about the maximal pressure at which bile can be secreted by the liver Rhythmical contractions of the common bile duct have been demonstrated also in animals

FUNCTIONS OF THE GALLBLADDER

Concentration and Storage of Bile—Secretion of Mucus. Gallbladder bile may have ten times more total solids than bile collected from the hepatic duct Water and inorganic salts are absorbed through the lymphatics and blood vessels of the gallbladder wall The composition of the absorbed fluid is virtually that of physiological saline Bile pigments, bile salts, and cholesterol are not absorbed to any appreciable degree under normal circumstances

It is undecided whether cholesterol is excreted by the normal gallbladder mucosa In

this connection, it may be mentioned that a pronounced diffuse deposition of a cholesterol ester in the connective tissue of the human gallbladder, ranging from 35 to 60% of its dry weight is seen as a pathological condition The tissue of the vesicle is stiff and greatly thickened as a result of its impregnation with lipid material The disturbances leading to this condition, which is spoken of as *cholesterosis of the gallbladder* or from the appearance of the mucosa, as the "strawberry gallbladder" are unknown The existence of this condition cannot, however, be used as evidence for the secretion of cholesterol by the gallbladder mucosa under physiological conditions

We owe the greater part of our knowledge of the absorptive powers of the gallbladder to the work of Rawdin and co-workers (1932 a and b) Rous and McMaster (1921), and more recently, that of Diamond (1962a, b, c) By means of a cannula placed in the bile duct, Rous and McMaster collected the bile as it came from the liver and compared its composition with the bile in the gallbladder The bilirubin percentages of the respective fluids were used as a measure of the degree of concentration that had been effected in the bile during its stay in the gallbladder The bladder bile was found to be darker, thicker and more "syrupy" than the bile collected from the ducts It contained from 3 1 to 10 8 times more bilirubin than the liver bile Absorption occurred with remarkable rapidity in some instances In one experiment about 50 ml of bile which entered the gallbladder was reduced to less than 5 ml in about 22 hr In experiments involving the drainage of the gallbladder through a cannula inserted into its fundus, it has been shown that the mere passage of bile through the organ causes a nearly fivefold concentration Inflammation of the gallbladder reduces or abolishes its concentrating power

Diamond (1962) has shown, in a series of beautifully designed experiments, that the gallbladders of fish and rabbit *in vitro* absorb sodium chloride and water in isotonic proportions The differences in composition between hepatic and gallbladder bile result secondarily from this transport process across the gallbladder mucosa Sodium and chloride are absorbed in 1:1 proportions and water movement is coupled to the salt movement. The differences in composition of hepatic bile and gallbladder bile of the dog are listed in Table 2 10

Table 2 10
Composition of canine hepatic and gallbladder bile

	Hepatic Bile	Gallbladder Bile
	mmoles	*mmoles*
Na	174	220-340
K	6 6	6-10
Cl	55 107	1-10
HCO_3	31 65	0 17
Bile acids	28 42	290 340
Ca	6	25-32
Mg	3 6	

After Diamond (1962a) From analyses by Rawdin, Johnston Riegel and Wright (1932) Reinhold and Wilson (1934) Wheeler and Ramos (1960)

Using the gallbladder of a freshwater fish, the roach, Diamond has studied its absorptive functions *in vitro* After the gallbladder is removed from the fish, the cystic duct is cannulated and the gallbladder is filled with a solution to be studied The cannula and gallbladder are then suspended in a beaker containing a bathing solution As a measure of absorption, the cannula and gallbladder are weighed at 5 to 10-min intervals Figure 2 40 shows the results of such an experiment when Ringer's solution was used to fill the gallbladder and also for the bathing solution in the beaker It was found that absorption occurred at a steady rate with the removal of approximately 38 mg/hr of the Ringer's solution in the gallbladder After 3½ hr, iodoacetate, a metabolic poison, was added to the solution in the beaker Absorption was promptly inhibited, as shown by no further loss of weight of the preparation, and so indicated that the absorptive process is metabolically dependent

Unlike most membranes that actively transport sodium or chloride, no potential difference is observed across the gallbladder mucosa during active absorption The "saline pump" is thus electrically neutral, due to the fact that for each sodium ion transported, one chloride ion is also transported. The limiting factor of the salt transport system appears to be the chloride concentration remaining in the gallbladder bile

It will be recalled that bile is in osmotic equilibrium with plasma The osmotic equilibrium exists even though the total electrolyte composition of bile may be as high as 600 mEq /liter This discrepancy in the total electrolyte composition and the osmolality of bile is observed in

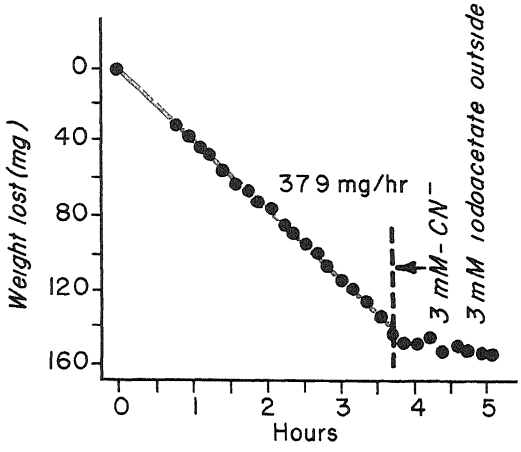

Fig 2 40 Absorption in the isolated gallbladder Both sides of the gallbladder were initially bathed in Ringer s solution Absorption from the gallbladder was determined by noting the decrease in weight of the preparation which averaged 37 9 mg /hr At 3 hr and 48 min NaCN and iodoacetic acid were added they blocked absorption as shown by no further decrease in weight (Redrawn from Diamond 1962a)

both common duct bile as well as in gallbladder bile, but it is much more marked in gallbladder bile that has been concentrated The explanation of this apparent discrepancy is found in the fact, previously mentioned, that bile salt exists as aggregates or micelles that are osmotically inactive As bile is concentrated, the formation of these macromolecular complexes (Juniper, 1964) reduced the osmotic effect of bile acid as well as the electrolytes in the bile, thus maintaining osmolality

The gallbladder mucosa also adds to the viscosity of the bile by the *secretion* of a thick mucinous material If the ducts are obstructed by ligation and the gallbladder is tied off, after some days, a clear, colorless fluid is found to have collected within the ducts This fluid, the so-called "white bile," is not uncommonly seen during an operation upon an obstructed bile duct associated with a functionless gallbladder The "white bile", under these circumstances, is furnished solely by the mucosa of the ducts It contains no pigment, bile salts, or cholesterol, and bears almost no resemblance to bile The secretion of the latter has been suppressed by the rise in pressure (to 300 mm or so of water) within the ligated duct system

If the gallbladder is healthy, and left in communication with the obstructed system, the sequence of events is entirely different Biliary stasis then causes thick, *greenish bile* to collect in the ducts and bladder as a result of the latter's concentrating activity, and of the mucinous material which it secretes After a lapse of weeks the imprisoned bile develops an almost tarry consistency The functions of the ducts and of the bladder are, therefore, antagonistic, the former tending to dilute, the latter to concentrate, the biliary fluid

Other Functions. *Other functions of the gallbladder*, subsidiary to its concentrating power, are the *reduction in the alkalinity* of the bile and the *equalization of pressure* within the biliary duct system Without the ability to absorb fluid and reduce the bulk of the bile, its power to equalize pressure would be negligible The amount of bile secreted in 24 hr is about 20 times or so greater than could be contained in the gallbladder The loss of its action in equalizing the pressure within the duct system is probably a factor leading to the dilation of the bile ducts, which so frequently follows removal of the gallbladder (cholecystectomy). After this operation, the flow of bile into the intestine is nearly continuous at first, but, later, the adaptation of the ducts permits intermittent discharge

The importance of the gallbladder in the control of pressure within the biliary ducts is apparent from the results of the experiments of Mann and Bollman (1925) They found that after ligation of the common duct in dogs, a rise in the bilirubin concentration of the blood did not occur until 24 to 36 hr had elapsed, and jaundice did not appear for 2 days If, on the other hand, the gallbladder was removed at the time that the duct was ligated, jaundice was fully developed within 24 hr due, presumably, to the rise in duct pressure and the "regurgitation" of bile into the blood

Menguy and associates (1958) have made measurements of biliary and pancreatic ductal pressures and the resistance of the sphincter of Oddi in dogs, under various conditions In intact dogs, the average biliary pressure was found to be 71 mm of water When pressures were simultaneously measured in the pancreatic ducts, the pancreatic intraductal pressure was always greater than the pressure in the common bile duct. After cholecystectomy, the pressure in the common bile duct was increased to an average of 111 mm. of water. This increased biliary pressure sometimes exceeded that measured in the pancreatic ducts. It was

also noted that the biliary pressure was much less stable after cholecystectomy The effects of a meal varied, according to whether or not the gallbladder was present In intact animals, a meal always caused a moderate rise in pressure due to contraction of the gallbladder In cholecystectomized animals, the already high fasting biliary pressure usually dropped after a meal The resistance of the sphincter of Oddi was markedly diminished after feeding

FILLING AND EVACUATION OF THE GALLBLADDER

The entrance of bile into the duodenum is blocked during fasting by the tonic contraction of the sphincter muscle (sphincter choledochus) at the duodenal end of the duct As the bile accumulates within the duct system, its pressure rises, and, reaching a height of 50 to 70 mm of water, forces its way along the cystic duct into the gallbladder During fasting, therefore, the viscus becomes gradually distended with retained bile

As the wall of the gallbladder is relatively thin, and its muscle fibers so sparse, it may seem unlikely that it could exert the pressure required to discharge its contents – especially since the gallbladder is evacuated with considerable difficulty by manual compression It has, however, been proved quite definitely, as a result of evidence derived from several modes of investigation, that the contractions of the gallbladder itself, despite the apparent muscular weakness of its walls, are responsible for the expulsion of its contents The times of emptying of the gallbladder are related to gastric digestion During fasting, it remains distended with bile.

When the walls of the gallbladder contract, bile is discharged along the cystic and common ducts into the duodenum. The sphincter (or sphincters) guarding the lower end of the common bile duct normally can withstand a pressure of 100 to 200 mm of water, but the pressure developed by the contractions of the gallbladder in dogs was shown by Mann and his associates to amount to over 250 mm of water Moreover, it is probable that relaxation of the sphincter occurs as part of a coordinated mechanism when the bladder wall contracts The duodenal muscle surrounding the oblique intramural portion of the common bile duct is capable, when contracted, of offering a resistance of over 750 mm of water. Since this is much higher than the pressure which contractions of the gallbladder can exert, the flow of bile is completely blocked during contractions of the duodenal muscle Therefore, during the evacuation of the gallbladder and during active duodenal movements, the bile may be observed to enter the duodenum in squirts This is not due to the "milking" action of the peristaltic movements of the bowel but is the result of the alternate blockage and release of the duct, the duodenal movements are incapable of causing any flow of bile when the gallbladder is not contracting

MECHANISM CONTROLLING EVACUATION OF THE GALLBLADDER

Nervous It has been mentioned that relaxation of the sphincter of Oddi probably occurs as the gallbladder contracts A coordinated action of this nature points to a nervous mechanism The latter may depend upon intrinsic nervous plexuses in the walls of the biliary passages The gallbladder contractions initiated by the stimulus of a meal might similarly be due to short reflexes through the intrinsic plexuses of the stomach or duodenum and biliary tract Nervous mechanisms are also indicated by the following observations Electrical stimulation of the stomach and duodenum in animals is followed by contractions of the gallbladder Contractions are occasionally induced by psychic influences, e g , the smell or taste of food The gallbladder also responds to experimental excitation of the vagus or sympathetic nerves Experiments attempting to demonstrate the precise actions of the extrinsic nerves upon the gallbladder movements have, however, given very conflicting evidence. Several observers have obtained weak motor effects from both vagal and sympathetic stimulation A motor action of the latter is also indicated by the fact that adrenaline is excitatory.

Hormonal Even in animals, nervous mechanisms are not essential to gallbladder activity This is evident from the fact that the reaction to the introduction of fat into the duodenum occurs after severing all nervous connections between the biliary and gastrointestinal tracts and between the former and the central nervous system That gallbladder contractions can occur under such circumstances suggests a hormonal or humoral mechanism Boyden (1928) found that the blood of an animal (taken at the height of digestion) injected into a

fasting animal causes the evacuation of the bile, blood from a starved animal has no such effect

Ivy obtained an acid extract from the musoca of the upper part of the intestine which caused contraction of the gallbladder when injected intravenously into animals Acid and other substances which are excitatory, when placed in the duodenum or when fed, act by causing the production or liberation of a hormone in, or from, the intestinal mucosa Ivy and Oldberg (1928) named this hormone "cholecystokinin "

The Actions of Drugs upon the Motility of the Gallbladder Epinephrine, pitressin, histamine and mecholyl stimulate the smooth muscle of the gallbladder, whereas morphine, ergotamine and atropine are inhibitory

Gallstones—Cholelithiasis

On the basis of autopsy data, it has been estimated that approximately 15% of Caucasians have gallstones The incidence of gallstones increases with age, cholelithiasis is rare in children and below the age of 20 years, but after the fourth decade, the incidence of gallstones is 25% and after the seventh decade, 50% Gallstones occur twice as commonly in women, and even in children who develop gallstones the ratio of females to males is 2 1 In children who have gallstones, the possible existence of hemolytic anemia should be considered strongly In both humans and animals, it has been observed that the incidence of gallstones in females is greatest in those who have borne offspring

The presence of gallstones is usually considered to be indicative of a diseased gallbladder The incidence of gallstones is higher in patients with diabetes, hemolytic anemia, and cirrhosis of the liver In patients with pancreatitis, approximately one-third will have cholelithiasis Except when producing obstruction of the biliary ducts, gallstones cause few symptoms Although the incidence of gallstones is extremely high (65 to 100% in various series reported) in patients with carcinoma of the gallbladder, only 1 to 2% of patients with gallstones develop carcinoma of the gallbladder

Gallstones are composed of constituents of the bile which have been thrown out of solution Cholesterol is present in greater or less amounts of the commoner varieties of gallstone Some stones may be composed almost entirely of this substance In other types of stone, bile pigment or calcium is an important or the predominant constituent Gallstones, therefore, differ considerably in size, color and inner structure, according to the materials of which they are composed The great majority of stones are formed in the gallbladder, but they also may form in the hepatic duct, or even in the smaller ducts within the liver

THE FORMATION OF GALLSTONES

The mechanism of gallstone formation is not clearly understood but the following are recognized as being the most important factors to be considered 1) *injury*, especially of an infective nature, to the gallbladder wall, 2) disturbance in *cholesterol metabolism*, 3) *stasis* of the bile, and 4) *reaction* of the bile

EXPERIMENTAL PRODUCTION OF GALLSTONES

Little experimental work has been done on the pathogenesis of cholelithiasis As in man, gallstones are not infrequently found in animals which possess gallbladders Small animals, which have been used as experimental models for inducing cholelithiasis in the laboratory, include the guinea pig (Okey, 1942), the hamster (Dam and Christensen, 1952), and the mouse (Tepperman et al , 1964) To induce cholelithiasis experimentally, manipulation of the diet of the animal has been the method most commonly employed For example, Okey found that with a high cholesterol diet with added vitamin B, gallstones would develop in 80% of guinea pigs A high cholesterol diet in itself would not induce cholelithiasis In both hamsters and mice, the ratio of cholic acid to cholesterol in the diet, and in the secreted bile, appears to be a critical factor It has already been mentioned that in normal bile, the cholesterol bile acid ratio is between 1 20 and 1 30 When this ratio falls to 1.13, deposition of cholesterol occurs In mice, a high incidence of cholelithiasis can be induced by simply adding 1% cholesterol and 0 5% cholic acid to the animal's regular laboratory chow diet On such a diet, the mice will begin to show stones within 3 to 4 weeks Females tend to develop stones earlier than males Tepperman and his associates (1964) have pointed out that the rate of bile flow is also important in the production of cholelithiasis in mice They found that female mice had a significantly higher rate of bile

production than did males, and that estrogen increased the rate of bile flow in the male while androgen decreased the rate in the female. This recalled the well-known relationship between pregnancy and gallstones.

In both hamsters and mice which have developed cholelithiasis due to the addition of cholesterol and cholic acid in the diet, the stones tend to disappear after several months on a normal diet (Caldwell et al., 1964). The spontaneous disappearance of gallstones in man has also been reported (Miller, 1956; Dworken, 1960). The factors involved in the dissolution of gallstones are not understood. The explanation for the disappearance of a few small stones might be that they are passed through the biliary system into the intestine. This is not the explanation for large stones, however. Although apparently very rare, gallstones, on occasion, can spontaneously disappear.

Further study of the various animal models for the production of cholelithiasis should yield information that will be helpful, not only in the understanding the etiology of cholelithiasis in humans, but also in prevention and therapy after gallstones have developed.

8 / SECRETION AND ABSORPTION IN THE INTESTINE

SECRETION

The food substances in the gastric chyme are far from being ready for absorption The products of peptic digestion of protein are still relatively large molecules containing many amino acids Starch digestion is incomplete and fat digestion has barely begun In the intestine, the enzymes of pancreatic juice carry the digestion of protein a step further but leave most of it still in the form of peptides, which need further digestion before being absorbed Starch and dextrins are reduced to maltose and some glucose Presumably, fat digestion is accomplished by pancreatic lipase but even this may be aided by lipase from the intestine Final food preparation for absorption is accomplished by enzymes found within the lumen of the small bowel and within the epithelial cells of the mucosa lining the small bowel

Secretions of the Small Intestine

The structure of the intestinal mucosa is particularly adapted to provide an extremely large surface area to the intestinal contents and thus enhance the process of absorption This increase in surface area is accomplished by the *villi* of the mucosa, and the brush border (composed of *microvilli*) of the epithelial cells covering the villi At the base of the villi are small tubular glands known as the *crypts of Lieberkuhn* It has long been taught that the "intestinal glands" secreted and that the villi absorbed Many enzymes have been identified in the contents of the small bowel and it was assumed that they were the products of secretion by the intestinal glands This secretion, known as the *succus entericus*, was supposed to complete the digestion of carbohydrates, proteins, and fats, in order that the products of digestion could be absorbed by the villi Recent evidence has cast considerable doubt on this concept of intestinal secretion and absorption It now appears that the primary function of the "intestinal glands" is to provide for the constant replacement of epithelial cells for tips of the villi In addition, it is now known that carbohydrates, proteins, and fats do not have to be completely reduced, respectively, to monosaccharides, amino acids, and fatty acids, prior to absorption

THE INTESTINAL GLANDS

The mucous membrane of the small intestine is covered everywhere with minute projections (about 1 mm in height and somewhat less in diameter) called intestinal villi The villi are invested with a layer of columnar cells, of the type characteristic of the intestinal mucosa set upon a basement membrane, beneath which is a fine layer of a smooth muscle fibers continuous with the muscularis mucosae In the center of each villus is a lymphatic vessel continuous with the lymph vessels of the mucous membrane This lymphatic is somewhat enlarged into a small sinus lined with endothelium In some of the larger villi there are several lymphatics Between the epithelium and the central sinus is a network of blood vessels Contraction of the smooth muscle of the villus causes a characteristic type of movement Between the villi are the openings of the *intestinal glands*, or *crypts of Lieberkuhn*, which are simple tubular glands The crypts do not penetrate the muscularis mucosae The epithelium covering the villi is of the same type as that lining the crypts, and consists of a single layer of columnar cells with certain specialized cells interspersed among them The free end of each columnar cell, next to the lumen of the intestine, is provided with a specialized cuticular border, resembling the brush border of certain renal tubular cells The brush border of the surface epithelial cells of the villi is composed of *microvilli* approximately 1 μ in length and about 0 1 μ in width Zetterqvist (1956) has estimated that each columnar absorbing cell in the mouse jejunum possesses about 600 microvilli and that 1 mm ^{2} of absorbing surface will contain 50,000,000 such structures

Here and there among the columnar cells are goblet cells that secrete mucus and specialized cells that stain with silver and are called *argentaffin* or enterochromaffin cells. Other cells with a large acidophile nucleus known as *Paneth* cells are also present. The argentaffin cells are of particular interest because they secrete serotonin, or at least synthesize its precursor 5 hydroxytryptophane (Erspamer and Asero 1952). The functions of serotonin in the body are not known, but it has many powerful pharmacological actions, among which are stimulation of gastrointestinal motility and inhibition of gastric secretion (Olson and Gray, 1958).

In the bottoms of the crypts many of the epithelial cells may be seen to be undergoing mitosis, and at the tips of the villi one can see that cells are being shed into the lumen of the intestine (Leblond and Stevens, 1948). Thus, there is going on in the intestinal mucous membrane a process of continuous replacement of the epithelial lining: new cells being produced in the bottoms of the crypts, and the older cells being continuously shed at the tips of the villi. The rate of renewal of shed epithelial cells has been estimated by means of autoradiography using tritiated thymidine to label the deoxyribonucleic acid (DNA) of the nuclei (Leblond and Walker, 1956). When tritiated thymidine is injected into an animal, it is rapidly incorporated in the cells of the crypts undergoing mitoses. The migration of the labeled cells up the villus can be observed by obtaining biopsies at various times after the injection, and exposing thin sections on a photographic emulsion. In man, the time required for this migration has been estimated as 3 days. Thus, every 3 days the lining of the small bowel is replaced due to the rapid turnover of epithelial cells. Crosby (1961) has estimated, on the basis of calculations of the epithelial cell mass of the small bowel of man, that about 250 g of epithelial cells are shed into the lumen of the small bowel each day.

In the first part of the duodenum, in addition to the regular intestinal glands, are special mucous glands known as *Brunner's glands*. These are similar in structure to the pyloric glands of the stomach. They are made up of long tubules, which branch frequently and are often tortuous, and which penetrate the muscularis mucosae. Their ducts empty into the crypts of Lieberkühn. Brunner's glands are very numerous in the duodenum between the pylorus and the entrance of the bile and pancreatic ducts. Below this level they are seen less frequently and none are found beyond the duodenojejunal junction.

INTESTINAL SECRETIONS OR SUCCUS ENTERICUS

The composition of the fluid secreted by the intestinal mucous membrane varies somewhat in different parts of the intestine. For example, in the duodenal area, due to the secretion of the mucous glands of Brunner, the secretion contains more mucus than is found elsewhere. In general, the secretion of the small intestine is a thin, colorless, or slightly straw-colored fluid, somewhat opalescent and containing flecks of mucus. On centrifuging and examining the sediment, it can be seen that the cloudy appearance of the juice is partly due to mucus and partly due to cellular debris, including some intact cells of the type characteristic of the intestinal mucous membrane (Florey et al., 1941). When collected from the duodenum only, the juice has a more glairy appearance and a heavier consistency, and evidently contains a greater proportion of mucus. The composition of the juice consists mainly of water, inorganic salts, and organic material.

The fasting intestinal fluid is the resultant of fluxes into and out of the intestine, and what is collected and measured is a *net* resultant.

The concentration of sodium, potassium, calcium, and total anions is relatively constant, and in both jejunum and ileum resembles the serum. Cl and HCO_3 display a reciprocal relation, in jejunal juice HCO_3 is low, and is high in the ileum.

The reasons for the differences in HCO_3, Cl are not established. It has been suggested that the difference between jejunum and ileum is due to a diminishing ability to secrete hydrogen ions along the gastrointestinal tract. Recently Fordtran and his colleagues (1968) have suggested a double exchange mechanism, Na^+ for H, and chloride for bicarbonate for electrolyte movement across the ileum, based on a nonelectrogenic transport system. It has also been argued that passive diffusion could explain the electrolyte movements.

Except in the duodenum, the quantity of fluid secreted by the small intestine is never very great, a few milliliters per hour being the usual amount that it is possible to obtain under conditions of stimulation. In the dog, pig, rab-

bit, and goat, spontaneous secretion of the Brunner's glands, amounting to 0 5 to 2 0 ml /hr , has been demonstrated Spontaneous secretion apparently does not occur in the cat In dogs, where more extensive studies have been done, the response of the Brunner's glands to feeding results in only 3 to 4 ml /hr It is difficult to determine with accuracy the amount actually secreted because of the tremendous absorptive capacity of the intestine Many times more than the amount that it is possible to collect may be secreted and reabsorbed during an observation period It is evident that the mucosa is capable, under some circumstances, of passing enormous amounts of fluid into the lumen of the intestine as shown by the great water loss that occurs through the intestine in pathological states such as cholera, diarrhea, or intestinal obstruction

The organic matter of the juice consists of mucus, enzymes, and cellular debris The source of the enzymes is unknown but it is assumed that they are produced by the columnar cells, although the argentaffin cells or the Paneth cells may be responsible for some of them There is no evidence that the mucosa of the small bowel *secretes* enzymes in the sense that secretion occurs in the gastric mucosa or in the pancreas The exfoliation of epithelial cells into the bowel lumen, and their subsequent dissolution probably accounts for the presence of enzymes in the intraluminal contents of the small intestine, although Florey and his colleagues have concluded that only enterokinase, the enzyme which converts trypsinogen to trypsin, and amylase were secreted into the lumen of the gut A really formidable array of enzymes have been reported as occurring in intestinal secretion A pepsin-like protease (from the duodenum only), an amylase, a lipase, at least two peptidases, sucrase (invertase), maltase, lactase, enterokinase, alkaline phosphatase, nucleophosphatases, and nucleosidases have been described Immunoglobulins have been identified in the secretions of the intestine Immunoglobulin A (IgA) is the predominant form throughout the intestinal tract of man, and is believed to be transferred from the blood to gut lumen by the addition of a "secretory piece" or transport "T" piece

The studies of Wright, Jennings, Florey and Lium (1940) raised a question as to the source of the enzymes ordinarily found in intestinal secretion They reported that when they took precautions to prevent injury to the mucous membrane while collecting the secretion, and then immediately centrifuged the collected secretion so as to remove cellular debris, only amylase and enterokinase were consistently present in the supernatant fluid They consider that those enzymes, and possibly maltase, are secreted by the intestinal glands in the usual sense The others, they believe, are intracellular enzymes which exist in the cells of the mucous membrane and appear in the juice only as a result of the shedding of these cells and their disintegration in the intestine

CONTROL OF BRUNNER S GLANDS

Secretion of Brunner's glands is controlled by nervous and humoral mechanisms which affect the other intestinal glands only to a slight extent Their secretion increases on stimulation of the vagus nerves or the administration of parasympathomimetic drugs such as pilocarpine and physostigmine, it is not augmented by stimulation of the sympathetic nerves (Florey and Harding, 1934) The amount of secretion is increased after meals (Blickenstaff et al , 1949), even in transplanted denervated pouches of the duodenum (Florey and Harding, 1935b) This proves that there is a humoral mechanism for regulating the secretion, in addition to whatever nervous mechanisms there may be Florey and Harding (1935a) were convinced that it was secretin More recent studies indicate that in addition to secretin, gastrin, pancreozymin, and glucagon stimulate Brunner's glands as well

Florey and Harding (1933) emphasized the protective function of the secretion of Brunner's glands and considered it an important factor in preventing duodenal ulceration Since, like other intestinal secretions, it contains enterokinase it helps to activate the trypsinogen of pancreatic juice

CONTROL OF SECRETION OF SUCCUS ENTERICUS

It has long been known that local chemical and mechanical stimuli can evoke secretion by the small bowel The neural and humoral mechanisms regulating secretion by the small bowel are poorly understood Except for "paralytic secretion," discussed below, there is little evidence that neural and humoral mechanisms normally play a significant role

Nervous Control Wright and his coworkers (1940) were able to obtain an increased secretion from the duodenum on stimulation of the vagus in decerebrated or decapitated animals, but were unable to obtain clear evidence that vagal stimulation caused secretion from the jejunum or ileum

Stimulation of the sympathetic causes no secretion, but cutting the nerves results in a marked increase in secretion This *paralytic secretion*, as it is called is increased by physostigmine and inhibited by atropine, it is therefore considered to be dependent upon some cholinergic mechanism in the intestine In general, parasympathomimetic drugs increase the paralytic secretion, and sympathotaimetic drugs tend to inhibit it From these observations we can conclude that secretion is augmented by a cholinergic mechanism One interpretation of the paralytic secretion is that section of the sympathetic nerves results in either unopposed acetylcholine stimulation or dilation of the blood vessels of the intestine, which increases the blood flow An increase in blood flow could provide a greater amount of fluid for secretion and, presumably, produce augmentation of secretion on section of the sympathetic nerves (Starling, 1906) Babkin (1950) has pointed out that cutting the sympathetic nerves to the small intestine increases its motility, which undoubtedly has a massaging effect on the mucous membrane

Humoral Control. The most effective stimulus for secretion of succus entericus is local, mechanical, or chemical stimulation of the intestinal mucous membrane Such stimuli are always present in the digesting intestine, due to the presence of chyme and the food particles which it contains Feeding is not very effective in increasing the rate of intestinal secretion from an isolated intestinal loop, provided the nerve supply is intact, but if the sympathetic nerves have been severed, a noticeable increase in secretion takes place when the animal is fed Nasset (1938) and his coworkers have prepared an extract of the intestinal mucous membrane which is free from secretin, from vasodilator material, and from toxic substances, but which causes an increase in the secretion of a denervated jejunal loop when given intravenously The material is thought to contain a hormone which augments the intestinal secretion, it is called "*enterocrinin*," but its existence has not been generally accepted by workers in the field

THE FUNCTION OF THE SUCCUS ENTERICUS

Enzymatic digestion of food, in all its phases, is a hydrolytic process, therefore, an abundance of water to serve as one of the reacting substances is essential The succus entericus provides this water in the area in which the major part of digestion of food occurs Water is also necessary to serve as a solvent and as a medium of suspension and transport for the solids which are dissolved or suspended in the chyme The enzymes, either in the secretion or in the cells, complete the digestion of protein and carbohydrate by reducing the peptides which result from peptic and tryptic digestion to amino acids, and the disaccharides which result from amylolytic digestion of starch to glucose Other disaccharides that may be present in the food are likewise digested, liberating their constituent monosaccharides In fat digestion, the succus entericus serves as a source of water and as a medium for suspension and emulsification of the fat particles, it may provide a certain amount of lipase

Secretion of the Colon

The mucosa of the mammalian cecum and colon is in many respects similar to that of the small intestine, crypts are present but there are no villi As in the small intestine, the cells at the bottoms of the crypts exhibit numerous mitoses, suggesting the continuous replacement of shed epithelial cells Goblet cells are more numerous than in the small intestine, and the epithelial cells between the goblet cells differ among themselves, but in the majority of cases, the protoplasm is clear and free from secretory granules The secretion is scanty (Wright et al, 1938), as is to be expected from the fact that a major function of the large intestine is absorption of water The decrease in volume of intestinal contents that occurs in this area indicates that secretion does not keep pace with absorption Actually, it is usually not possible to collect any secretion from a colonic fistula unless the mucous membrane is stimulated mechanically by insertion of a catheter or other instrument Even with this stimulation only a few tenths of a cubic centimeter per hour can be collected When anything can be collected, it consists of watery fluid with clumps of white mucus; often it is viscous and opalescent The reaction is alkaline, due to sodium bicarbonate which may be present in concentrations as

high as 80 to 90 mEq /liter, according to DeBeer et al (1935)

NERVOUS CONTROL OF COLONIC SECRETION

Florey (1930) and Wright et al (1938) found that stimulation of the nervus erigens caused the colon to secrete a clear mucoid fluid In contrast to absence of spontaneous secretion, stimulation produced as much as 55 ml in one 8-hr period from the distal half of the colon, the average rate was about 5 ml /hr Reflex secretion was observed on stimulation of the cut end of one nervus erigens, the other being intact, the reflex center was located in the lumbar spinal cord It should be recalled that the nervus erigens supplies only the distal portion of the colon with parasympathetic fibers, the parasympathetic supply for the proximal colon comes from the vagi Acetylcholine and pilocarpine increase colonic secretion, atropine inhibits it Cutting the sympathetics does not produce "paralytic secretion" in the large intestine, but stimulation of the sympathetics diminishes the secretory response to stimulation of the nervus erigens

ABSORPTION

The mucous lining of the small intestine is one of the most remarkable organs of the body It secretes a variety of hormones which help to regulate gastric secretion and motility, the secretion of the pancreas and of the intestine itself, and the movements of the gallbladder and the intestinal villi During absorption, the mucosa cells perform a variety of hydrolytic and synthetic operations upon the food substances passing through them, greatly modifying the character of the absorbed material Even while producing their own secretions, the epithelial cells are transferring water and dissolved substances from the lumen of the intestine into the interstitial fluid to be taken up by the blood This activity is highly selective and frequently involves the expenditure of considerable energy Probably nowhere, except possibly in the liver, is so great a variety of functions performed by a single tissue

The ultimate aim of digestion is absorption Only after the products of digestion have passed through the epithelial lining of the digestive tract and entered the blood stream are they able to serve their purpose of providing nourishment for the tissue cells of the body Absorption of such materials takes place almost entirely from the small intestine Although the stomach is capable of absorbing small amounts of water and certain food substances, notably glucose, and some foreign substances such as alcohol, the absorption that occurs there is negligible Although absorption of nutrients occurs mainly in the small intestine, water and salts are absorbed in significant amounts from the large intestine

The mucous lining of the small intestine is admirably adapted to its absorptive function The structure of the epithelium has been described in connection with the discussion of intestinal secretion It has been estimated that the presence of the villi results in an increase of 7- or 8-fold in the surface area of the mucous membrane of the intestine The microvilli increase the surface area by another 20-fold (Fig 2 41)

Methods for Study of Intestinal Absorption

In acute experiments, one places the material, the absorption of which is to be studied, in an isolated loop of intestine and, after a measured time, removes it and observes the volumetric or chemical changes that have taken place The Thiry or Thiry-Vella loop may be used in the same manner In the case of substances that can be readily detected in the blood, the material can be placed in the intact

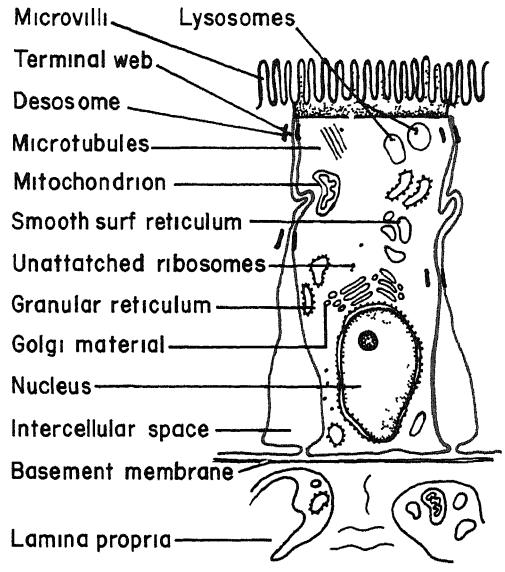

Fig 2 41 Schematic diagram of the intestinal absorptive cell (From Trier and Rubin 1965)

intestine and its absorption estimated by the rate of its appearance in the circulating blood, in the portal blood, or in the intestinal lymph, if the experiment is of such a nature as to make these vessels available

In man, intestinal absorption can be studied by an intubation technique A multilumen tube, or two or more separate small polyethylene tubes may be used After localization in the desired segment of intestine, the material to be studied, along with a nonabsorbable reference "marker," is introduced through the lumen of the proximal tube at a constant rate Sampling is done through one or more of the distal tubes, whose openings are a measured distance from the opening of the proximal tube used for introduction The concentration of absorbable material recovered is compared to the concentration introduced, and a correction is made for any change in volume as indicated by the change in concentration of the "marker" Polyethylene glycol (PEG) and phenol red are commonly used as "markers" for such studies

The development of in vitro techniques for the study of excised segments of intestine has greatly increased our knowledge in recent years A variety of techniques for this purpose have been described, all depend upon maintaining the vitality of a portion of the intestine that has been removed from the body by keeping it in contact with oxygenated fluid of appropriate composition The preparation can be arranged so that the fluid inside the intestine can be kept separate from that on the outside and the changes in composition of the internal and external fluid are used to measure the degree of absorption by the mucosa A small segment of intestine can also be turned inside out, as described by Wilson and Wiseman (1954), and is known as the everted sac method The method has the advantage of collecting high concentrations of the absorbed material in the small volume contained inside the serosal lined sac

Absorptive Functions of the Intestines

ABSORPTION OF WATER

The human intestine absorbed about 8 liters of water, but until recently it has been impossible to distinguish between the water that was secreted into the intestine and water that left the intestine by absorption. Changes observed in the volume of water in the intestine do not represent total absorption of water but merely the difference between the volume of water secreted into the intestine and that absorbed Since there is reason to believe that water moves freely through the intestinal mucosa, it is essential that we know how much water entered the intestine in a given time if we are to make an intelligent estimate of the amount leaving by way of absorption in the same time It has been possible to get around this difficulty, and to determine accurately the amount of water leaving the intestine by absorption in a unit of time, by the use of heavy water Water containing heavy hydrogen can be readily detected in the blood, also, the amount remaining in the intestine can be accurately measured Since, in a short period of time the water secreted into the intestine will be normal water, the change in heavy water content represents water actually absorbed Or if, as in experiments on human subjects, it is not possible to determine the amount of water remaining in the intestine, the amount of heavy water appearing in the blood can be used as an estimate of the water absorbed

Scholer and Code (1954) studied absorption of water from the human stomach and small intestine using heavy water as a tracer They found that when 50 g. of water were given, 2 5% of this amount was absorbed per minute, so long as it remained in the stomach When the water was placed in the small intestine, it was absorbed at about 10 times that rate, 26 1% of the dose being absorbed per minute If the water remained in the stomach, it required 34 2 min to absorb 67% of the administered amount; whereas in the intestine, this percentage was absorbed in 3 7 min In the intestine, 95% of the administered water was absorbed in 10 min In these experiments only absorption was measured, and the net volume change was not observed, hence, no account was taken of the water that might have been secreted into the stomach or intestine during this same period of time One interesting fact brought out in these studies is the extremely rapid absorption of water from the intestine Another is that there is an appreciable absorption of water from the stomach. Considering net absorption only, that is, the decrease in the volume of intestinal contents, it appears that water is absorbed more rapidly from the terminal ileum than from other parts of the small

intestine Most of what remains is absorbed from the large intestine, except the rectum

The movement of water is generally held to be passive, determined by osmotic and hydrostatic pressure gradients, which in turn are the result of the permeability characteristics of the intestinal membrane, active transport of solute, and tissue pressures due to the effects of active transport and blood and lymph pressures Absorption is accelerated by an increase in hydrostatic pressure up to the point where there is interference with blood and lymph flow

In general terms, modern studies treat the intestinal membrane as a lipid membrane perforated with water-filled pores, or a series of membranes In the model of Curran and Schultz (1966), the active transport of sodium leads to the absorption of water since sodium is concentrated in a continuing compartment, which thus establishes an osmotic gradient Water follows this osmotic gradient and isotonic flow ensures

MONOVALENT ELECTROLYTES

In considering the absorption of water and salt, the porosity of the intestinal membrane would obviously influence these movements By determining the reflection coefficient (the ratio of observed to theoretic osmotic pressure) for nonlipid solutes of varying molecular sizes, Fordtran and his colleages (1968) have made estimates of the "pore" size, and from a study of the filtration coefficient (the flow of water induced by an osmotic gradient) suggested that the "pores" in the jejunum were either more numerous or larger than those in the ileum

Sodium. Sodium is considered to be actively transported, i e , absorbed from lumen to blood or intestinal fluid against an electrochemical gradient The transmucosal potential difference of 4 to 8 mV (serosa positive to mucosa) has been attributed to this active sodium transport Further sodium absorption is accelerated by actively transported nonelectrolytes such as glucose and some amino acids such as alanine

Chloride Chloride is believed to follow sodium absorption passively but the situation may be more complex In rat jejunum, chloride is absorbed more slowly than sodium, in ileum at least as fast In man, with perfusion studies, Fordtran et al (1968) found in the jejunum that sodium was absorbed against a small concentration gradient and influenced by glucose In the ileum, sodium was absorbed against a sharp gradient, unaffected by glucose In the upper small intestine, they concluded that the majority of sodium absorption was accomplished by bulk flow along osmotic gradients

Potassium. Potassium is believed to move passively in response to concentration gradients

Bicarbonate Bicarbonate has been alluded to above, being lower than plasma in jejunal contents and high in ileal, and its reciprocal relationship to chloride has been commented upon The absorption of HCO_3^- could be secondary to the secretion of H^+ ion, formation of CO_2 and its diffusion from the lumen, or perhaps to the double exchange model (Na^+ for H^+, and Cl^- for HCO_3^-) mentioned before

ABSORPTION OF DIVALENT CATIONS

Calcium Calcium is absorbed in most species in the proximal small bowel by active process which involves two steps from the lumen into the mucosa, and from the mucosa to the underlying tissues Both steps require vitamin D, and the latter is dependent on oxidation phosphorylation At present, it is believed that vitamin D is converted into its active metabolite 25-hydroxycholecalciferol by the liver, and that this steroid induces the synthesis of a calcium-binding protein in the duodenal mucosa Parathormone plays a facilitory role in calcium absorption Calcium is absorbed more readily by individuals suffering from a calcium deficiency, indicating some control of calcium absorption by systemic factors Excess of magnesium interferes with calcium absorption, as does phytic acid (which occurs in cereal grains, and which may be responsible for the tendency of these grains to produce rickets when fed exclusively or in excess)

Magnesium. In man, magnesium is probably absorbed along the course of the entire small bowel Although calcium and magnesium are often thought to share a common transport system, workers have been unable to demonstrate magnesium transport against a concentration gradient using in vitro preparation of rat intestine

Iron. Like calcium, but unlike almost all nutrients, the absorption of iron is influenced by the body's needs, and it is held at present that the regulator of absorption is the columnar epithelial cell of the upper small bowel

In Crosby's formulation (1961) the columnar cell contains a variable amount of iron supplied by the body stores This deposit regulates within limits, the quantity of iron which can enter the intestinal cell Part of this accepted iron may proceed from the cell to body stores by way of the iron binding β globulin of the plasma (transferrin) and part fixed in the cellular cytoplasm is sloughed at the end of the cell's life span Within the cell there is an interplay of iron stored as ferritin iron-containing enzymes, and hemoglobin iron in two mucosal pools divalent iron for transport and trivalent ferritin iron which is concerned with temporary storage

It should be recalled that the bulk of dietary iron is derived from hemoglobin and organically complexed iron of food which must be digested to be available for absorption

ABSORPTION OF CARBOHYDRATES

Under the influence of salivary, pancreatic, and intestinal amylase, the carbohydrates of our diet are presented to the upper small bowel for absorption mainly in the form of various disaccharides and the monosaccharides glucose, fructose, and galactose Glucose occurs as the final product of starch digestion, and as one of the two products of hydrolysis of sucrose and lactose Fructose occurs as a product of sucrose digestion, and also in certain natural products, such as some fruits and in honey Galactose is one of the constituents of lactose Other simple sugars such as mannose and pentoses are quantitatively unimportant The three simple sugars, galactose, glucose, and fructose, are all actively absorbed from the small intestine, galactose more rapidly, and fructose less rapidly than glucose In addition, some disaccharides are also presented for absorption These include maltose, sucrose, and lactose derived from partially digested starch and ingested cane sugar and milk These, as will be pointed out below, are hydrolyzed to their corresponding monosaccharide by enzymes contained in the brush borders of the intestinal absorptive cell, which in general, is impermeable to polysaccharides

Absorption of Monosaccharides. The ability of the intestine to absorb glucose against a concentration gradient has been repeatedly demonstrated, i e , glucose can be absorbed when the concentration of glucose in the intestinal contents is lower than the concentration in the blood

It is interesting to note that although the pentoses are more diffusible than the hexoses, the pentoses are absorbed at a much slower rate proving again that the hexoses are actively absorbed With most sugars, particularly those that are not actively absorbed, the rate of absorption increases with increasing concentration in the intestinal contents With glucose and galactose however this is true only up to about a 5% concentration, which for these sugars is approximately isotonic with the blood Further increase in concentration of these sugars fails to increase or decrease their rate of absorption Furthermore if glucose and galactose are given simultaneously each suppresses the absorption of the other (Cori, 1931) so that the total amount of sugar absorbed is not more than would be absorbed if only one of the sugars were present These facts indicate that the mechanisms for active absorption can be saturated in a manner somewhat analogous to the tubular maximum for glucose in the renal tubules

Glucose is absorbed much more rapidly from the upper than from the lower small intestine Fisher and Parsons (1949) have shown that, in the rat, there is a linear gradient in the ability of the intestine to absorb glucose from the intestinal contents The rate of absorption is directly proportional to the distance of the segment in question from the ileocecal valve (Fig 2 42)

Using various segments of hamster intestine,

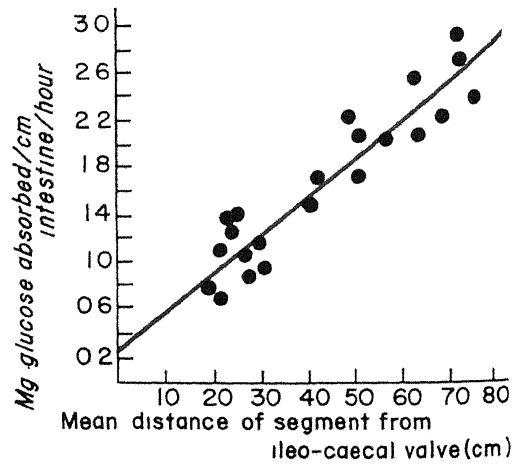

Fig 2 42 Glucose absorption in surviving intestine Relation between glucose disappearance from inner fluid and mean distance of segment from ileocecal valve in 1 hr experiments (From Fisher and Parsons 1949 Courtesy of Cambridge University Press)

Crane and Mandelstam (1960) have shown that the midportion of the small intestine is the site for the most active rate of absorption of monosaccharides as glucose Borgstrom and his associates in Sweden (1957) have studied the site of absorption of glucose and lactose in the small bowel of man They used an intubation technique, with polyethyleneglycol as a nonabsorbable indicator substance The subjects were fed a test meal containing 55 g of glucose and 20 g of lactose Samples were then collected from various levels of the small bowel, and it was found that absorption began in the duodenum and was completed by the time the meal had reached a level about 100 cm from the duodenum

As to the specific site of absorption in the mucosa, Kinter (1961), using autoradiographic techniques, has shown that absorption of glucose occurs mostly in the upper third of the villus Crane (1962) has presented evidence that the active transport of glucose actually occurs across the plasma membrane of the microvilli in the brush border

Absorption of sugars is diminished in the presence of sodium chloride deficiency such as may occur in adrenal cortical insufficiency, is accelerated in hyperthyroidism, and is depressed in hypothyroidism Pantothenic acid, thyamine, and pyridoxine, members of the B vitamin group, are essential for normal sugar absorption

For optimal absorption of glucose it is necessary that both sodium and potassium be present If sodium is completely replaced by potassium, lithium, magnesium, or mannitol, active glucose transport ceases If sodium transport is inhibited by cardiac glycosides, active glucose transport is also interfered with It is now thought that mechanisms of glucose and sodium transport are closely coupled (Crane, Miller, and Bihler, 1961) and dependent on one another Whether the sodium "pump" and the glucose mechanism are the same for entry into the cell is not known, however, Bihler, Hawkins, and Crane (1962) have suggested that two processes, both dependent on sodium, are involved in sugar transport *1*) an *entry* step that is sodium dependent but requires no energy, and 2) an *accumulation* step, also sodium dependent, but which requires energy to maintain a concentration gradient within the cell (Fig 2 43)

In addition to the specific dependence of glucose absorption and transport on the Na^+ ion, it is now known that there are specific structural requirements of the monossaccharide molecule for it to be actively transported The absorption of a great many naturally occurring and synthetic monosaccharides has now been studied in relation to the structural configuration of the molecule To be actively transported, the following specific structural requirements of the monosaccharide molecule are known *1*) The hydroxyl (OH) group at carbon-2 must be present and have the same stereoconfiguration as exists in D-glucose If the hydroxyl group at carbon-2 is replaced by H (as in 2-deoxyglucose), or if the H of the OH group is replaced by a methyl group (as in 2-O-methyl glucose), active transport does not occur 2) A pyranose (6-membered) ring must be present, as in glucose and galactose *3*) One or more carbons must be attached to carbon-5 The structural requirements necessary for the active transport of monosaccharides are illustrated in Figure 2 44

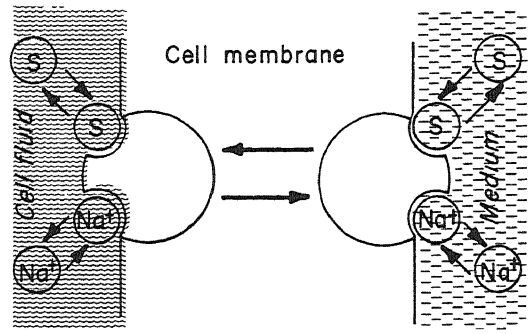

Fig 2 43 Model of mobile carrier with two sites one specific for substrates and one specific for Na (From Crane 1965)

From the above, it might be reasoned that 5-carbon sugars such as xylose will not be actively transported, yet recent data suggests that *d*-xylose is actively absorbed If a monosaccharide is a 7-carbon sugar, it may be actively transported if it has the specific structural requirements outlined above The hydroxyl group at carbon-1,3,4, or 6 is not essential for active transport Thus, phosphorylation which occurs at carbons-1 and -6 is not essential for active transport In other words, monosaccharides with the necessary specific structural requirements can be actively transported in the absence of phosphorylation Fructose is absorbed as such by passive diffusion and converted in part in the cell to glucose

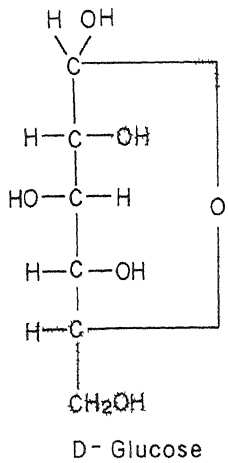

Fig 2 44 The minimal structural requirements for the active transport of monosaccharides by the intestine (From Isselbacher and Senior 1964)

Absorption of Disaccharides It has long been believed that disaccharides were hydrolyzed in the lumen of the small bowel by disaccharidases secreted by the small bowel into the "succus entericus" There is now much evidence that this is not the case, and that some disaccharides are absorbed and hydrolyzed *within* the epithelial cell by specific intracellular enzymes Much of the evidence in support of intracellular hydrolysis of disaccharides has been due to the work of Miller and Crane (1961) These investigators incubated inverted segments of hamster small bowel in a sucrose solution, and found that glucose accumulated in the epithelium to a concentration 20 to 30 times that in incubating medium This suggested that the sucrose was hydrolyzed after absorption, rather than before In another experiment, maltose was used in the incubation medium but glucose oxidase was added also A molecule of maltose results in two molecules of glucose on hydrolysis, but in the presence of glucose oxidase, the glucose would be oxidized and unavailable for absorption if hydrolysis occurred prior to absorption Their findings were the same as when sucrose was used in the incubation medium and glucose accumulated in the tissue, in spite of the fact that glucose oxidase was in the medium Other experimental evidence provided by Miller and Crane, in support of intracellular hydrolysis of disaccharides, is their demonstration that practically all of the maltase and invertase activity of the small bowel mucosa can be found in the isolated brush border of the epithelial cells.

Within the past few years a new clinical entity has been described in patients who are unable to absorb certain disaccharides The condition is now recognized as an *hereditary disaccharide intolerance* (Dahlqvist 1962) and is due to the congenital absence of one or more of the disaccharidases normally found in the mucosa of the small bowel When a patient with a congenital absence of a disaccharidase is fed the corresponding disaccharide he develops diarrhea with watery stools of low pH, and containing large amounts of the disaccharide as well as lactic acid Removing the specific disaccharide from the diet promptly causes the symptoms to disappear Due to the inability to absorb certain disaccharides by these patients, a *disaccharide tolerance test* can be done to demonstrate the disorder The test is similar to the oral glucose tolerance test and consists of giving a loading dose of the disaccharide and observing whether or not a rise in the blood glucose level occurs The interpretation of disaccharide tolerance tests must take into account the specificity of the various disaccharidases that have been identified in the small bowel mucosa of man Dahlqvist (1962) has listed the specificity of various disaccharidases, as shown in Table 2 11.

A congenital absence of lactase without intolerance to maltose or sucrose has been observed frequently This condition is usually recognized in newborns and infants who are unable to tolerate milk Sucrose and maltose intolerance are usually not recognized until later when these sugars are introduced into the diet Combinations of sucrose and isomaltose intolerance have

Table 2 11

Specificity of disaccharidases isolated from human intestinal epithelium and their quantitative importance for hydrolysis of different disaccharides

Enzyme		Substrate	Activity[a]
			%
Isomaltase	maltase Ia	Isomaltose	100
		Maltose	50
Invertase	maltase Ib	Sucrose	100
		Maltose	25
Maltase II		Maltose	15
Maltase III		Maltose	10
Trehalase		Trehalose	100
Lactase		Lactose	100
		Cellobiose	100

From Dahlqvist (1962).

[a] Total activity against each substrate

been recognized From a study of Table 2 11 it will be seen that four different maltases have been identified Thus, maltose intolerance is extremely rare, as it requires the absence of all four of these enzymes Such a patient would also be intolerant to isomaltose and sucrose

ABSORPTION OF PROTEIN

It has been estimated that approximately 225 g of protein may be absorbed per day by the small bowel of an adult man The protein available for absorption in the small bowel has both an *exogenous* and *endogenous* origin To maintain nitrogen balance, a 70-kg man requires approximately 50 g of dietary, or *exogenous*, protein per day The source of *endogenous* protein is protein contained in the gastrointestinal secretions and the desquamated epithelial cells of the gut The protein of the secretions may amount to 150 g /day, and that from desquamated cells 25 to 30 g /day Thus, the exogenous dietary protein is considerably diluted by the endogenous protein

Although some absorption of native protein and of intermediate products of protein digestion take place in the small intestine, the amount absorbed is insignificant from a nutritional standpoint The greater part of protein in the food is reduced to amino acids before being absorbed Protein absorption is, therefore, essentially amino acid absorption

All evidence indicates that amino acids are readily absorbed throughout the entire length of the small intestine They are taken up about as rapidly as they are produced, consequently, only small amounts of amino acids can be found at any time in the intestinal contents In fact, due to the dilution of exogenous protein previously mentioned, Nasset et al., (1955) have shown that feeding a dog a protein meal has little effect on the distribution of free amino acids in the intestinal contents that can be recovered from the lumen Any excess of amino acids in the portal blood due to absorption disappears rapidly Although all the amino acids are rapidly absorbed from the intestine, some are absorbed more rapidly than others The following list is in the order of rapidity of absorption glycine, alanine, cystine, glutamic acid, valine, methionine, leucine, tryptophane, isoleucine, norleucine, and isovaline (Verzar and McDougall, 1936)

Mechanism of Amino Acid Absorption. Wiseman (1953) demonstrated that the levorotatory, or naturally occurring forms of alanine, phenylalanine, isoleucine, valine, methionine, and histidine are absorbed more rapidly than the dextrorotatory isomers, and that the levoforms could be transferred through the intestinal wall against a concentration gradient, whereas the dextroforms tended to reach the same concentration on the two sides of the membrane (as did glutamic and aspartic acids) This and the fact that there are differences in the rate of absorption of amino acids that are not related to their diffusibility, as well as the rapid disappearance of amino acids from the intestine, all indicate that there is an efficient mechanism for the active absorption of many of the amino acids This is further supported by the fact that amino acid absorption is inhibited by the absence of oxygen, and by several metabolic inhibitors (Fridhandler and Quastel, 1955) Phloridzin, which interferes with the active absorption of glucose, does not interfere with active absorption of amino acids Nevertheless, amino acids are said to compete with sugars for the absorptive mechanism, that is, sugars are absorbed more slowly from a sugar-amino acid mixture than from a pure sugar solution (Cori, 1931)

At present, the mechanisms for the transport of amino acids may be classified as follows *1*) Neutral amino acids (including histadine) most efficient and operates at high concentrations *2*) a mechanism shared by the basic amino acids (ornithine, arginine, and lysine) Cystine may use this route in addition to pathway 1 *3*) Another pathway is shared by proline, hydroxyproline, sarcosine, N-dimethylglycine, and betaine The first two may use pathway 1 *4*) Proline and glycine may have an alternative pathway

A number of neutral amino acids compete with each other for the same transport system through the cell membrane The α-carbon of a neutral amino acid has four different groups attached to it a carboxyl group, an amino group, a hydrogen ion, and a side-chain radical, usually referred to as R An alteration in any of these groups attached to the α-carbon may interfere with the active transport of the amino acid Thus, when the charge on the carboxyl group is removed by the formation of an ester or an alcohol, a compound is produced that is not actively transported by the small bowel The removal of the charge of the amino group by acetylation, or by replacement of the amino group by a hydroxyl group, also results

in an inactive compound The α-hydrogen also has been shown to be essential for active transport to occur Replacing the α-hydrogen by a methyl group reduces the rate of transport A wide variety of side chains or radicals may be attached to the α-carbon and be actively transported Thus, the carrier system for neutral amino acids is not selective in regard to the side chain, as long as the side chain does not contain a charge If either a negative or positive charge is introduced into the side chain, active transport is interfered with

The levoforms of the basic amino acids lysine, arginine, and ornithine, are transported at rates of only about one-tenth of that of most of the neutral amino acids Like the neutral amino acids, the basic amino acids seem to share a common, but separate, transport system Thus, any two of the above-mentioned basic amino acids will inhibit the transport of the remaining basic amino acid in the group For some unknown reason, cystine, which is a neutral amino acid, appears to share the same transport system as the three basic amino acids

As previously mentioned, the transport of substances through the small bowel mucosa may involve a number of "steps" During absorption, amino acids accumulate in the mucosal cells and their intracellular concentration may exceed that in the lumen Thus, entry into the cells appears to be the active step With accumulation within the cell a favorable concentration gradient is created for diffusion out of the cell into the portal blood

Transamination During Absorption Most amino acids are not altered during transport through the epithelial cells lining the small bowel However, glutamic acid and aspartic acid may undergo transamination with pyruvic acid so that alanine is produced and released into the portal blood Thus, some amino acids are not necessarily delivered to the blood in the same form in which they are absorbed In the case of glutamic and aspartic acids, if the absorption rate is slow, practically all the glutamic and aspartic acids undergo transamination to alanine, on the other hand, during rapid absorption, there is less transamination, and considerable quantities of glutamic and aspartic acids appear in the blood (Neame and Wiseman, 1957) It has been suggested that in this way the intestinal mucosa can modify an amino acid mixture that is being absorbed from a particular meal, reducing the amount of amino acids that are in excess in the digesting mixture and increasing the amount of those which are in short supply and so more nearly meet the needs of the organism for specific amino acids

Absorption of Peptides, Proteoses, and Native Protein Many of the intermediate products of protein digestion are soluble in water and some are diffusible Thus, the question naturally arises as to whether peptides, proteoses and peptones may be absorbed from the intestine without being reduced to amino acids Peptone solutions certainly disappear from intestinal loops but this does not prove that the peptone is absorbed as such It will be recalled that the peptidases of the intestinal secretion are believed to be intracellular enzymes, which are not actually secreted, but appear in the intestinal contents as a result of a breakdown of shed epithelial cells It seems unlikely that peptides could get through the mucosal cell in any considerable quantity without being reduced to amino acids by the intracellular peptidases

This same reasoning does not apply to native protein, however, which may have escaped digestion by the pepsin of gastric juice or the proteolytic enzymes of pancreatic juice for one reason or another Except for traces of pepsin in the Brunner's gland secretion, there are no proteases in the intestinal secretion or in the mucosal cells which are known to attack native protein Native proteins are absorbed by the small bowel by a process similar to phagocytosis known as *pinocytosis* The absorption of native proteins by the process of pinocytosis has been demonstrated in the newborn of many mammalian species The ability of the small bowel mucosa to absorb protein in this fashion disappears, however, from a few days to a few weeks after birth, depending upon the species The mechanism is particularly valuable in those species that do not receive a passive immunity from the mother through the placenta In these species, passive immunity is induced by the absorption of immunoglobulins from the colostrum

The adult mucosa, in all mammalian species studied, is very resistant to the absorption of native protein except in antigenic amounts Thus, it is not surprising to find that egg albumin and milk protein can sometimes be demonstrated in the blood by immunological methods after these proteins have been placed in the intestine Absorption of native protein is

not necessarily a result of a pathological condition of the intestinal mucosa, although the absorption may be greatly increased by an inflammatory condition

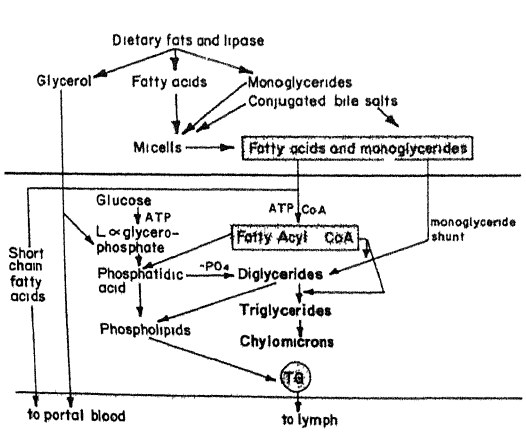
ABSORPTION OF FAT

Dietary fat, consisting mainly of triglycerides, is insoluble in water, yet manages to be absorbed by the intestinal mucosa and appears in the thoracic lymph carried there as chylomicrons To accomplish this transfer, complex physicochemical reactions take place both in the lumen of the gut and in the intestinal columnar cell, in which the dietary triglyceride is hydrolyzed to monoglyceride, fatty acid, and glycerol and resynthesized back to triglyceride In this process, pancreatic lipase and bile salts play critical roles

Lumen Phase In the upper small bowel emulsified triglyceride is acted upon by pancreatic lipase This enzyme acts at the interface between the oil droplet of the triglyceride emulsion and the water phase in which it is suspended The emulsified triglyceride is hydrolyzed at the 1 and 3 position forming 2-monoglyceride and fatty acids

The monoglycerides and fatty acids then in the presence of bile salts form polymolecular aggregates termed "micelles," (already referred to in the section on bile salt formation and secretion) which also contain some cholesterol and phospholipid It is from these micellar aggregations that the lipids penetrate the columnar cell As a result, if the intestinal contents are sampled after a fatty meal, a clear and an oily phase can be distinguished Hofmann and Borgström (1966) have shown that the heavier clear phase contains fatty acids and monoglyceride, while the oily layer contains some di- and triglycerides

Penetration phase. The diameter of the micelle particles varies from 40 to 200 A It is thought that fat in this form is presented to the epithelial surface for absorption The exact mechanism whereby the fatty acids and monoglycerides penetrate the plasma membrane of the microvilli is not known However, the conjugated bile acids in the micellar dispersion are not absorbed in the upper small bowel at the site of the absorption of fatty acids and monoglycerides The conjugated bile acids are turned back to the lumen of the gut and are re-used in the formation of new micelles At present, the mechanism of penetration is presumed to be by diffusion, independent of temperature, and nonenergy requiring, and the available evidence certainly favors diffusion as the primary mechanism



Intracellular phase This phase concerns the re-esterification of fatty acids and monoglycerides to restore triglycerides This is accomplished by the migration of monoglycerides and fatty acids to the endoplasmic reticulum, where fatty acids are activated to the coenzyme A (CoA) derivatives and resynthesized to triglyceride by the acylation of monoglycerides in a multi-enzyme complex

Resynthesis of fatty acids into triglycerides within the epithelial cells has been abundantly confirmed Bergstrom and others (1954) found that when free oleic acid labeled with ^{14}C was fed, 63% of the fed acid was recovered in the lymph as neutral fat When triolein was fed, 65% was recovered in the lymph These authors also found that when fatty acids containing 10 or fewer carbon atoms were fed, they were absorbed by way of the portal blood, where they were transported mainly as free fatty acids Longer-chain fatty acids were synthesized in the epithelial cells into triglycerides and were absorbed by way of the lymphatics Kiyasu, Bloom, and Chaikoff (1952) also found that short-chain fatty acids were transported mainly by the portal pathway and long-chain saturated fatty acids by way of the lymph Therefore, a sort of partition does occur in the intestine

It is now recognized that one of the major functions of the small bowel is the resynthesis of triglycerides from fatty acids and monoglycerides, and packaging them in the form of *chylomicrons* The current state of knowledge regarding the intracellular synthesis of triglycerides has been recently reviewed by Johnson (1968) The synthesis of triglyceride requires energy which is supplied in the form of adenosine triphosphate (ATP) from glycolysis or oxidative phosphorylation In addition, magnesium ions and coenzyme A (CoA) are necessary The fatty acids are first "activated" by the formation of a CoA derivative, which not only makes the fatty acids more reactive, but also water soluble As a result of glucose breakdown, glycerophosphate is formed The glycerophosphate combines with the activated fatty acids to form phosphatidic acid, which after loss of its phosphate group becomes a diglyceride The diglycerides are then esterified further to triglycerides, or converted to phospholipids

These events are shown diagrammatically in Figure 2-45. The direct esterification of absorbed monoglycerides to diglycerides has been suggested, and has been referred to as a "monoglyceride shunt." Senior and Isselbacher (1962) have obtained evidence for the direct esterification of monoglycerides and have demonstrated the presence of a monoglyceride lipase within the epithelial cell. This lipase is distinct from pancreatic lipase and can split β-monoglycerides equally or even more readily than α-monoglycerides. It is relatively inert towards di- and triglycerides. Thus, if activated fatty acids are not available for combining with monoglycerides, the monoglycerides can be hydrolyzed into glycerol and a fatty acid. If the fatty acids are not available for combining with available monoglycerides, the biosynthesis of triglyceride can occur via the α-glycerophosphate pathway. In the resynthesis process, it is now held that the free glycerol liberated in the intestine is available for incorporation.

The final step in the synthesis of triglycerides by the epithelial cells is the formation of chylomicrons for transport in the lymph. The chylomicrons are covered by a fine protein surface coating, amounting to less than 1% of the weight of the chylomicron. While the triglycerides are being synthesized, synthesis of phospholipid and protein is also occurring within the columnar cell, which, in combination with cholesterol esters, forms a β-lipoprotein which is the coating referred to. There is electron microscopic evidence that the chylomicrons are extruded from the lateral margins of the epithelial cells by a process analogous to the pancreatic secretion of zymogen granules. The chylomicrons leave the epithelial cells at about the level of the nucleus, passing into the intercellular spaces. They eventually pass across the basement membrane and into the lymphatic vessels by passage between the endothelial cells.

Short-chained fatty acids absorbed by the epithelial cells are passed to the portal blood for transport to the liver. The fate of glycerol hydrolyzed in the lumen of gut during the process of digestion has been debated. From early isotope studies, Reiser and his co-workers (1952) concluded that glycerol released in the lumen of the gut during the process of digestion was not utilized in the resynthesis of triglycerides within the epithelial cells, but apparently took some other metabolic pathway. Recently, Saunders and Dawson (1962) have demonstrated that, if labeled glycerol is administered with a bile salt-fatty acid mixture, considerable incorporation of the label into lymph triglyceride glycerol occurs. Thus, apparently two sources of glycerol are available to the epithelial cell for the synthesis of triglycerides, that absorbed directly from the intestinal lumen and that available from the conversion of glucose to glycerophosphate. Hogben (1960) has pointed out that the observed absorption of fatty acids against a concentration gradient may be due to differences in pH on each side of the membrane as a consequence of ion transport rather than some "active" process which is specific for fatty acids.

Site of Fat Absorption. Fat absorption takes place most rapidly in the upper intestine, particularly in the duodenum and upper jejunum. In man, Borgström and his associates (1957) have demonstrated that fat absorbed mainly from the upper small bowel-duodenum and proximal jejunum. They fed a measured quantity of fat in a meal containing a nonabsorbable marker, polyethylene glycol, and sampled the intestinal contents at different levels. By comparing the concentration of intraluminal fat to the concentration of polyethylene glycol, they were able to calculate fat absorption at different levels of the small bowel, and found that practically all of the fat had been absorbed by the time the meal had reached the distal jejunum.

Fat absorption is impaired following bilateral adrenalectomy, due to the absence of cortical hormones. The role of the cortical hormones in

fat absorption has not been clarified but it has been suggested that they modulate the enzymes involved in the synthesis of triglycerides in the mucosal cells

ABSORPTION OF CHOLESTEROL

Normally, about a half a gram of cholesterol is consumed each day in the diet This dietary cholesterol is mixed with 2 to 3 g of endogenous cholesterol within the lumen of the small bowel The source of the endogenous cholesterol is the *bile* which may contain cholesterol in the amount of 1 5 to 2 5 g /day, and from *desquamated epithelial cells* which may contain up to half a gram of cholesterol per day Thus, the small bowel normally absorbs $2^1/_2$ to 3 g of cholesterol per day Only about one-fifth or one-sixth of this amount is represented by the dietary cholesterol Borgström (1960) has demonstrated that cholesterol absorption in man occurs at higher rates in the upper small bowel than in the lower small bowel He used a cholesterol labeled with radioactive carbon and determined its rate of disappearance from various levels of the small bowel It has long been known that cholesterol absorption differs from fat absorption in a number of important respects Only 40 to 60% of dietary cholesterol is absorbed, as opposed to the absorption of 95% of dietary fat When radioactive cholesterol is administered as a single dose orally, and the radioactivity of the venous blood is determined, it is found that the peak radioactivity does not appear until 2 to 3 days later (Biggs et al , 1952) When a similar study is done using radioactive fat, peak blood radioactivity is usually found 3 to 4 hr after the oral dose Although cholesterol probably enters the intestinal epithelium at a rate comparable to that of fat, once inside the cell, it is accumulated and released very slowly This accounts for the delay in appearance of labeled cholesterol in the blood

Bile is essential for cholesterol absorption, and pancreatic juice also plays an important role Fats in the diet appear to stimulate cholesterol absorption Vahouny (1958) and coworkers found that optimal absorption of cholesterol occurred from a mixture of fatty acid, taurocholate, and cholesterol Fatty acids markedly stimulate the absorption of cholesterol The stimulatory effect of triglycerides may be due to the fact that they provide a source of fatty acids through the hydrolysis of fat by pancreatic lipase

Most of the cholesterol in the diet is in the form of esters, but in the small bowel these esters are hydrolyzed by a cholesterol esterase present in pancreatic juice Cholesterol esters are not absorbed as readily as free cholesterol However, once absorbed, cholesterol is again esterified, and approximately two-thirds of the cholesterol appearing in the lymph is in the esterified form As dietary cholesterol esters are being hydrolyzed to free cholesterol, dietary triglycerides are being hydrolyzed to monoglycerides and fatty acids Under proper conditions, these substances (bile salts, phospholipids, monoglycerides, and fatty acids) form mixed micelles containing free cholesterol The free cholesterol within the mucosal cell is esterified in major portion and transferred to the lymph along with triglyceride, phospholipids, and protein in the form of chylomicrons Figure 2 46 diagrams the current concept of cholesterol absorption

ABSORPTION OF VITAMINS

The *water soluble vitamins* are assumed to be absorbed by the intestinal mucosa, along with

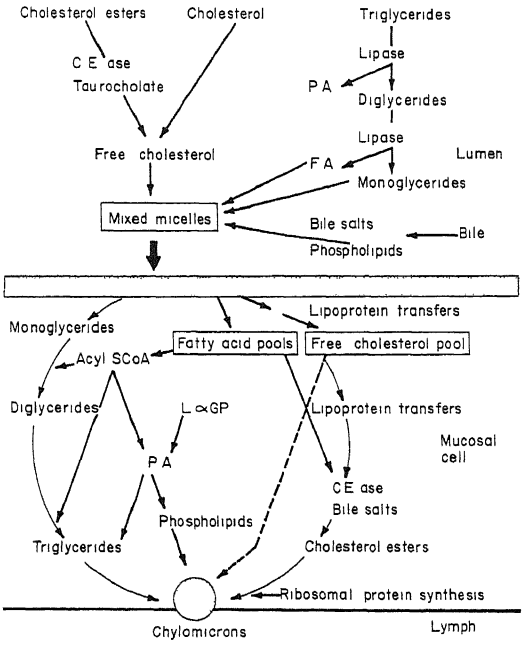


Fig 2 46 Mechanism of cholesterol absorption Abbreviations C E ase cholesterol esterase F A fatty acids Diglyc diglycerides Monoglyc monoglycerides L ∝-GP L-∝-glycerolphosphate P A phosphatidic acid (From Treadwell and Vahouny 1968)

the other constituents of the foods in which they occur by passive diffusion and by the mechanisms which facilitate water movement, but this may not be true for folic acid It is generally believed that thiamin is less readily absorbed by older people than by young people in good health This may be applicable also to some of the other vitamins

Absorption of *fat soluble vitamins*, A D and K, probably takes place under the same conditions as the absorption of fat In any disease or dietary deficiency in which fat absorption is inadequate, the absorption of these vitamins is apt to be impaired This is demonstrated by the deficient absorption of vitamin K in obstructive jaundice A deficiency of this vitamin causes inadequate prothrombin production by the liver and a tendency to hemorrhage This situation is remedied by the parenteral administration of vitamin K Absorption of vitamin E is also said to be impaired in the absence of bile

Vitamin A is absorbed chiefly in the form of esters of the vitamin A alcohol with fatty acids The esters are hydrolyzed in the intestinal lumen but are re-esterified in the epithelial cells This mechanism parallels the one that is operative in the absorption of fat, it is not surprising, therefore, to find that the conditions that favor fat absorption also favor absorption of vitamin A The presence of bile in the intestine apparently is necessary for the absorption of carotene, a precursor of vitamin A, but not for vitamin A itself The absorption of the fat-soluble vitamins is adversely effected by the presence in the intestine of unabsorbable oil, such as mineral oil

Intestinal Absorption of Vitamin B_{12}. Both passive and active mechanisms exist for the absorption of vitamin B_{12} The passive mechanism probably diffusion, occurs throughout the entire small intestine, and is important only in the presence of pharmacological amounts of vitamin B_{12}, whereby approximately 1% of free vitamin B_{12} is absorbed The active mechanism is intrinsic-factor mediated, operative only in the ileum and of primary importance in the absorption of physiological (2 μg or less) amounts of vitamin B_{12} Intrinsic factor (IF) a glycoprotein secreted by the parietal cells of the stomach forms a complex with the free vitamin B_{12} molecule released from food and facilitates the delivery of vitamin B_{12} to specific ileal receptor sites and also protects vitamin B_{12} from intestinal enzymatic degradation and from bacterial utilization The attachment of the IF-B_{12} complex to the ileum requires an intact ileal receptor is pH dependent, and requires the presence of divalent cations (Ca^{++} and/or Mg^{++}) The nature of the IF-B_{12} ileal receptor is unknown but it appears to be particulate and either a glycoprotein or mucopolysaccharide The fate of IF once the IF-B_{12} complex attaches to the ileal mucosal cell is unknown, but most evidence suggests that IF is not absorbed and that the B_{12} is released prior to entering the mucosal cell Little is known of the intracellular pathway of the B_{12} molecule but the actual uptake is temperature, oxygen, and glucose dependent Once vitamin B_{12} traverses the lining of the intestine, it enters the portal blood bound to a carrier serum protein which is distinct from IF

9/MOVEMENTS OF THE ALIMENTARY CANAL

Disturbances of motility of the alimentary canal account for more symptoms of gastroenterological disorders than alterations in absorptive or secretory mechanisms In fact, most of the major diseases of the digestive tract are manifested by a disturbance of motor activity Dysphagia, vomiting, retching, crampy abdominal pain, diarrhea, and constipation are examples of such symptoms

Mastication

The first mechanical process to which the food is subjected in its progress through the alimentary tract is mastication, or chewing, which serves to break down the food particles into smaller masses, to enable the saliva to lubricate and moisten dry food, and to distribute the salivary constituents throughout the food mass The decrease in the size of the food particles is accomplished by the action of the teeth through the movements of the lower jaw The moistening is accomplished by the addition of saliva to the food, and lubrication is due to the mucus secreted by the salivary glands Starch digestion in the mouth by the salivary amylase is unimportant, but the presence of food in the mouth gives rise to stimuli which serve to initiate reflexes that are important in the later stages of digestion

The movements of the lower jaw in chewing are brought about by the muscles of mastication, which include the masseter, the temporal muscles, and the internal and external pterygoid muscles, all of which receive their nerve supply from the mandibular division of the trigeminal nerve The buccinator muscle, which may also be considered a muscle of mastication, is supplied by the facial nerve Through the action of the jaw muscle, the mandible may be moved in any one of several directions Simple closing of the mouth, as in biting or crushing food, is accomplished by the combined action of the masseter and temporal and internal pterygoid muscles Opening the mouth is accomplished by the action of the relatively weak digastric and myloid muscles and is aided by gravity The grinding movements of the molar teeth are accomplished by a rotational movement of the jaw This kind of chewing is accomplished by the alternate contraction of the right and left pterygoid muscles When all four pterygoid muscles contract, protrusion of the jaw results Retraction of the jaw is accomplished by contraction of the posterior fibers of the temporal muscles and the geniohyoid muscles

The force of the bite is limited by the sensitivity of the peridental membrane and not necessarily by the power of the muscles of mastication In man, the molars have been observed to exert a pressure in excess of 270 lb The pressure exerted by the incisor teeth is less, due to the lesser mechanical advantage in this location According to Howell and Manly (1948), pressure exerted by the incisors ranges from 11 to 25 kg These authors found a force of 29 to 90 kg for the molars A dog, when chewing bones, may exert a force as great as 165 kg (Triska, 1924)

Chewing may be carried on voluntarily, but for the most part it is a reflex act The dual nature of the nervous mechanism is indicated by the fact that chewing movements may be elicited by electrical stimulation of appropriate areas of the cerebral cortex

Deglutition

Magendie (1847) described the act of swallowing as occurring in three stages which he described as follows "For the better understanding of the subject we shall divide deglutition into three stages In the first the aliments pass from the mouth into the pharynx, in the second they pass over the opening of the glottis and nasal fossae and arrive at the esophagus, in the third they pass through this canal into the stomach " It is convenient to refer to Magendie's first stage as the oral stage, the second stage as the pharyngeal stage, and the third as the esophageal stage

NEURAL CONTROL

The Swallowing Reflex The first stage of swallowing, like chewing, may be initiated voluntarily but is normally a reflex action The second and third stages of swallowing are entirely involuntary If one wishes to swallow when the mouth is free of food or foreign material, a little saliva is passed backwards by the tongue and thus serves as a mechanical stimulus for the initiation of the second and third phases of the act which are purely reflex If the mouth is kept perfectly free of saliva, deglutition becomes impossible

Like chewing, swallowing may be produced by stimulation of appropriate areas of the cerebral cortex or by stimulation of local receptors, even in the decerebrate preparations The receptors for initiation of the swallowing reflex are situated in the vicinity of the entrance to the oral pharynx in all animals but are distributed somewhat differently in different species

In man, the receptors for the swallowing reflex are distributed in a ringlike fashion around the entrance to the oral pharynx and are found in the mucous membrane covering the anterior and posterior pillars of the fauces, the tonsils, the soft palate, the base of the tongue, and the posterior pharyngeal wall According to Pommerenke (1928), the most sensitive areas in the human are in the vicinity of the anterior and posterior pillars of the fauces and the tonsils

The Swallowing Center Coordination of the numerous somatic and visceral muscles involved in the act of swallowing is controlled by a group of neurons in the floor of the fourth ventricle known as the swallowing center, first described by Markwald in 1889 He found that destruction of the brain substance above and somewhat lateral to the alae cinereae of the medulla eliminates the swallowing reflex while leaving respiration intact Destruction of the alae cinereae stops respiration but does not interfere with swallowing Thus, the swallowing center is closely associated with, although distinct from, the respiratory center This fact is of considerable clinical interest, because in diseases of the medulla, such as bulbar polio or brain tumor, difficulty in swallowing often precedes respiratory failure

Innervation of the Muscles of Deglutition. The efferent nerve fibers involved in the act of swallowing are chiefly in the hypoglossal, glossopharyngeal and vagus nerves. The hypoglossal and glossopharyngeal nerves are chiefly concerned with the buccopharyngeal stage, the vagus with the esophageal stage of swallowing The vagus nerves supply the striped muscle of the esophagus with motor fibers, hence, one of the more serious consequences of cutting the vagi above the origin of the main esophageal branches is interference with swallowing The striped muscle of the esophagus is permanently paralyzed after a high vagotomy (e g , in the neck) but the smooth muscle of the lower third shows some degree of recovery, peristalsis in this portion may return and swallowing may again become possible In animals such as the dog and rabbit in which the entire esophagus is made up of striped muscle, high vagotomy results in permanent inability to swallow Paralysis of the esophagus, with the resultant accumulation of food and liquid in the esophagus and pharynx and associated with the loss of the sensory innervation of the larynx results in the aspiration of food and liquids into the lungs, the animal either suffocates or dies of aspiration pneumonia Aspiration pneumonia is the most common cause of death after a high vagotomy in dogs

The striped muscle is directly innervated by the vagus nerves, the fibers ending on the muscle cells without the intervention of any local ganglion cells In the smooth muscle portion, however, there is an extensive local plexus including nerve cells and their branches similar to the myenteric plexus in other parts of the gastrointestinal tract In this part the vagus fibers do not go to muscle cells but end on nerve cells within the esophageal plexus

THE FIRST OR ORAL STAGE OF SWALLOWING

The first stage of deglutition consists of passage of material through the oral cavity into the pharynx This stage of swallowing is initiated voluntarily With solid food, the act is usually preceded by mastication The movements of the tongue against the hard palate and the cheeks help to form a bolus by moistening and mixing the material with saliva, thus softening and lubricating the bolus for passage through the pharynx and the esophagus After this intraoral preparation, the bolus is maneuvered to a position on the posterodorsal surface of the tongue Bosma (1957) has described this as the "preparatory position," as he has observed that the bolus is always maneuvered to a constant position on the surface of the tongue

With the bolus in the preparatory position, swallowing is initiated The front portion of the tongue is retracted and depressed, the hyoid is elevated slightly, mastication ceases, respiration is inhibited reflexly, and the back portion of the tongue is elevated and retracted against the hard palate This latter action of the tongue is produced principally by the myelohoid, styloglossus and hypoglossus muscles, which force the bolus into the pharynx Intraoral pressures recorded during swallowing have demonstrated that in the anterior part of the mouth near the incisor teeth, negative pressure changes as great as minus 300 cm of water may occur (Miyakawa et al , 1957) In the posterior part of the oral cavity, positive pressure changes occur due to the forceful contraction of the tongue against the hard and soft palates Positive pressures as great as 100 cm of water are not uncommonly recorded in the posterior part of the oral cavity during swallowing (Hightower, 1958)

Disturbances of the first stage of swallowing Disturbances may be caused by a number of conditions Any painful inflammatory process involving the mouth or tongue may make swallowing difficult Neoplasms of the tongue or pharyngeal strictures may obstruct the passage of the bolus into the pharynx Paralysis of the tongue can interfere markedly with swallowing Congenital anomalies of the lips, tongue, and palate are commonly associated with difficulty in initiating the act of swallowing

THE SECOND OR PHARYNGEAL STAGE OF SWALLOWING

The contact of material from the mouth with the pharyngeal and peripharyngeal structures initiate reflexes that complete the second and third stages of deglutition Anesthetization of these structures inhibit the swallowing reflexes The swallowing act, once initiated, is dominant over other functions occurring in this area Thus, respiration and speech are interrupted by the second stage of the swallowing act The complexity of the act, and the high degree of integration necessary, is appreciated when one recalls the timed sequence of events in this stage of deglutition and that the second stage is completed in less than 1 sec

Understanding of the second stage of swallowing will be easier if we keep in mind the fact that the alimentary tract crosses the respiratory tract in the region of the pharynx, so the swallowing movements have to serve two quite different functions one, to propel the food through the pharynx and into the esophagus, and the other, to protect the airway, both above and below, from the possible entrance of food particles Although the propulsive and protective mechanisms operate simultaneously it is simpler to describe them separately

When the bolus reaches the base of the tongue, its movement is accelerated by a rapid downward and backward movement of the tongue which takes place at the same time as the forward movement of the larynx With the entrace of the bolus into the larynx, contraction of the superior pharyngeal constrictor occurs, initiating a rapid pharyngeal peristaltic wave which moves down the pharynx, propelling the bolus in front of it The walls and structures of the hypopharynx are elevated to engulf the oncoming bolus The cricopharyngeus muscle, which has kept the esophagus closed until now, relaxes as the bolus approaches and allows it to enter the upper esophagus The peristaltic contraction continues into the esophagus to become the primary esophageal peristaltic contraction

As a result of the combined forces acting on it, the bolus moves with such speed that it is often projected deep into the esophagus Rushmer and Hendron (1951) using cinefluoroscopy to study pharyngeal transport, observed that a bolus approached the pharynx with the velocity of 9 ft /sec , passing through the pharynx, it attained a velocity of 19½ ft , 24 ft , and 28½ ft /sec in successive frames, then slowed to 12 ft /sec , and finally to 5 ft /sec as it passed into the esophagus. These data were obtained with the subject in a horizontal position, in the erect position, the bolus moved even faster

We must now consider how the airway is protected while the food is passing the pharyngeal crossroads It will be recalled that there are four possible outlets from the oral pharynx through which food may be expelled These are back into the mouth, up into the nasopharynx, forward into the larynx, and downward into the esophagus The swallowing reflex has to be so coordinated that the food takes only one of these possible paths, namely, into the esophagus Return into the mouth is prevented by the position of the tongue against the roof of the mouth and the high pressure developed in this area Passage into the nasopharynx is normally prevented by the combined action of the tensor veli palatini and the levator veli palatini

muscles which together stiffen the soft palate and cause it to press against the posterior pharyngeal wall. It thus forms a protective partition between the oral pharynx and the nasopharynx. If these muscles are paralyzed or if there should be a defect in the soft palate, food enters the nasopharynx and swallowing becomes extremely difficult or impossible. An important factor in preventing entrance of food into the respiratory tract during swallowing is the inhibition of respiration which occurs during the second stage of swallowing (Magendie, 1847).

The laryngeal opening is closed during the act of swallowing by the approximation of both the true and false vocal cords. In addition, the epiglottis serves to divert the oncoming bolus to one side or the other of the larynx. Only when liquid is being swallowed in considerable volume does the swallowed material cascade over the end of the epiglottis. Most observers agree that the epiglottis is carried into a horizontal position by the backward movement of the tongue and the forward movement of the larynx. This same combination of movements results in the larynx being drawn up under the base of the tongue where it is completely out of the way of the oncoming bolus.

Disturbances of the second stage of swallowing. Disturbances of the second stage of swallowing are not unusual. Acute pharyngitis is probably the most common cause of painful dysphagia of the second stage of swallowing. Tonsillitis is another example. Pharyngeal paralysis is indicative of serious neurological disease and dysphagia developing in poliomyelitis, syringomyelia, multiple sclerosis, or after a cerebrovascular hemorrhage points to bulbar involvement. In these patients, it may be impossible for the soft palate to be elevated, thus allowing liquids to be regurgitated through the nose. The pharyngeal constrictions may be unable to initiate the peristaltic contraction which empties the contents of the pharynx into the esophagus. Cranial nerve (glossopharyngeal) neuritis also may result in pharyngeal paralysis. Diptheria is sometimes followed by palatine and pharyngeal paralysis.

Mobility of the larynx is essential to the second stage of deglutition. Any disease process that prevents the larynx from ascending to lie beneath the base of the tongue causes marked dysphagia. Neoplasms, such as carcinoma of the larynx and thyroid, and infectious conditions, such as tuberculosis and syphilis, may result in fixation of the larynx, thus making swallowing extremely difficult.

THE THIRD OR ESOPHAGEAL STAGE OF SWALLOWING

At the junction of the esophagus with the pharynx above and with the stomach below, there exist physiological sphincteric mechanisms that effectively maintain and separate the slightly negative intraluminal pressure of the esophagus from the positive pressures of the pharynx and stomach. Except during deglutition these esophageal sphincters are normally closed and prevent the aspiration of air from above, or gastric juice from below, into the esophagus. They respond to deglutition by first relaxing and then contracting in a sequential manner with the primary peristaltic wave as it passes over these junctional zones. In describing the third stage of deglutition, the motor activity of the esophageal sphincters will be considered separate from that of the body of the esophagus.

The Upper Esophageal Sphincter. The pharyngeal junction is characterized by a short zone of high-resting intraluminal pressure in the region of the inferior pharyngeal constricture or cricopharyngeus muscle at the level of the cricoid cartilage (Fyke and Code, 1955). The circular muscle fibers in this area remain in a stage of tonic contraction, producing this zone of high-resting intraluminal pressure, and effectively separating the pharyngeal and esophageal luminae. The zone is approximately 4 cm in length and usually is located between 15 and 20 cm from the incisor teeth. The basal-resting pressure in the high pressure zone varies from 20 to 30 cm of water above atmospheric pressure (Fig. 2.47).

When intraluminal pressures are recorded from the upper esophageal sphincter during deglutition, the pattern of pressure change is distinctly different from that recorded from the pharynx or upper esophagus (Fig. 2.48). Immediately after the onset of deglutition, usually within 0.5 sec, a brief increase in the high resting pressure first occurs, but this lasts only a few tenths of a second, to be followed by a marked decrease in pressure below the resting basal pressure, and usually negative in comparison with atmospheric pressure. The decrease in pressure in the pharyngoesophageal junction occurs almost simultaneously with the increase

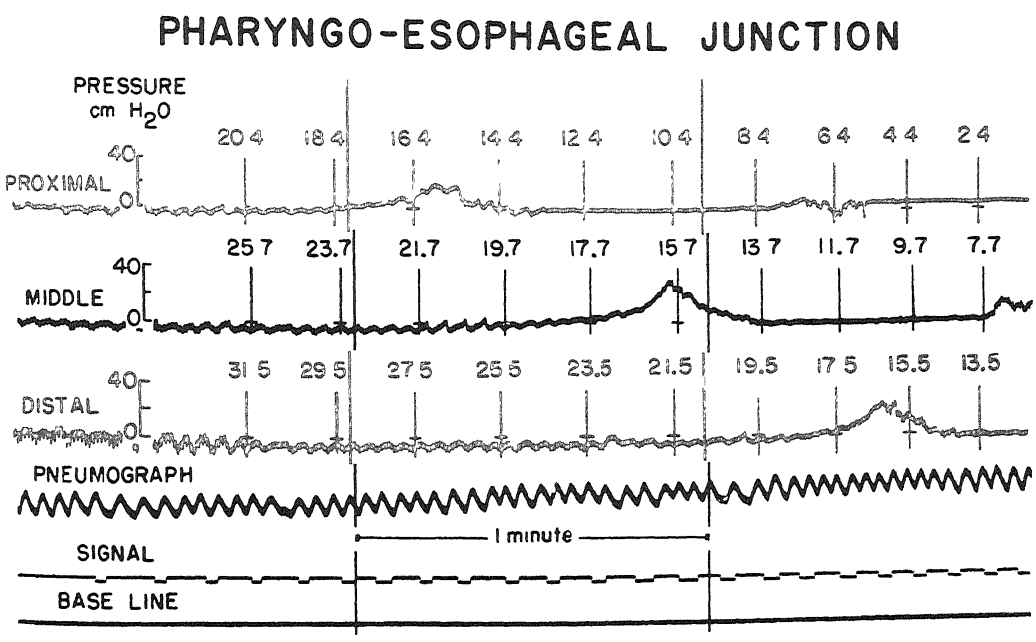

Fig 2 47 Demonstration of the zone of high pressure at the pharyngoesophageal junction The catheters were placed in the esophagus and slowly withdrawn through the upper esophageal sphincter while recording pressure continuously Each centimeter of withdrawal is indicated by the signal and the vertical lines indicate the distance in centimeters from the incisor teeth to the tip of each catheter The pull through technique clearly demonstrates the negative basal pressure in the esophagus and the zone of high pressure extending from 14 to 17 cm in the upper esophageal sphincter (From Hightower 1958)

in pressure in the pharynx produced by the peristaltic wave resulting from the contraction of the superior and middle pharyngeal constrictors These events markedly increase the pressure gradient from the pharynx across the upper esophageal sphincter With the arrival of the swallowed bolus at the pharyngoesophageal junction, the previously relaxed fibers of the upper sphincter contract and propagate the peristaltic contraction and pressure gradient into the upper esophagus

The small initial positive pressure wave observed in the pharyngoesophageal junction with deglutition may be due to an increase in the tonic contraction of circular fibers of the cricopharyngeus muscle, or it may be related to the elevation of the larynx and increased tension in this area The duration of the negative component of the junctional pressure pattern of deglutition is usually 0 7 to 1 0 sec , after which time the pressure has returned to the previous basal level The pressure continues upward, however, and a positive pressure wave, forming the third component of the pattern is observed This positive pressure wave represents a continuation of the pharyngeal peristalsis through the pharyngoesophageal junction The maximum

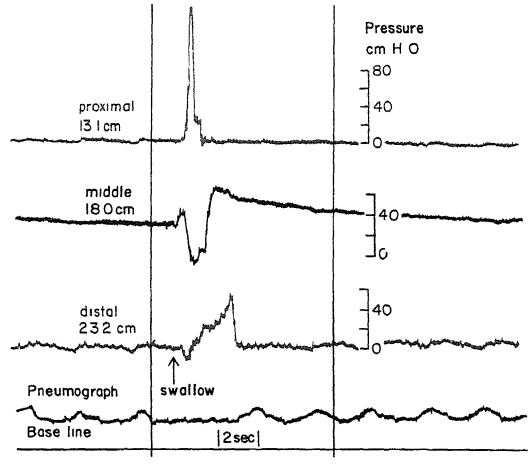

Fig 2 48 Pressure changes in the upper esophageal sphincter during deglutition The proximal catheter is recording pressure from the lower pharynx the middle one from the sphincteric area and the distal one from the upper esophagus The sequential appearance of peak pressures in each complex from above downward indicates the passage of the peristaltic contraction from the pharynx over the pharyngoesophageal junction into the upper esophagus (From Hightower 1958)

pressure produced by this wave is usually 70 to 90 cm of water above atmospheric pressure The pressure within the junctional zone then

returns to its previous basal level within 3 to 4 sec

Motility of the Body of the Esophagus

Primary peristaltic contractions previously described as originating in the pharynx and passing over the pharyngoesophageal junction continue into the esophagus sweeping the bolus onward and maintaining the pressure gradient The pressure pattern consists of an initial negative wave followed by three positive pressure components (Fig 2 49) The initial negative component is of brief duration and occurs immediately after the onset of deglutition It is observed more frequently in the upper than in the lower esophagus, and is thought to be due to the sudden stretching of the closed esophagus by elevation of the larynx The negative component is followed by an abrupt increase in pressure of 10 to 15 cm of water The third component consists of a slowly increasing positive pressure change or else a plateau of positive pressure is maintained The fourth and most prominent component of the deglutition pressure pattern is a large, simple, monophasic positive pressure wave that rises rapidly to a peak pressure and declines with equal speed The abrupt rise in intraluminal pressure following the initial negative component has been attributed to the sudden injection of the bolus or liquid into the esophagus, as it is observed to occur simultaneously at different levels of the esophagus The gradual increasing or plateau of pressure is related to the approaching peristaltic contraction Its duration and time is directly proportional to the depth of the recording catheter in the esophagus The large monophasic positive pressure wave that terminates the complex is recorded as the peris

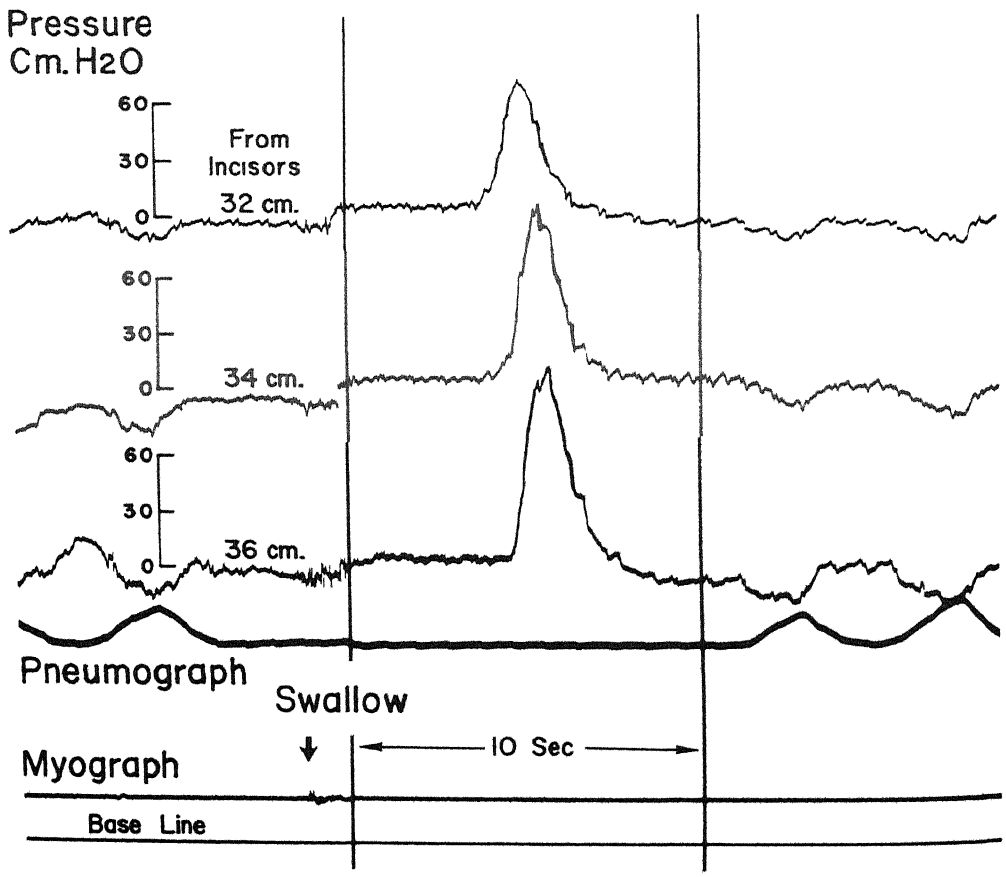

Fig. 2 49. Normal deglutition pressure complexes recorded from the lower esophagus See text for detailed description. The pneumograph is recording respiration Note that respiration was voluntarily stopped at end expiration a few seconds prior to deglutition The myograph records the action potentials of the accessory muscles of deglutition in the neck and indicates the precise onset of swallowing

taltic contraction passes over the open tip of the catheter

In man, the *rate of propagation* of the primary peristaltic contraction has been determined with the subjects in the horizontal position (Hightower and Salem, 1958) The time required for the primary esophageal peristaltic contraction to traverse the entire esophagus is from 8 to 12 sec As the peristaltic wave descends the esophagus, its rate of propagation becomes progressively slower It has been found that the rate of propagation of a primary contraction is quite rapid in the pharynx and upper esophagus Soon after it is initiated, it is traveling at a rate of approximately 50 cm /sec The rate rapidly decreases, however, as shown in Figure 2 50 When the peristaltic wave has traveled to a level 25 to 30 cm from the incisor teeth, its speed has decreased to about only 3 cm /sec For some unknown reason, the rate then increases slightly as the contraction ring approaches the esophagogastric junction After reaching the esophagogastric junction, the rate markedly decreases again until it is moving at less than 1 cm /sec

In the upright position, liquids travel through the esophagus at a speed that greatly exceeds the rate of propagation of the primary peristaltic wave This rapid transport is considered to be due to the propelling force created by the contraction of the pharyngeal constrictors during the second stage of deglutition, as well as by the action of gravity upon the swallowed liquid In the pharynx, near the end of the second stage of deglutition, pharyngeal pressure is mounting due to contraction of the pharyngeal constrictors and when the cricopharyngeus muscle suddenly relaxes and opens the upper end of the esophagus, which has a negative intraluminal pressure, the liquid is then more or less squirted into the lumen of the esophagus In the upright position, the rapid passage of liquid through the esophagus requires only a second or two Fluoroscopy demonstrates that swallowed liquids usually are arrested at the lower end of the esophagus and await the arrival of the peristaltic contraction before they are admitted into the stomach At times, however, when a series of swallows occurs rapidly, as when drinking a glass of water, the liquid may pass on through the esophagogastric junction with little pause and enter the stomach within a second or two after drinking has begun

Secondary peristaltic contractions are also observed in the esophagus These contractions arise locally as a result of distention, and progress down the esophagus in a manner similar to the primary contraction Secondary peristaltic contractions produce a pressure wave similar to the final pressure wave of the deluti tion pressure pattern It is a simple monophasic positive pressure wave that rises rapidly to a peak then returns promptly to the base line Secondary waves are usually of less amplitude than primary waves In the normal esophagus, secondary peristaltic contractions may be caused by local distention by fluid or a solid bolus If the primary wave is unable to propel the swallowed material, secondary contractions originate and complete the transport of the substance

Tertiary esophageal contractions also have been observed in the esophagus These contractions occur irregularly and locally, and are observed most frequently in the lower esophagus in elderly individuals They are not peristaltic

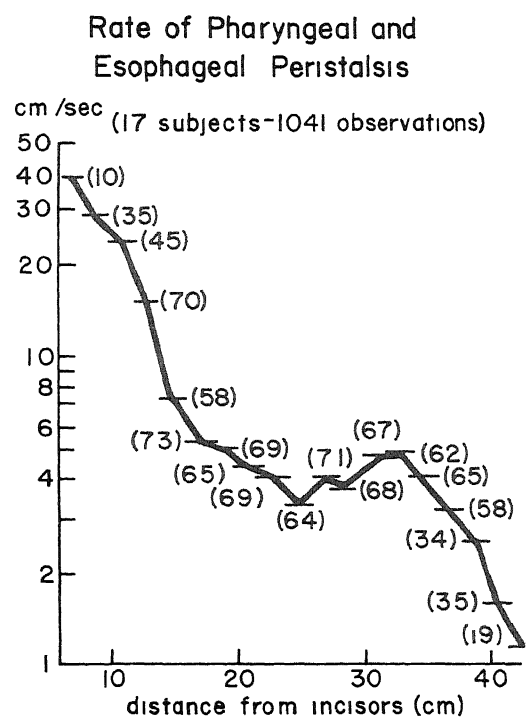

Fig 2 50 The rate of propagation of primary peristaltic contractions in the pharynx and esophagus as determined in 17 healthy adults The number of observations at each level is indicated in parentheses The short horizontal line indicates the distance over which the groups of observations were made

Their function is not known. Roentgenologically, they may produce a varied picture with a serrated or beaded appearance or like multiple diverticula-like pockets. The roentgenological picture of tertiary contractions has been referred to as "curling" and the "corkscrew esophagus." Lerche (1950) has suggested that contraction of the spiral muscular coat of the lower esophagus accounts for the tertiary contractions.

The Lower Esophageal Sphincter. Probably no other area of the alimentary canal has caused more confusion and diverse opinion than the terminal few centimeters of the esophagus. Only within the past few years have anatomists, physiologists, radiologists and endoscopists been able to reach some common agreement and understanding of the structure and function of the esophagogastric junction. It was Lerche's (1950) classic studies correlating anatomic and radiological observations that stimulated reinvestigation of this area. Sanchez, Kramer, and Ingelfinger (1953) demonstrated that the distal 2 to 5 cm. of the esophagus has a characteristic motor function. They found that the characteristic deglutition pressure pattern observed in the upper esophagus was not propagated into the vestibule. In addition, these same authors later demonstrated that the body of the esophagus and the vestibule react inversely to cholinergic and anticholinergic stimulation (Ingelfinger et al., 1954).

Fyke, Code, and Schlegel (1956) explored the esophagogastric junction of normal persons with a miniature pressure transducer and found a zone of high pressure similar to that encountered at the pharyngoesophageal junction. The high pressure zone extended from about 1 to 2 cm. below the hiatus of the diaphragm to 1 to 2 cm. above the hiatus. The mean resting maximum pressures in this region, expressed as centimeters of water above the pressure in the fundus of the stomach, were 10.7 at the end of expiration, and 3.5 at the end of inspiration.

As the peristaltic contraction approaches the lower esophagus, the deglutition pressure complex changes slightly as it reaches the slightly dilated or bulbar portion of the terminal part of the body of the esophagus known as the ampulla. The complex is more prolonged due to the slowing of the rate of propagation of the peristaltic contraction, and the large positive pressure wave terminating the complex tends to decrease in amplitude.

With deglutition, the high basal pressure that exists in the esophagogastric junction decreases to form a slow negative wave of 7 to 10 sec. duration. This decrease in pressure occurs while pressure is increasing in the lower esophagus, thus greatly extending the pressure gradient from the lower esophagus to the esophagogastric junction. The slow decline in pressure is followed by an equally slow increase to form a smooth negative pressure wave. This is continued into a similar slow positive pressure wave which appears to occur in sequence with the peristaltic pressure wave of the lower esophagus. The high pressure zone of the esophagogastric junction extends slightly above and below the diaphragmatic hiatus, and pressure changes due to deglutition are similar in each part but are of less magnitude when recorded from the segment below the diaphragm than from that part located just above the diaphragm.

The lower esophageal sphincter thus relaxes reflexly, as does the cricopharyngeus muscle at the pharyngoesophageal junction, allowing esophageal contents to be emptied into the sphincteric area by the progressing high pressure gradient between the lower esophagus and the sphincter segment. The sphincter then contracts slowly with higher pressures in the part of the segment above the diaphragm than in that below. This provides for emptying of the sphincteric segment into the stomach. The motor function of the lower esophageal sphincter is distinct and separate from that of the body of the esophagus, however, the relaxation and contraction of this sphincteric segment in sequence with the advancing peristaltic contraction permits esophageal emptying into the stomach.

It has been demonstrated recently that the lower esophageal sphincter is under the humoral control of both gastrin and secretin. When small amounts of gastrin are administered intravenously or when the antrum is alkalinized to release endogenous gastrin, the lower esophageal sphincter markedly increases its tone. Secretin has the opposite effect. Pure intravenous secretin or acidification of the duodenum to release endogenous secretin causes a significant decrease in intrasphincteric resting pressure. When gastrin is released to produce high rates of HCl secretion, its effects on the lower esophageal sphincter thus helps prevent reflux of the acid contents of the stomach into the esophagus.

Disturbances of Esophageal Motility. Dis

turbances of esophageal motility usually result in dysphagia, or difficulty in swallowing, which may, or may not, be associated with pain Some of the more common causes of dysphagia will be discussed briefly

Diffuse spasm of the esophagus produces dysphagia which characteristically occurs intermittently and is associated with pain In this disorder, the esophageal musculature appears to be hypersensitive to the stimuli produced by deglutition and also by local distention Following deglutition, long segments of the esophagus may go into a marked spasm, which produces severe substernal pain When esophageal intraluminal pressures are measured in these patients, deglutition may result in a marked distortion of the normal pattern Intraluminal pressure may exceed 300 cm of water pressure

Achalasia results in a progressive dysphagia from an inability of the lower esophageal sphincter to relax reflexly in response to deglutition In this disorder, the primary peristaltic contractions originate in the pharynx in a normal manner, but when they have reached a level of the upper esophagus, they become ineffective, weak, and finally fade away Secondary contractions often occur due to the local distention by retained foods and secretions, but once initiated, these contractions move purposelessly up and down the esophagus for a short distance, then they too disappear Without normal propagation of peristaltic contractions, little intraluminal pressure gradient is created and esophageal transport is markedly retarded As the normal motor function progressively fails, the retention of solid foods, liquids, and secretions occur, and this leads to marked dilatation and elongation of the esophagus

Numerous investigators have demonstrated a marked degeneration of Auerbach's plexus, especially in the lower parts of the esophagus in patients with achalasia The cause of the degeneration of the myenteric plexus is unknown The unusual sensitivity of the esophagus in patients with achalasia to mecholyl supports the pathological findings that achalasia is due to a disorder of the intrinsic nerve plexuses When mecholyl is administered subcutaneously in small doses of only 1 or 2 mg , the esophagus responds by going into marked spasm (Kramer and Ingelfinger, 1951, Hightower, et al , 1954) The response to mecholyl has been used as a diagnostic test in establishing the diagnosis of achalasia

Scleroderma is an example of a systemic disease that may produce dysphagia by interference with the third stage of deglutition The primary disorder of esophageal motility is the defective propagation of the primary peristaltic contraction due to a myogenic failure Also, there is rather marked loss of muscular tone in the esophageal wall As in achalasia, scleroderma involves most of the esophagus, and is not confined to any particular segment, although changes are usually more evident in the lower esophagus

Few deglutition pressure complexes reach the lower esophagus and those that do are usually at low amplitude The esophagogastric junction is also involved in this disease, with a loss of the normal high pressure zone With the loss of the pressure barrier between the esophagus and the stomach, gastroesophageal reflux is a common finding Mecholyl does not increase esophageal intraluminal pressure in patients with scleroderma, as is observed in patients with achalasia

Hiatus hernia is a very common disorder that may produce dysphagia due to the anatomical alterations of the normal esophagogastric junction In these patients, the esophagogastric junction is displaced upward out of the diaphragmatic hiatus into the chest When the esophagogastric junction is displaced into the chest, the high pressure zone is decreased and reflux from the herniated portion of the stomach above the diaphragm into the esophagus is a common finding Some degree of peptic esophagitis is not at all uncommon and this probably accounts for the increased irritability and spontaneous contractions frequently observed in pressure records of the esophagus in patients with hiatal hernia

Chalasia is a term applied to a relaxed esophagogastric junction, the esophagogastric junction is not displaced out of the diaphragmatic hiatus as in hiatal hernia, but there is a decreased high pressure zone within the lower esophageal sphincter This permits frequent gastroesophageal reflux This condition is usually seen in infants but it may occur in adults

Obstruction of the esophagus due to *neoplasm* or *stricture* is a common cause of dysphagia In the case of neoplasms, dysphagia develops slowly but becomes progressively worse Difficulty is usually first noticed with solid foods, and later with liquids The patient will complain that foods "stick" or "hang-up" in the esophagus, and usually he can point to a

site that indicates the level of the lesion Strictures of the esophagus in children are frequently due to drinking caustic solutions

HEARTBURN AND BELCHING

Heartburn is a painful sensation located retrosternally in the midline between the xiphoid process and the manubrium Its duration is variable and it may radiate to the upper abdomen the anterior chest wall, the jaws and even into the arms Heartburn is frequently experienced by patients with hiatal hernia and occurs during the second half of pregnancy in approximately 50% of cases

Tuttle, Bettarello, and Grossman (1961) measured intra-esophageal pH in patients who complained of heartburn not associated with belching, and found that the heartburn was associated with a drop in pH to below 4 0 in the lower esophagus There was no evidence of disturbed esophageal motility when heartburn was induced by instilling hydrochloric acid into the stomach Siegel and Hendrix (1961), on the other hand, found pain and abnormal esophageal motility to occur at the same time when they perfused acid into the esophagus of patients with esophagitis The cause of "heartburn" is still not completely understood In patients with esophagitis, the instillation of a number of noxious substances into the esophagus may cause the distress Abnormal esophageal motility may or may not be associated with heartburn

Belching The tendency, after a meal, for small amounts of gas to be expelled from the stomach into the esophagus and mouth is experienced by most normal persons The gas in these instances is, as a rule, simply air which has been previously swallowed and it has the composition of atmospheric air Aerophagia is seen in the nervous type of subject, or in one who has some gastric discomfort, he resorts to the air swallowing trick in an effort to gain relief

In a study of the mechanism of belching (McNally, Kelley, and Ingelfinger, 1964), radiological and pressure recordings were made during the distention of the human stomach with air Pressures were recorded from both the esophagus and the stomach As the stomach was slowly distended with air there was an initial increase in intragastric pressure of 2 to 6 mm of Hg., but no further increase occurred, even when up to 1600 ml of air was introduced Within 3 min after the stomach had been distended with air they observed that sudden equalizations of gastric and esophageal pressures took place at inconstant and intermittent intervals in their subjects Cineradiography showed that the sudden equalization of gastric and esophageal pressures was associated with escape of air from the stomach into the esophagus Usually within 6 to 10 sec , a secondary esophageal peristaltic wave occurred, returned the refluxed air to the stomach, and reestablished the esophagogastric barrier The authors referred to this as "simple reflux"

Pressure changes associated with belching were different from those observed during simple reflux When belching occurred, a simultaneous pressure spike was recorded from the stomach and the esophagus in all subjects The pressure spike and the associated belching were superimposed on the pattern of simple reflux After the belch, the intraesophageal pressure remained elevated and identical with intragastric pressure for 6 to 10 sec , until secondary esophageal peristalsis emptied into the esophagus and returned esophageal and gastric pressure to their control level

Gastric Motility

Before attempting to describe the movements of the stomach, it is desirable to define the anatomical terms that will be used (Fig 2 51) The stomach consists of a *fundus*, a *body*, and a *pyloric portion* (antrum) The fundus is that portion of the stomach which, in the human in the upright position, lies above a horizontal plane passing through the esophageal opening The body of the stomach (corpus ventriculi) extends from the fundus to the *incisura angularis* on the lesser curvature, and to a corresponding notch on the greater curvature The incisura is a conspicuous notch on the lesser curvature, which serves not only to separate the anatomical divisions of the stomach, but also marks the position of a band of smooth muscle which has a higher degree of tonus than most of the remainder of the gastric muscle and causes a narrowing of the gastric lumen at this point The pyloric portion (pars pylorica) extends from the incisura angularis in the lesser curvature, and the corresponding notch on the greater curvature, to the junction of the stomach with the duodenum The pyloric portion differs from the remainder of the stomach in having much heavier musculature

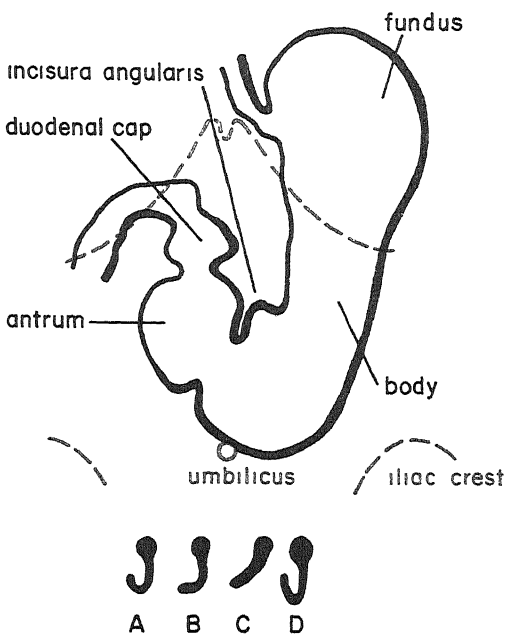

Fig 2 51 Diagram showing the position and subdivisions of the stomach *A B* and *C* represent *J* reversed *L* and steer horn types of stomach respectively *D* stomach of the J-shaped type with the greater curvature lying well below the level of the umbilicus Antrum is also known as the vestibule

The cardia is simply the esophageal orifice, that is, the opening between the esophagus and the stomach Properly speaking, it refers to no anatomical structure, nevertheless, the term is often used to refer to the entire region of the stomach surrounding the cardia, and in that sense it includes the mucous membrane and muscle in the immediate vicinity of the orifice

The pylorus is the opening between the stomach and duodenum and, like the cardia, refers to no anatomical structure However, the term is often used to designate the pyloric portion of the stomach Likewise, the pyloric sphincter is sometimes referred to as the pylorus These usages are incorrect and often give rise to misunderstandings The lumen of the pyloric portion may be divided into an antrum and a pyloric canal The separation between these two portions is marked by a sulcus intermedius when this is present The portion to the right of the sulcus is known as the pyloric canal, and the portion to the left as the pyloric antrum The antrum is not a structure but a space, nevertheless, the entire pyloric portion is often called the antrum in clinical literature

THE PERIODIC ACTIVITY OF THE EMPTY STOMACH

The smooth muscle of the stomach is seldom completely inactive, but its activity increases during gastric digestion and periodically when the stomach is empty

Types of Contractions Carlson (1913) recognized three types of contractions in the empty stomach

Type I occurs when the tone of the stomach is feeble It consists of single contractions superimposed on a low tone level The tonus of the stomach does not rise between contractions and there is always an interval of time between the end of one contraction and the beginning of the next Each contraction lasts for about 20 sec and the interval between contractions is from ½ sec to 3 or 4 sec When recorded by means of a small balloon in the antrum, type I contractions produce a pressure change of approximately 5 cm of water (Hightower and Code, 1950) They occur in both rhythmic and nonrhythmic patterns When present rhythmically and recorded from the antrum, their rate is constant at 3/min Carlson (1912) referred to this as the "20-second rhythm " It is felt that the type I waves of the stomach represent a "mixing" type of motor activity One gets the impression from balloon-kymographic records, and also from fluoroscopic observations, that this type of motor activity represents a kneading of the gastric contents

Type II contractions occur when the tonus of the stomach is strong Cannon (1911a) referred to these as "hunger" contractions There may be no intervening pause between the contractions and each lasts for 20 sec Type II contractions may occur also in a nonrhythmic pattern, and when they do, their duration is more variable, ranging from 12 to 25 sec Pressure changes produced by these contractions usually range from 10 to 50 cm of water, although at times pressures of 100 cm of water are observed Type II gastric contractions represent peristalsis In the antrum, this type of motor activity creates the pressure gradient that effects gastric evacuation into the duodenum

Type III gastric contractions have been described as an "incomplete tetanus " They are usually observed at the end of a period of gastric motor activity and are followed by a period of quiescence They occur rarely in man and seldom make up more than 1% of the activity observed in motility records The type III con-

traction is recorded as an increase in basal pressure lasting 1 to 5 min with rhythmic type II contractions superimposed upon the increase in basal pressure From a functional standpoint, it is thought that this type of motor activity represents a change in tonus or decrease in diameter of the lumen The increase in the basal pressure observed during a type III contraction is usually less than 10 to 15 cm of water

When recorded from man, after an overnight fast, antral gastric motility records show that some type of activity is present approximately 40% of the time and this activity is broken down as follows type I contractions about 25%, type II about 15%, and type III 1% during the period of observation Examples of the three types of gastric contractions are illustrated in Fig 2 52

DIGESTIVE PERISTALSIS

As soon as food is taken, the "hunger" contractions cease, and after a variable period of time, they are replaced by digestive peristalsis The outstanding characteristic of this type of gastric peristalsis is the constancy of its rhythm When the stomach contains food, peristaltic waves occur regularly, at a frequency of about 3/min in the human, 4/min in the dog, and about 5/min in the cat Each wave begins as a slight circular constriction of some part of the body of the stomach The exact point of origin varies with conditions, one of which is the amount of food in the stomach The contraction appears in the x-ray silhouette as a slight indentation on the greater and lesser curvatures which travels toward the pylorus, becoming deeper meanwhile, until it finally ends with a contraction of the pyloric sphincter

A peristaltic wave takes 1 min , more or less, to travel from its point of origin to the pylorus Since there are three waves per minute, the stomach will usually be occupied by three waves at one time, or by four or more if the origin is near the fundus (Fig 2 53) If the origin is low, only one or two may be seen

During digestion, the body and fundus of the stomach, which serve the reservoir function primarily, behave quite differently from the pyloric portion (which serves mainly the function of mechanical digestion and propulsion) The muscle of the body and fundus are relatively thin and participate to only a moderate extent in visible peristalsis It is this portion of the stomach that undergoes the greatest changes in size and shape, accommodating itself through changes in tonus to the volume of its contents

ELECTRICAL ACTIVITY OF THE STOMACH

When electrodes are placed on the muscle layers of the wall of the stomach, a rhythmic, cyclical, electrical potential charge can be recorded When multiple electrodes are placed in the long axis of the stomach it can be determined that the electrical activity is propagated from the fundus to the pylorus This cyclical potential charge is due to periodic depolarization of the cells making up the muscle layers in the wall of the stomach and has been termed "basic electrical rhythm" (BER) or "pace setting potential" (PSP) (Code and Carlson, 1968) The exact site of the "pacemaker" is not known but is presumed to be in the fundus near the cardia The basic electrical rhythm of the stomach is omnipresent, whether or not contractions of the wall of the stomach are present The cyclical rate of the potential change is exactly the same as the maximal rate of type I and type II contractions, i e , 3/min in the antrum of man When type I or type II contractions occur, a spike or burst of fast electrical activity occurs which is superimposed upon a cycle of BER In dogs, the rate of conduction of the BER at the junction of the antrum and body of the stomach is about 0 5

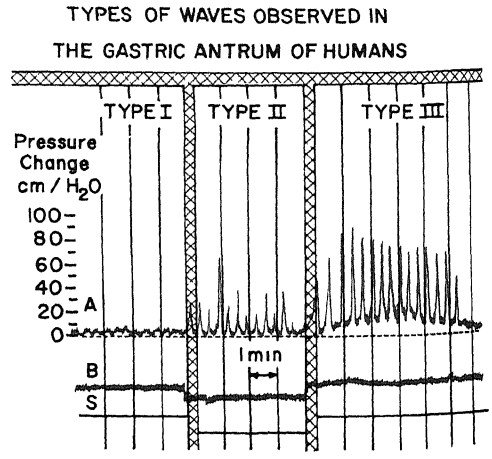

Fig 2 52 Types of antral motility recorded from normal human being Note that the rhythmic rate of type I and type II waves is identical at 3/min The type III complex consists of a rise in basal pressure on which is superimposed rhythmic type II waves (From Code et al 1952)

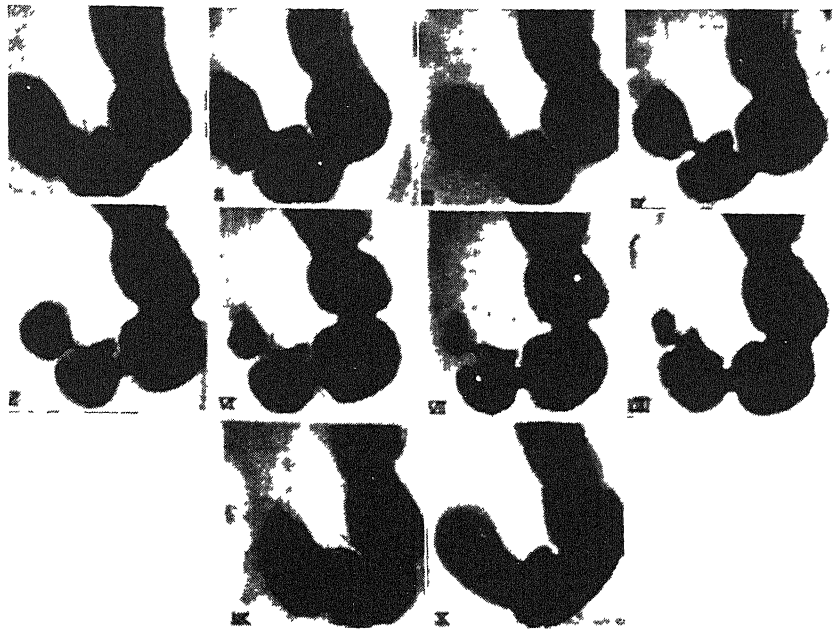

Fig 2 53 Serial x-ray photographs of human stomach taken at 2-sec intervals during digestion (From Cole 1917)

cm /sec , while in the distal antrum, the rate is 2 to 4 cm /sec Thus, conduction is increased as the pylorus is approached

THE GASTRODUODENAL PRESSURE CYCLE

When a peristaltic wave approaches the pylorus, the antral pressure increases, usually to between 15 and 30 cm of water, followed by an increase in bulbar pressure However, the bulbar pressure rises more rapidly than the antral pressure, so that the two reach their peaks simultaneously, after which they both fall again to basal levels This cycle is repeated, with only quantitative variations, with each gastric cycle Contraction of the pyloric sphincter usually begins near the start of the rise in bulbar pressure but outlasts the increase in bulbar pressure

In fluoroscopic studies, passage of gastric contents through the pylorus could be seen to begin as the antral wave approached the pylorus but before the elevation in antral pressure could be detected Evacuation continued through the early part of the rise in antral pressure but ceased some time during the succeeding rise in bulbar pressure (and the sphincteric contraction) Consequently, the time during which gastric contents could be seen passing into the duodenum could be divided into two distinct but continuous phases, one, during which only basal pressures served as a driving force and resistance at the pylorus was low (designated evacuation period "A"), and another during which the antral pressure substantially exceeded the duodenal pressure and the pyloric resistance was rising (called evacuation period "B" (Quigley, 1943, Quigley and Brody, 1950) (See Fig 2 54)

GASTRIC FILLING

It is possible to determine how solid or semisolid food arranges itself within the stomach of an animal by marking successive portions of the food with dyes or pigments so that they can be identified later After the stomach is filled, the animal is killed, and the stomach removed and frozen, or otherwise fixed, and sectioned In this way it has been found that the first food eaten lies against the greater curvature in the body and fundus of the stomach Successive layers lie progressively nearer the lesser curvature until the last portion eaten is near the upper end of the lesser curvature in the vicinity of the cardiac orifice Liquids, on the other hand, tend to remain near the lesser curvature of the stomach and to flow toward the pylorus along a V-shaped groove formed by the muscle in this region This is the so-called *Magenstrasse* which is evident in some animals, but less so in the human In any case, if a large

volume of liquid is swallowed, it flows around the food mass and tends to be distributed over the entire interior of the stomach between the food mass and the stomach wall

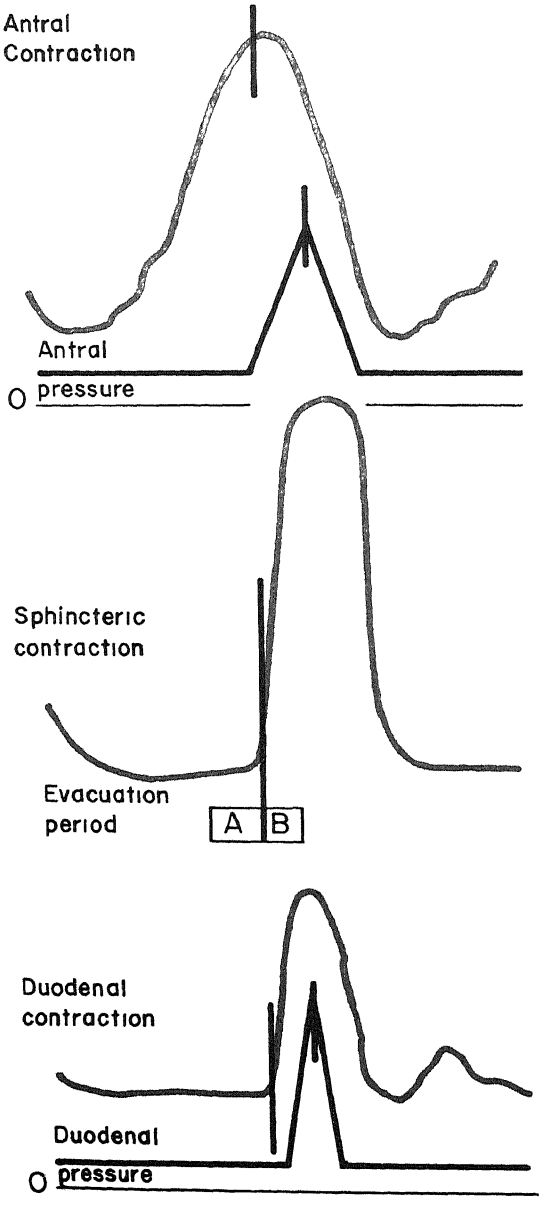

Fig 2 54 Composite diagram showing the successive contractions of the pars pylorica (antrum ') pyloric sphincter and duodenum during a single gastric cycle and the associated intraluminal pressure changes Evacuation periods A and B are also shown The contraction curves were traced from a kymographic balloon water-manometer record The pressure curves are approximate copies of the curves published by Quigley and Brody (1950) Vertical lines mark simultaneous points

CONTROL OF GASTRIC EMPTYING

A relatively small part of the energy expended by the gastric muscle is utilized in propelling food from the stomach into the intestine through the pyloric orifice The vigor of the gastric muscular contraction is such that if it were all utilized in propulsion the stomach would empty itself within a very few minutes By far the greater part of the work is utilized in mechanical digestion, serving to macerate the food particles and break them up into small fragments This work is done largely by the pyloric portion, which in some ways resembles in function the gizzard of birds The powerful contractions of the pyloric muscle drive the food against the pylorus All but the small part that escapes into the duodenum is forced back through a narrow orifice, formed by the contraction wave, into the body of the stomach It is this manipulation of the food mass which results in its being broken down and mechanically digested in the pyloric portion of the stomach

The rate at which food leaves the stomach is determined by a variety of factors, among which are the total volume of the gastric contents, and the consistency, chemical composition, pH, and osmolar concentration of the food Hunt and Spurrell (1951) have shown that for any individual, and for any type of meal, the amount evacuated in a unit of time is a function of the volume of the gastric contents The effect of consistency on the rate of emptying is best seen by comparing the emptying of liquids with the emptying of solids Inert liquids, which neither stimulate the stomach chemically nor osmotically, leave the stomach rapidly Water, for example, begins to leave the stomach almost as soon as it is swallowed Solids, on the other hand, are not normally evacuated from the stomach until they are reduced to a fluid or semifluid consistency Undigested solids are not normally allowed to pass the pyloric sphincter but are returned to the body of the stomach (Cannon, 1911b)

The influence of the chemical composition of the food on emptying is shown by the relative rate of emptying of the three major foodstuffs Cannon (1904) showed that for meals of a given size, a meal consisting mainly of carbohydrate left the stomach more rapidly than one consisting mainly of protein or fat, and that a protein meal left more rapidly than a fat meal Fat, especially if eaten in large quantities, re-

mains in the stomach for a very long time It is not unusual to find food in a dog's stomach as long as 24 hr after a meal consisting largely of fat meat

The osmolar concentration of the gastric contents has a profound effect upon the rate of gastric emptying One of the earliest facts to be determined with respect to gastric emptying was that physiological saline leaves the stomach faster than does salt solutions of either greater or lesser concentration Hunt (1956) has shown that in human subjects, adding salt to water hastened emptying of the water from the stomach, up to a concentration of about 100 mEq /liter Above 150 mEq /liter the emptying was delayed In this way, he showed that making the gastric contents either hypertonic or hypotonic with respect to the blood caused a delay in emptying This is an important factor in the slow emptying of sugar solutions although, as will be pointed out later, sugar slows gastric emptying in another way

The effect of acid on gastric emptying has been the subject of considerable study and extensive speculation It is well known that strong acid solutions leave the stomach slowly, and that the rate of emptying of such solutions can be accelerated by neutralizing the acid The acidity of the gastric and intestinal contents is usually not great enough during digestion to affect gastric emptying materially For example, a pH of 3 0 in the duodenum is necessary in order to influence the rate of emptying of the stomach, but the intestinal contents usually have a pH that is well above this level, pH values of 4 0 to 6 0 being most common Nevertheless, the inhibitory effect of acid on gastric emptying has an important function in protecting the duodenal mucous membrane against excess acidity

Enterogastrone. The inhibitory effect of fat on gastric motility has been known for many years and was recognized by Cannon Fat exerts its effect in the absence of any available nerve supply (Farrell and Ivy, 1926) Kosaka and Lim (1930, 1933), and Quigley, Zettelman, and Ivy (1934) showed that fat inhibition is caused by a hormone which Lim (1933) called *enterogastrone* This hormone is released from the intestinal mucous membrane by fat or fatty acids and some other substances in the duodenum While circulating in the blood, it is carried to the stomach, where it has an inhibitory effect on the gastric muscle

In summary, we can visualize the events following a meal approximately as follows gastric emptying begins as soon as any part of the gastric contents become fluid enough to pass through the pylorus Once started, it proceeds rhythmically a small amount being evacuated about every 20 sec in man Regulation of emptying begins as soon as the evacuated material has accumulated in the intestine to the point where any one of the numerous stimuli to the intestine associated with the chyme reaches threshold value These stimuli are comprised in the chemical constituents of the chyme and to some extent in its volume The chemical stimuli include the following, listed in the order of inhibitory potency in the concentrations in which they are usually encountered fats, fatty acids, proteoses, peptones, amino acids, sugars and other products of starch digestion, and hydrogen ions, also effective are osmotically active substances and nonspecific irritants The effect of these stimuli is to decrease the tone and peristaltic activity of the stomach, thus reducing the pressure gradient which develops with each gastric cycle and which is responsible for the passage of fluid through the pylorus With the more powerful inhibitors e g , fat, the gradient may be reversed, and duodenal contents will then be regurgitated into the stomach The inhibitory effect is exerted through a reflex involving the vagus nerves (*the enterogastric reflex*) or through a hormone (*enterogastrone*) released into the blood from the intestinal mucous membrane, or both The pyloric sphincter plays a part by preventing regurgitation of the duodenal contents into the stomach, it also contracts rhythmically in such a way that it apparently limits the volume evacuated at each cycle, but as yet there is no evidence that this function is utilized in regulating the overall rate of gastric emptying

ABNORMAL GASTRIC MOTILITY

Cardiospasm and *pylorospasm* are conditions in which these sphincter muscles are supposed to be in a state of sustained contraction Doubtless such abnormalities can occur but probably much less frequently than they are diagnosed Cardiospasm, for example, could be easily confused with loss of power in the esophageal muscle or absence of esophageal peristalsis, likewise, pylorospasm is often diagnosed when the true condition is failure of the gastric peristaltic mechanism to develop adequate gastric pressure, e g , following the operation of

vagotomy True pylorospasm occurs as a congenital condition in infants who suffer from hypertrophy of the pyloric muscle More accurately, the term pyloric stenosis or hypertrophic pyloric stenosis, should be applied to this condition Pylorospasm rarely occurs in adults but when present it is associated with irritative lesions in the region of the pylorus, either of the duodenum or pyloric portion of the stomach

VOMITING

Vomiting is a reflex which serves to relieve the upper gastrointestinal tract of its contents This may occur either because the contents are irritating, or because the organs themselves are more irritable than normally In either case, there is an unusual degree of stimulation of some part of the tract The most sensitive area is the first portion of the duodenum (Luckhardt, Phillips, and Carlson, 1919), but adequate stimulation of other parts of the intestine, or of the stomach, can induce the reflex Even mild mechanical stimulation of the pharynx or fauces is effective in most people Inflammation of mechanical disturbances in the intestine (appendicitis, obstruction, or strangulation) may induce violent emesis Vomiting may be induced by abnormal stimulation of sensory receptors in organs outside the gastrointestinal tract, such as the uterus, kidneys, heart, or semicircular canals Effective stimuli may also enter by way of the eyes, nose or mouth in the form of nauseating sights, odors or tastes, these give rise to what is called "psychic" vomiting It is not unusual for a soldier to vomit on going into battle, or at some time during the battle experience, some people vomit at the sight of blood

Vomiting that is induced by irritation of organs other than those of the gastrointestinal tract is sometimes referred to as "reflex" vomiting This is an incorrect distinction however, since nearly all vomiting is reflex in origin Even psychic vomiting is probably the result of conditioned reflexes

Vomiting may be induced by certain types of motion such as seasickness, air sickness and car sickness, or the nausea that some people experience when in a swing This is probably the result of unusual stimulation of the equilibratory sense organs of the labyrinth.

The Vomiting Center. The vomiting center lies in the dorsal part of the lateral reticular formation of the medulla oblongata close to (and to some extent including) the tractus solitarius It lies in close relation to (but is quite distinct from) the respiratory centers It is one of a constellation of visceral centers in this situation which includes salivary nuclei defecation, and vasomotor centers as well as the vestibular nuclei These form a relationship consistent with the physiological reactions (salivation vasomotor respiratory etc) associated with the vomiting act The *efferent* fibers are contained chiefly in the phrenics the vagi and the sympathetics but fibers are also conveyed by spinal nerves to the abdominal muscles and by cranial nerves to the muscles of the pharynx, palate, etc The *afferent* impulses reach the center along a multitude of routes the chief being the vagal and sympathetic fibers of the stomach and abdominal viscera

"Central" Vomiting Vomiting may occur as a result of direct stimulation of the vomiting center in the medulla Certain substances, such as *apomorphine*, *ipecac (or emetine)*, and *picrotoxine*, when administered intravenously, cause vomiting through a specific action upon the center These substances induce vomiting in animals when applied directly to the center Typical vomiting efforts (retching) follow the injection of apomorphine after removal of the stomach and intestines

The central vomiting caused by traumatic stimulation of the center due to head injuries, increased intracranial pressure, brain tumor, or meningeal irritation is most important clinically This type of vomiting is characterized by the great force with which the vomitus is ejected (*"projectile vomiting"*) There is also a minimum of nausea and a relative absence of participation of the voluntary muscles

The persistence of pernicious *vomiting of pregnancy* is probably due to increased excitability of the center resulting from some metabolic disturbance Ordinary morning sickness is looked upon as a minor form of this condition, and differing from pernicious vomiting only in degree Thus, morning sickness merges insensibly into the pernicious type of vomiting A neurotic element is also frequently a potent influence in the development and persistence of the condition The usual corrective measures are high carbohydrate feeding, the free administration of fluids, intravenous glucose if necessary, mild sedatives, and rest and quiet

The Vomiting Movements. Vomiting or

emesis usually begins with nausea, which is characterized by the secretion of excessive quantities of saliva containing a large amount of mucus, and certain well-known disagreeable sensations In the dog, it has been possible to analyze by graphic methods the sequence of events in vomiting The first muscular movement is a strong, sustained contraction of the upper small intestine Next, the pyloric sphincter contracts, then the pyloric portion of the stomach contracts These changes all take place during the period of nausea, and result in emptying the contents of the upper jejunum, duodenum, and pyloric portion of the stomach into the fundus and body of the stomach, which are relaxed and dilated After this has occurred, the voluntary muscles come into play, and at the same time the lower esophageal sphincter, esophagus, and upper esophageal sphincter relax Following an inspiratory movement, the glottis is closed and the abdominal muscles contract in a characteristic jerky manner (retching), compressing the stomach between the contracted diaphragm and the abdominal organs The resulting pressure on the gastric contents causes their evacuation through the relaxed esophagus

During the ejection of the vomitus the esophagus is relaxed throughout, the glottis is closed, the respirations are inhibited, and the larynx and hyoid bone are drawn upward and forward and are held rigidly in this position The throat is thus enlarged to allow free exit for the stomach contents, which are prevented from entering the nasopharynx by the elevation of the soft palate

Small Bowel Motility

The major part of the smooth muscle of the small intestine is distributed in a thick, circular layer and a much thinner, longitudinal layer The circular layer is responsible for most of the visible intestinal movements The outstanding characteristic of the muscle is its *rhythmicity*, which is manifest under appropriate conditions by alternate contractions and relaxations at a remarkably regular frequency

RHYTHMIC SEGMENTING CONTRACTIONS

The more common type of rhythmic contractions occurs at regularly spaced intervals along a section of the intestine, dividing it into short segments, also, they may occur singly, in pairs, or in a variety of other arrangements The area involved in each segment may be less than 1 cm In the cat, Cannon (1902) saw a certain type of rhythmic contraction in which a section of intestine was divided into short segments by rings of contractions occurring at regularly spaced intervals When the contracted areas relaxed, the relaxed areas between them contracted, dividing each segment into halves The two halves of adjacent segments joined together to form a new segment (Fig 2 55) Cannon described these contractions as *segmenting contractions*, and that is the name most commonly applied to them at present

In a study of duodenal motility in man, using simultaneous cineradiographic and pressure measuring techniques, Friedman and his associates (1965) observed two types of segmenting contractions One type consisted of a contraction localized in a segment less than 2 cm in length which was most marked on the free or external border of the duodenum and was therefore *eccentric* in appearance These eccentric contractions were observed to occur in two or three areas simultaneously or successively and were not followed in any sequential fashion by contractions in adjacent segments These local eccentric contractions rarely succeeded in emptying the area of the duodenum completely and were not associated with any change in intraluminal pressure From a visual point of view, they appeared to have a mixing function

The other type of segmenting contraction observed in the duodenum was *concentric* and consisted of a local contraction involving a segment usually longer than 2 cm and relatively uniform circumferentially These concen-

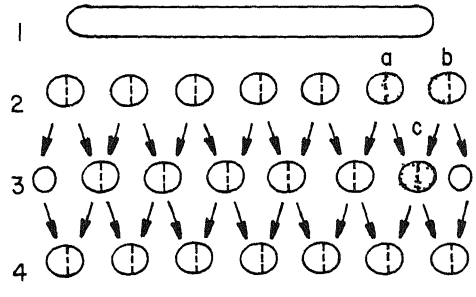

Fig 2 55 Diagram representing the process of rhythmic segmentation Lines *1 2 3 4* indicate the sequence of appearances in a single loop The dot lines represent the regions of division The arrows show the relation of the particles (e g *a* and *b*) to the segments they subsequently form (*c*) (After Cannon 1911b)

tric segmenting contractions were observed to empty the barium from the segment Most of the barium leaving the segment was displaced distally, although a small amount was occasionally displaced proximally As the segment relaxed, barium usually refilled the area, returning from both the proximal and distal adjacent segments The concentric segmental contraction was associated with an intraluminal pressure change that produced a positive monophasic pressure wave on the pressure record

The frequency of the rhythmic contractions varies with the species of animal and with the region of the intestine in which they occur For example, in the rabbit the contractions occur at a frequency of about 20/min in the duodenum and about 10/min in the lower ileum In the dog they occur at a frequency of about 18/min in the duodenum and 8 to 9/min in the lower ileum In man, segmenting contractions occur at a rate of 11/min in the duodenum, and in the ileum their rate is 8 to 9/min (Figs 2 56, 2 57) The frequency in other parts of the intestine is intermediate between these extremes, becoming less frequent as the distance from the pylorus increases The frequency is surprisingly constant in any one area and is not affected by stimulation of the extrinsic nerves or by neurotropic drugs In excised material the frequency varies with the temperature

The variation in frequency at different levels of the intestine suggested to Alvarez and his

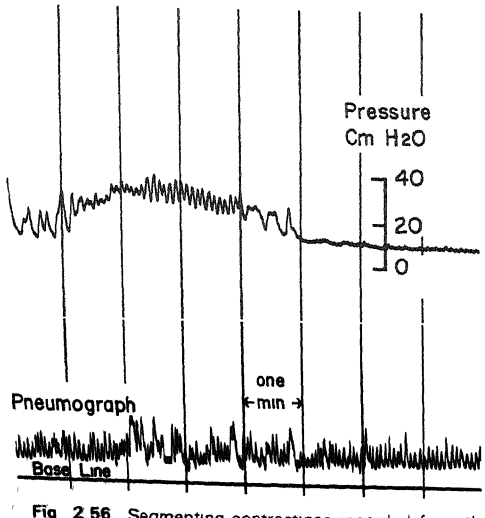

Fig 2 56 Segmenting contractions recorded from the duodenum of man by means of balloon-kymographic system Note that the rate of the rhythmic contractions (type I waves) was 11/min. (From Hightower 1959)

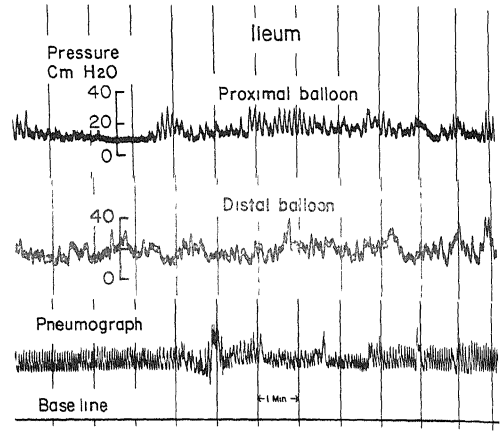

Fig 2 57 Motility tracing obtained from lower ileum in a patient with an iliac stoma A tandem system of balloons was used The proximal balloon record shows short bursts of rhythmic segmentation with the rate of contractions being 8/min (From Hightower 1959)

pupils the idea that there is a *gradient* in the various physiological properties of the intestine, activity being highest at the duodenal end and lowest at the ileal end of the small intestine Among the properties for which a gradient has been established are rhythmicity, irritability, shortness of latent period, susceptibility to drugs, and others of less obvious importance (Alvarez and Hosoi, 1929) The most easily observed is the gradient of rhythmicity manifested by the variation in frequency of rhythmic contractions (Fig 2 58)

The studies of Ambache (1947), Bozler (1949), and Milton and Smith (1956) have described the electrical activity of the intestine as consisting of slow waves which are frequently, but not necessarily, associated with local muscular contractions, and rapid, spikelike waves which appear only when the muscle contracts The slow waves have the same frequency as the rhythmic contractions, whether or not these are present, and (according to Milton and Smith) they are regularly conducted along the intestine in an aboral direction

The electrical activity of the small intestine is due to periodic depolarization of the muscle cells in the gut wall The BER is thought to originate in a "pacemaker" located near the ampulla of Vater in the duodenum The BER is propagated down the intestine in the longitudinal muscle layer The spike potentials occur when the circular muscle contracts and they are superimposed upon the slow wave activity

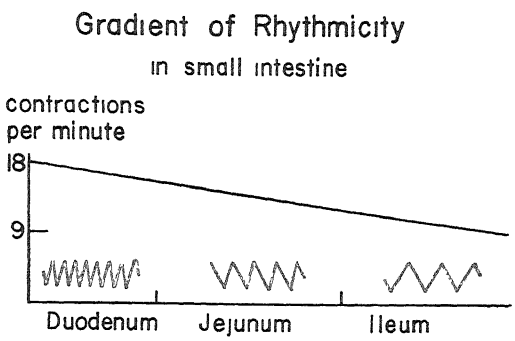

Fig 2 58 Diagrammatic representation of the gradient of rhythmicity in the small intestine The zig-zag lines are stylized representations of kymographic records of the contractions and relaxations of segments taken from the indicated levels of the intestine The sloping line suggests a linear distribution of the gradient however there is no direct evidence that this is so

Bass, Code, and Lambert (1961) have studied the electrical activity of exteriorized loops of duodenum in trained dogs Intraluminal pressures were recorded simultaneously to detect motor activity They found, like others, that cyclical changes in the electrical potential of the duodenum occurred This slow cyclical change was designated as the basic electrical rhythm (BER) In addition, irregular bursts of spike potentials were observed to be superimposed upon the BER When recorded from one site the cyclical changes in the BER were observed to be identical with the maximal rate of rhythmic type I contractions (18/min) When recorded from different levels of the duodenum the BER was observed to be propagated down the intestine at a rate of approximately 20 cm /sec The BER was recorded continuously, whether or not the intraluminal pressure catheter indicated the presence of motor activity

Spike potentials were noted in about one-third of the cycles of the BER They occurred in bursts of one to three spikes and were always located on the descending or negative slope of the slow potential change When spike potentials occurred, they were uniformly associated with an increased pressure within the lumen of the gut There was also an obvious correlation between the number and amplitude of the spikes and the magnitude of the increase in pressure in the gut, indicating a relationship between the number and amplitude of the spikes and the strength of the contractions occurring in the gut wall

PERISTALSIS IN THE SMALL INTESTINE

Stimulation of the intestinal smooth muscle causes contractions which tend to travel from the stimulated point in both directions However, under normal circumstances the progress of the contractions in an oral direction is quickly inhibited and the contractions disappear The contractions which travel in an aboral direction tend to persist, so that the intestine may be said to be polarized in the sense that conducted contractions travel normally in only the aboral direction Such aborally conducted contractions are commonly described as peristalsis The term has been used to describe a variety of contractile phenomena which have only one thing in common, namely the direction of travel The common conception of peristalsis as consisting of a wave of contraction progressing smoothly over otherwise relaxed intestine is erroneous Usually the peristaltic movement is superimposed upon the rhythmic segmenting contractions in such a way that the two are present simultaneously The peristaltic contraction makes itself manifest as a rise in the tone level of the intestinal muscle, without any interruption in the rhythm of the segmenting contractions, indeed, these are usually increased in amplitude at the peak of the wave This has the effect of narrowing the lumen of the intestine at the point at which the increase in tonus occurs and it may actually obliterate it As this wave of contraction, or tonus, travels down the intestine, it tends to sweep the contents forward, or toward the distal end of the intestine. In another type of propulsive movement, rhythmic contractions, although retaining their character, recur at successively more aboral levels and thus appear to travel along the intestine as a wave of peristalsis Ordinarily, peristaltic waves appear in the small intestine at irregular intervals and travel for varying distances (Bayliss and Starling, 1899), some travel only a few inches, others a few feet

In the duodenum of man, Friedman et al (1965) observed that some concentric segmenting contractions, instead of remaining localized in one area, would move distally over the duodenum into the jejunum When these peristaltic contractions occurred, pressure waves were recorded in a sequential manner, from above downward, by the three intestinal catheters localized in the duodenum The speed of the peristaltic contractions or stripping

waves were about 1 cm /sec Figure 2 59 illustrates intraluminal pressure changes occurring in the duodenum with peristalsis

The Law of the Intestine Bayliss and Starling (1899, 1901), to whose classical studies we owe most of our basic knowledge of intestinal motility, observed that the response of the small intestine to local stimuli consists of a contraction of the smooth muscle above and relaxation below the stimulated area "This," they said, "is the law of the intestine" Since the contraction wave and the preceding inhibition usually travel down the intestine in an aboral direction from the stimulated point, Bayliss and Starling thought that intestinal peristalsis might consist simply of a succession of responses to stimuli manifesting the law of the intestine In their opinion, a particular mass might give rise to stimulation resulting in contraction above the stimulated point, with relaxation below, and this would cause the mass to move aborally In its new position it would also act as a stimulus and again cause contraction of the muscle above and relaxation below, again being moved by this to a new, lower level A succession of such responses could according to them, constitute a peristaltic wave

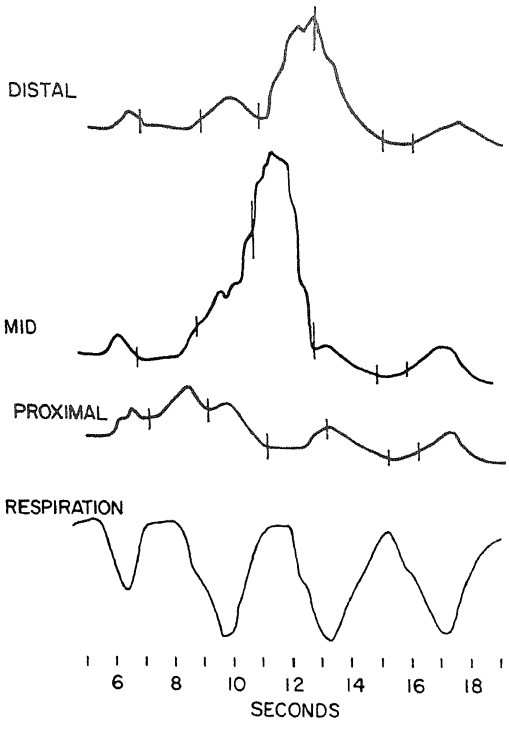

Fig 2 59 Duodenal intraluminal pressure changes with peristalsis The recording sites designated as proximal mid and distal are located at 2-cm intervals The short vertical lines indicate the frames of a cine sequence that were recorded simultaneously This series of three monophasic contractions occurring in timed sequence was associated with the transport of barium in an aboral direction In this patient the peristaltic contraction traveled at about 1 cm /sec (From Friedman et al 1965)

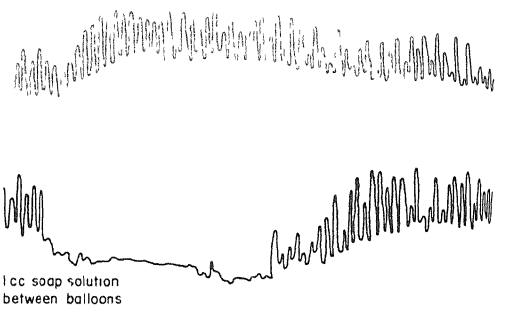

Fig 2 60 Myenteric reflex in a dog s duodenum Water manometer records from two balloons 5 cm apart in the lower duodenum Upper record is from the upper balloon A stimulus consisting of 2 ml of 2% soap solution in the intestine between the balloons caused contraction above (over the upper balloon) and relaxation below (over the lower balloon) the stimulated point (Thomas 1955)

Cannon (1912) proposed that the reflex responsible for the law of the intestine be designated the *myenteric reflex* (Fig 2 60) The myenteric reflex disappears if the intestine is paralyzed by applying such drugs as nicotine or cocaine to the serosal surface Presumably these drugs penetrate the longitudinal muscle layer and paralyze the underlying nervous mechanism Under these circumstances, the polarity of the intestine (Fig 2 61) is also abolished, and contractions initiated by local stimulation travel equally well in the oral and aboral directions Evidently, both the myenteric reflex and the polarity of the intestine are dependent upon the integrity of the myenteric plexus Of course, this does not prove that intestinal polarity is due to the myenteric reflex In fact, most observers have failed to find evidence of the occurrence of a myenteric reflex in ordinary peristalsis in the intestine Although the *Roll bewegungen* or rush waves are usually preceded by a phase of inhibition, the inhibitory phase has been difficult to demonstrate in spontaneous peristalsis of the intestine

THE INTESTINAL VILLI AND THE MUSCULARIS MUCOSAE

The absorbing surface of the small intestine is much greater than the serosal surface because

of the superabundance of the mucosa which under normal conditions, is thrown into circular folds called *plicae circulares* A still greater increase in surface is provided by the *intestinal villi* These are titlike projections of the mucous membrane about 1 mm in length which occur everywhere on the mucosal surface and which macroscopically resemble the pile on a piece of velvet Our interest is these structures at this point has to do with the activity of the *muscularis mucosae*, which lies everywhere beneath the mucous membrane, following each fold, and extending into each villus as a filament of smooth muscle fibers In the fasting animal, the villi are inactive and lie flat on the mucosal surface when first exposed for study Covering them with a liquid, such as a solution of sugar, salts, amino acids, weak alkalies, or even with distilled water, causes them to become active In the fed animal, activity of the villi can be observed without special stimulation The activity is of two kinds a lashing movement and a more or less rhythmical shortening and lengthening These movements accelerate the flow of blood and lymph and increase absorption The movements of the villi are partly under nervous control, being augmented by stimulation of the splanchnic but not the vagus nerves, and by sympathomimetric drugs They are depressed by atropine and nicotine Their activity is also increased by *villikinin*, one of the postulated intestinal hormones

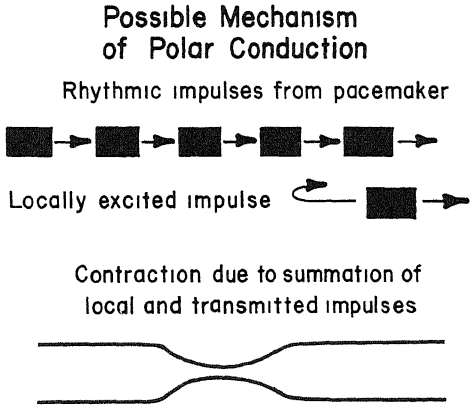

Fig 2 61 Mechanism of polar conduction in the intestine suggested by physiological evidence for a pacemaker mechanism in the upper intestine The block rectangles represent excitatory impulses those in the upper row presumably arose in the pacemaker and are being conducted analward A local excitory process cannot be conducted oralward because of the refractive phase following each conducted impulse from the pacemaker (Thomas 1955)

DISTURBANCES OF SMALL BOWEL MOTILITY

Disturbances of small bowel motility are rare, except when due to infections or inflammatory conditions, and in these instances there is increased motor activity of the propulsive type usually associated with diarrhea In some malabsorptive states, such as nontropical sprue small bowel transit time may be slow Abnormal motility patterns in the small intestine are seen in some nervous and endocrine disturbances and also in vitamin deficiency Their significance when they occur is not always clear Small bowel motility may be affected by intraluminal contents Saline cathartics markedly increase small bowel transit time due to the hyperosmolarity From a clinical standpoint, paralytic ileus and intestinal obstruction deserve further consideration

Paralytic Ileus. Although the small intestine usually shows some degree of activity in the intact animal, a dramatic and persistent quiet ensues when the abdomen is opened It is rare to see activity in the exposed intestine at surgery unless stimulating drugs are given Abdominal surgery, particularly if it involves handling the intestine, is apt to be followed by a period of *ileus*, as the loss of motility is termed clinically Peritoneal irritation from any cause, including bacterial peritonitis, may cause ileus As a rule, recovery is prompt following removal of the cause but if the condition persists for some time it tends to be self-perpetuating, due to the paralytic effect of the gaseous distention that usually develops When this occurs, removal of the gas through an intestinal tube of the type described by Miller and Abbott (1934) may save the patient's live (Fig 2 62)

The cause of the postoperative ileus is reflex inhibition of motility through reflexes from the irritated peritoneum in which the splanchnic nerves are an essential part of the reflex path Cutting the splanchnic nerves prevents the ileus

Intestinal Obstruction Symptoms of intense severity result when the lumen of the small bowel is completely obstructed as a result of constriction by an adhesive band, kinking, twisting or pressure by new growth, intussusception, strangulation by a hernial ring, etc The

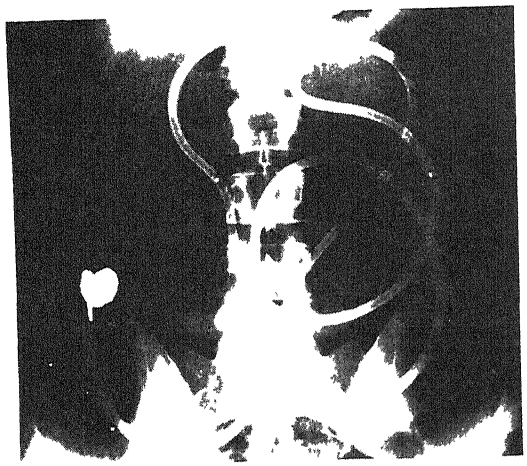

Fig 2 62 X-ray of abdomen showing Miller-Abbott tube in the small intestine

condition is ushered in by severe cramplike abdominal pain, vomiting, and shock If the condition is not relieved by operation, reverse peristalsis arises above the point of obstruction, intestinal contents pass into the stomach, and vomiting becomes fecal in character Later, the bowel above the obstruction loses its tone and becomes dilated and filled with intestinal secretions and gas The loss of fluid in the vomitus and the drainage of large quantities of fluid into the distended bowel leads to a *fall in blood chloride, alkalosis, and dehydration* The former is the result of tissue destruction combined with impairment of renal function Great prostration occurs, ending in death

Experimental obstruction When the intestine of an animal is tied across, the symptoms which follow are chiefly weakness, prostration, and vomiting The animal shows little or no evidence that it is suffering pain The higher in the intestinal tract the obstruction is made, the more severe are the symptoms, and the shorter is the duration of life after the operation Following obstruction of the colon the animal may survive for some weeks, whereas after obstruction of the jejunum or duodenum it dies as a rule within 5 or 6 days

The importance of distention as a factor in acute obstruction of the intestine is now generally recognized, and it has become the practice to decompress the bowel by suction-drainage through a tube passed from the nose to the small bowel and allow it to be carried to the level of the obstruction The tube has a double lumen and is provided at its tip with a small balloon which can be moderately inflated after it has entered the duodenum The balloon serves as a stimulus to motility which carries it and the tubing along the bowel to the point of obstruction (Fig 2 62)

THE ILEOCECAL VALVE

Most textbooks of anatomy describe the ileocecal valve as a slit-like orifice with a mucosal fold above and below on the colonic side of the orifice After death, the ileocecal junction does look like this when the cecum is opened at autopsy During life, however, if the cecum is opened during surgery, the ileocecal junction will be seen to be an invagination of the terminal ileum into the cecal wall, producing an appearance remarkably like, in both size and shape, the cervix of the uterus extending into the vagina The valve can withstand a high pressure in the cecum but yields to a low pressure from the ileal side Materials introduced by enema may in some instances pass through the valve into the lower ileum The ileocolic opening has been observed in man through a cecal fistula It appears as an oval or round opening from 2 to 3 cm in diameter situated in the center of a small papilla When tightly closed, the valve was found to offer considerable resistance to the passage of the finger While digestion was in progress, the papilla was observed to flush, its color altering from a pale pink to a vivid red The orifice opened rhythmically at frequent intervals and allowed a jet of fluid to escape into the cecum Emotional excitement or the swallowing of food increased the frequency of the ejections (*gastroileal reflex*) During fasting, nothing passed through for long periods, but in ½ to 4 min. after food was taken into the mouth, fluid appeared in gushes of about 15 ml every half minute or so

Kelley et al (1965) have made pressure studies of the ileocolonic junctional zone in dogs He prepared his animals by making ileal and colonic stomas and then measured pressures on either side of, and within, the ileocolonic junctional segment When a water-filled catheter tip, for recording pressures, was withdrawn at 0 5-cm intervals from the colon into the ileum of the fasted, conscious animal, a zone of high pressure was demonstrated at the ileocolonic junction. Mean pressures at the center of the junctional area were 20 cm of water above ambient The length of the high pressure zone was approximately 1 cm

The functions of the ileocolic valve appear to be 1) to prevent the contents of the ileum from passing into the cecum before the digestive processes have been completed, and 2) to serve as a barrier which prevents the bacteria-laden contents of the large bowel from contaminating the small intestine

Large Bowel Motility

The colon receives the mixed residues remaining after completion of intestinal digestion and absorption These consist of undigested or undigestible food residues, whatever remains of the digestive secretions including considerable quantities of water, and the fluid that has been swallowed or secreted and has escaped absorption in the small intestine The colon extracts the water and electrolytes from this mixture and forms the indigestible residues into fecal masses which are later evacuated The motor activities are appropriate to these functions They may be divided into two classes first, those that appear to be designed primarily to mix colonic contents and facilitate absorption, and second, those concerned principally with propulsion

COLONIC MOTILITY IN MAN

Four types of motility waves may be recorded with balloon or direct pressure measuring systems from the colon of man (Code et al , 1954, Hightower, 1959) When balloons are used to record colonic motility, they are usually water-filled, under low pressure, and small in size, with a length of approximately 5 cm and a diameter of approximately 3 cm Frequently, two or more such small balloons may be used in tandem to record colonic motility, being separated by 5 to 7 cm

Type I waves are small, simple, monophasic, positive pressure waves of low amplitude and short duration, similar to the same type of wave occurring in other parts of the alimentary canal The exact function of the type I wave is not known but presumably it serves as a component of motor activity which contributes to mixing of the colonic contents Type I waves usually have an amplitude of 5 to 10 cm of water pressure and their duration varies from 5 to 10 sec When occurring in a rhythmic pattern, the rate varies from about 8 to 12/min , depending upon the site from which they are recorded

Type II waves are similar to type I They are, however of much greater amplitude and of longer duration These waves are usually 25 to 30 sec in duration and the amplitude usually varies from 15 to 40 cm of water pressure This type of activity accounts for the major portion of total colonic motility They sometimes occur in rhythmical patterns with a rate of about 2 waves/min The type II waves are caused by the contractions in the large bowel which produce the haustra seen by radiologists Type II waves represent, predominantly, a mixing type of motor activity, although they may contribute to some extent to propulsive motility

Type III waves are of a complex pattern and consists of an increase in basal pressure or a change in tonus on which superimposed type I or type II waves, or both, appear These waves usually last from 1 to 4 min and the pressure change in base line tonus is usually less than 10 cm of water The exact function of the type III wave is not clear but it probably is predominantly mixing in its action

Type IV waves result from the "mass movement" activity of the colon These waves are rarely recorded from a normal individual unless the recording is obtained shortly after or during the act of eating These waves rarely occur in a rhythmical pattern, except in patients with chronic ulcerative colitis, and then the rate is usually about 1 wave every 2 to 3 min The amplitude of the type IV wave may reach 80 to 100 cm of water pressure The duration of the wave is characteristically prolonged and lasts from 2 to 4 min Their configuration is rather characteristic in that there is a fairly rapid increase in pressure at the beginning of the wave, the peak is reached, and then there is a rapid decline for 50 to 60% of the elevation The rate of decline changes and becomes much slower, producing a prolonged wave See Figures 2 63 to 2 66 for types of colonic motility waves recorded in man

The mass movements of the colon serve to empty the contents of the proximal colon rapidly into the more distal portions Frequently such movements are followed by a desire to defecate, and it is assumed that, on these occasions, the movement has been vigorous enough to carry fecal masses into the rectum Since normally a desire to defecate does not follow every mass movement of the colon, it must be assumed that, on some occasions, the forward movement of the colonic contents stops short of the rectum People differ considerably with re-

spect to their susceptibility to the gastrocolic or gastroileac reflex

In normal individuals who have fasted for 8 to 12 hr, some type of motor activity can be recorded from the colon for approximately 35 to 40% of the period of observation The predominant activity is the type II wave and accounts for 90 to 95% of the total activity Type I waves usually occur during 1 to 2% of the period of observation, and type III waves, 2 to 4% Type IV waves are rarely observed normally and are present for less than 1% of the period of observation

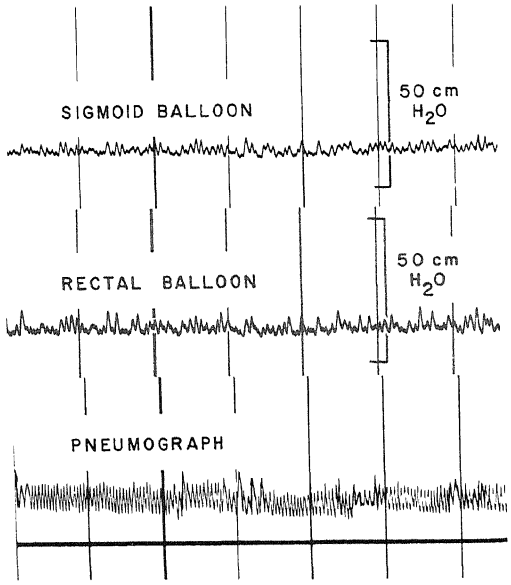

Fig 2 63 Type I waves Record of sigmoidal and rectal motility obtained from a normal individual Short bursts of rhythmical type I waves were observed with a rate of 11/min Distance between vertical lines is 1 min camera speed 0 4 mm /sec (From Hightower 1959)

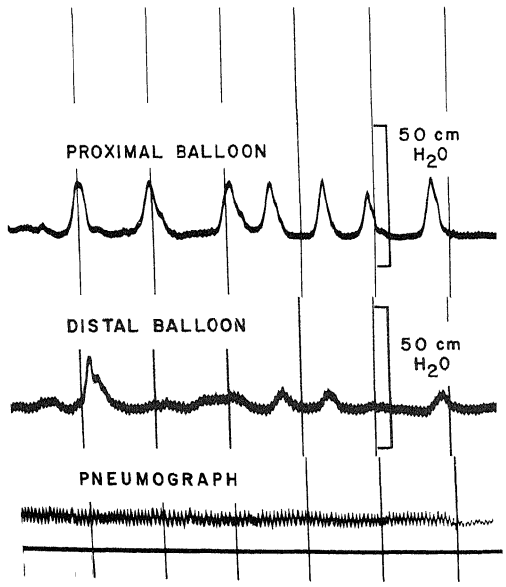

Fig 2 64 Type II waves Record obtained from transverse colon in a patient with a colonic stoma showing type II waves The balloons were separated by a distance of 7 cm Camera speed and time lines were the same as Figure 2 6 3 (From Hightower 1959)

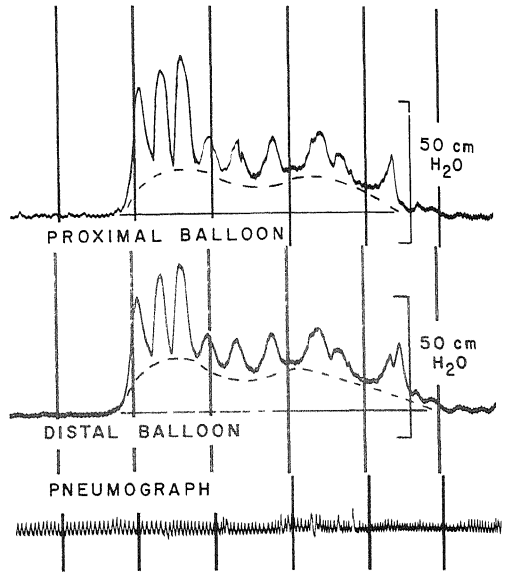

Fig 2 65 Type III waves Record from descending colon via colonic stoma Note rise in basal pressure with superimposed type II waves Both balloons were recording the type III complex indicating that a segment of colon at least 7 cm in length was involved in the motility being recorded Camera speed and time lines same as Figure 2 63 (From Hightower 1959)

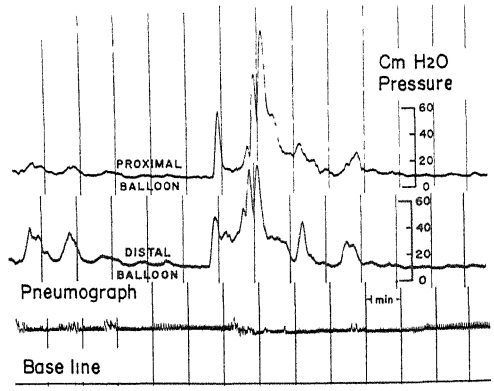

Fig 2 66 Type IV waves This type IV contraction was recorded from the sigmoid colon of a patient with chronic ulcerative colitis Note that pressure exceeded 100 cm water in the proximal balloon Type II waves are present at the left side of the tracings

Alterations of Colonic and Rectal Motility The effects of *emotions* on colonic motility has been extensively studied (Almy et al., 1947, 1949a, 1949b, 1950, Grace, Wolf and Wolff, 1948, 1951) Discussion of life situations which produce emotional conflict resulting in feelings of anger, anxiety, apprehension, resentment, hostility, or guilt cause increased motor activity However, when fear, fright, or dejection is the predominant feeling of the subject, hypomotility has been reported In patients with *chronic ulcerative colitis*, colonic motility records show rather characteristic differences from the normal There is a marked increase in the incidence of type IV waves, associated with propulsive action leading to the expulsion of fecal matter Type I activity is also increased There is a significant decrease in type II activity and usually a complete lack of type III waves Thus, total motor activity is decreased in these patients, due mainly to the reduction in the mixing type of motor activity At the same time, propulsive motility is increased

The Effects of Drugs on Colonic Motility. Many drugs influence the motor activity of the colon *Anticholinergic agents* of the quaternary amine type are potent inhibitors of colonic motility *Parasympathomimetic agents*, such as neostigmine and methancholine, stimulate colonic motility Neostigmine is particularly effective in producing a predominantly propulsive type of motor response *Morphine* increases the amount of nonpropulsive motility and tends to eliminate propulsive activity Morphine also markedly increases the tone of the large bowel Most of the so-called *antispasmodic and spasmolytic agents*, when administered by mouth in the recommended therapeutic doses, have little or no effect on motility of the large bowel

DEFECATION

The rectum is normally empty The fecal masses driven forward by the mass movements of the colon are stored, not in the rectum, but in the sigmoid or pelvic colon Fecal matter does not collect elsewhere if defecation is regular, however, if defecation is long deferred, the descending colon becomes filled when the pelvic colon can hold no more The desire to defecate occurs when, as a result of a mass movement, some feces enter the rectum An increase in rectal intraluminal pressure of 20 to 25 cm of water will usually elicit the desire to defecate While the usual stimulus is the taking of food, a glass of warm water, a cup of coffee, or smoking a cigar or cigarette may have the same effect Many people find that a glass of cold orange juice, or lemon juice and water is an effective stimulus to the gastrocolic reflex The desire to defecate may be induced by straining efforts, which may raise the abdominal pressure to as much as 200 mm of mercury and force feces into the rectum

When the rectum is filled with solids (feces), liquids, or gas to an extent which raises the intraluminal pressure to 20 or 25 cm of water, the desire to empty the rectum is experienced The receptors within the wall of the rectum are not only able to detect increases in pressure (pressorectors) but they can also, with a high degree of accuracy, differentiate whether the increase in pressure is due to feces, liquids, or gas The discriminating ability of these sensors is relied upon heavily by individuals who risk flatulating in a public place In patients with infectious diarrhea or proctitis due to ulcerative colitis or other inflammatory conditions, the ability to discern the contents of the rectum is frequently lost, and these patients find the risk is too great to relieve themselves of an increase in rectal pressure which is suspected of being due to gas

The act of defecation is, in the adult, preceded by a voluntary effort consisting of assumption of an appropriate posture, voluntary relaxation of the external anal sphincter, and usually, compression of the abdominal contents by means of straining efforts These movements in turn probably give rise to stimuli which augment the visceral reflexes, although these originate primarily in the distended rectum As a result of these reflexes, a mass contraction may involve the entire colon and the internal anal sphincter relaxes The mass contraction of the colon carries its contents into the pelvic colon, which in turn transfers them into the rectum, eventually to be evacuated by way of the anus, hence, the entire distal colon from the splenic flexure to the anus may be emptied at one time A prominent mechanical feature of the final act of evacuation is contraction of the longitudinal muscle of the distal colon, which is more pronounced in the rectum itself The shortening of the distal colon tends to elevate the pelvic colon and obliterate the angle which it normally makes with the rectum This straightening of the passage doubtless facili-

tates evacuation Shortening of the rectum itself is an important factor in expelling the feces through the anal orifice

The act of defecation provides another instance of a reflex that is under some degree of voluntary control The voluntary regulation consists of the ability to inhibit the reflex under normal circumstances and to initiate it voluntarily, provided the necessary visceral stimulus (recent distention of the rectum) is present Reflex centers for defecation have been located in the hypothalamus, in the lower lumbar and upper sacral segments of the spinal cord, and in the ganglionic plexus of the gut The intrinsic intestinal plexus of the lower colon is able to take over the function of controlling defecation, even in animals in which the spinal cord has been destroyed For this reason, in severe spinal injury the defecation reflex suffers less than does, for example, the reflex of micturition

The Composition of the Feces According to Cantarow and Schepartz (1954, p 276), adults on an average diet excrete from 75 to 170 g of feces daily, about 25 to 30% of which is made up of solids, the remainder is water If the diet is rich in vegetables the quantity is greater, especially if the vegetables are eaten raw Bacteria comprise about one-third of the dry weight of the feces under average conditions The pH is 7 0 to 7 5 The feces contain those inorganic substances which are relatively insoluble at alkaline pH ranges, such as calcium phosphate and oxalate, iron phosphate and similar compounds The organic material is principally cellulose, protein, and fats About half the protein nitrogen of the feces is of bacterial origin, the remainder represents unabsorbed intestinal secretions and digested fluids, mucus, and desquamated epithelial cells from the mucosa Only a small amount is actual food residue Enzymes are also present but in very small quantities, these are pancreatic amylase and trypsin, nucleases, maltase, sucrase, lipase and lysozyme Fats comprise 5 to 25% of fecal solids under normal circumstances They are greatly increased in conditions in which there is interference with pancreatic or biliary function In the total absence of pancreatic juice from the intestine, as much as 90% of the ingested fat may be excreted in the stools Much of the fecal fat has undergone digestion, as indicated by the following average composition of fecal lipids neutral fat 7 3% of dry weight of feces, free fatty acids, 5 6% and soaps 4 6%

The color of the feces is due chiefly to bile pigments, stercobilin (*urobilin*), which is produced by reduction of bilirubin by the intestinal bacteria The characteristic odor is due largely to indole and skatole, but is contributed to also by hydrogen sulfide and other odoriferous substances

Gas in the Intestine A variable amount of gas is always found in the large intestine Gas is seldom observed in the small intestine Intestinal gas consists of oxygen, carbon dioxide, nitrogen, methane, hydrogen, and small amounts of other gases including the rare atmospheric gases The average composition according to Pogrund and Steggerda (1948) is as follows carbon dioxide, 7 5%, oxygen, 3 0%, methane, hydrogen and other rare gases, 9 5%, and nitrogen, 80% The source of the oxygen, nitrogen, and carbon dioxide is swallowed air and diffusion from the blood Bacterial fermentation and putrefaction of food residues in the intestine produce the methane and hydrogen No matter what the composition of swallowed air may be, it quickly comes into equilibrium with the venous blood with respect to oxygen and carbon dioxide, and more slowly with respect to nitrogen, hence, the relative constancy of composition of intestinal gas with respect to these gases The amount of putrefactive gas is much more variable It is the rapid expansion of these gases that gives rise to intestinal cramps on ascending to high altitudes in an unpressurized plane Some of this gas is absorbed into the blood and some escapes from the rectum as flatus The amount in the intestine can be reduced by giving the subject pure oxygen to breathe

ABNORMAL COLONIC MOTILITY—CONSTIPATION

The most frequent manifestation of malfunction of the large intestine is constipation For a discussion of the various causes and the treatment of this condition, appropriate clinical texts should be consulted It may be mentioned here that one of the most frequent causes of chronic constipation is neglect of the call to stool The desire to defecate is experienced whenever the pressure within the rectum is increased An increase in the volume of the contents of the rectum of from 15 to 25 ml has

been shown to be sufficient to produce an urge. If the rectum is not emptied at such a time, the sensory mechanism becomes adapted to the pressure and the urge is no longer felt; it then requires further increase in volume with a corresponding increase in pressure to produce a sensation. This will also pass if neglected and a still further increase in volume is required to arouse a sensation; finally the irritability of the rectum is so reduced that an urge is no longer induced. Usually the subject will then take a cathartic which further injures the sensory mechanism. Frequent repetition of this cycle results ultimately in dependence on cathartics.

Circulation

3 / THE CARDIOVASCULAR SYSTEM

The blood transport system functions to distribute and to collect blood from diffusion sites within the body It operates within definite limits of pressure and flow required for adequate perfusion of organs and tissues Complex control mechanisms govern the activities of its various parts and their functional interrelations with body tissues

The adult mammalian heart consists of two fluid pumps in series, the right heart supplying blood to the lung circulation, and the left heart to the remainder of the body (systemic circulation) Exacting equalization of the output of these two pumps is required to maintain the disparate blood volume distribution between these two circulations which is compatible with life This coordination must be accomplished despite increases in total cardiac output which can amount to 500% or more as cardiac output adjusts to body needs (e g , rest vs exercise)

The vascular system is an enormous network of viscoelastic tubes Through serial bifurcations the single outflow vessel from the left ventricle divides in the mesenteric vascular bed alone into more than two billion channels with a total cross section over one thousand times greater than the parent vessel, these then rejoin in repeated confluences forming the two venae cavae which return the blood to the right heart

The vascular system can be classified into three general types of vessels with different functions the arteries, a distributing system, the microcirculation, a diffusion and filtration system, and the veins, a collecting system

The grossly visible distributing arteries carry blood to the microcirculation (vessels less than 100 μ in diameter), which includes the capillary beds (actual diffusing portion) From here blood flows into the collecting venous system (see Figs 3 1 and 3 2)

The blood moves through each segment of the branching and reuniting vascular network in equal volume flow along a progressively decreasing pressure gradient (Fig 3 2*A*, *B*, and *C*) in both the pulmonic and systemic circuits The beginning and end of each circuit is the heart, which, through mechanical work and one-way valvular action, provides the energy required to maintain the pressure and flow gradients

The level of arterial blood pressure maintained must be sufficient to insure adequate perfusion of the microcirculation bed against the forces of gravity (upright posture) acceleration, and deceleration (inertial effects), mechanical distortion and pressures on distributing arteries and the tendency for some vessels to close altogether owing to their own wall tension The biological significance of differing blood pressure ranges characteristic of various species has not been systematically analyzed However, certain correlations can be cited For example the resting systemic mean arterial pressures at heart level decrease from giraffe to ox to man (219, 135, 90 mm Hg, respectively) in proportion to the characteristic distance of the brain above the heart (160 64, 34 cm respectively) in the erect posture (Patterson et al , 1965b) The mean arterial pressures at brain level in these three species (obtained by subtracting a correction for pressure exerted by a column of blood equal to the heart-brain distance), would be less disparate (100, 88, 65 mm Hg, respectively) (see Fig 3 3 *A* and *B*) Birds, subject to marked alterations in gravitational, accelerational, and decelerational effects associated with flying, have, as a class, higher arterial pressures than mammals Finally, in mammals and birds the pulmonic circulation, protected from mechanical effects in the rigid thoracic cage and situated at all times close to heart level, operates at a mean arterial pressure about one-seventh that of the large systemic arteries

There is also an interesting relation between plasma colloid osmotic pressure and blood pressures characteristic of various species (Figs 3 4 and Table 3 1)

The microcirculation consists of a system of small arterioles which lead blood into the capillaries, where diffusion and filtration take place, and small venules which carry the blood into

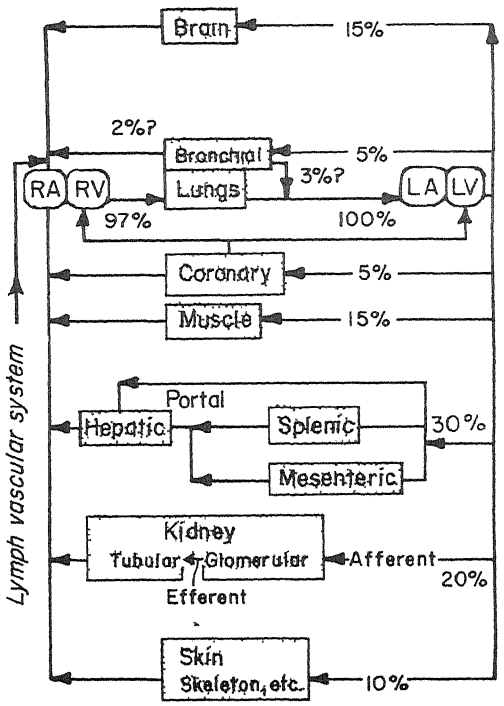

Fig 3 1 Stylized block diagrams of the circulatory system A schema of the circulatory system including the major vascular components (heart arteries microcirculation veins) which distribute to and collect blood from the tissues The special circulatory beds to be discussed separately are indicated and the relationship to the lymphatic collecting duct system represented Solid lines depict arteries and veins arrowheads show the direction of flow and shaded blocks indicate the microcirculation (arterioles capillaries and venules) Approximate percentages of cardiac output going to the various circulatory beds are indicated near each line

the collecting veins At this level, lymph capillaries occur These function as fluid- and particle-collecting vessels They unite by confluence to form the lymphatic network, an auxiliary fluid-collecting system which ultimately conducts fluid back to the blood in the veins (Fig 3 5)

Distribution of Blood Volume, Pressure, Flow, and Resistance

The proportional distribution of blood volume in systemic arteries, capillaries, and veins is depicted in Figure 3 2C The arteries contain about 20, capillaries 5, and veins 75% The relative distribution between the pulmonic and systemic circulation is illustrated in Figure 3 6 Volume distribution estimates for an adult man appear in Table 3 2 and for the mesenteric circuit of the dog in Table 3.3

Pressure gradients typical of the human circulatory system are diagrammed in Figure 3 2C and 3 7, volume flow in Figure 3 2A, and blood flow velocity in Figure 3 2B A tabulation of blood velocity in the systemic circuit is given in Table 3 4

Chief among the hemodynamic features of the cardiovascular system are those determined by the mechanical relations between the pressure flow gradients, blood volume distribution and capacity, and compliance and flow resistance of the vessels in different segments of the circulation In simplest terms flow, pressure, and resistance are related as follows

$$\text{Volume flow } (V) \quad \frac{\text{Pressure gradient } (\Delta P)}{\text{Resistance } (R)}$$

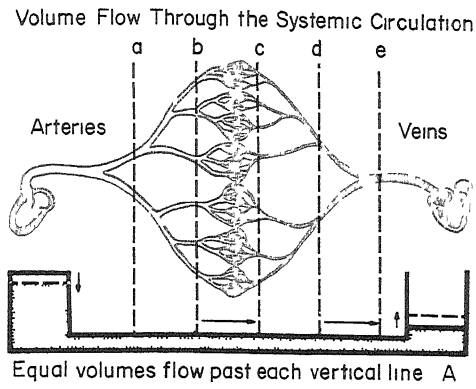
The equation $\dot{V} \quad \Delta P/R$ or $\Delta P = \dot{V}R$ is analogous to Ohm's law of electrical circuits $I = E/R$ or $E = IR$

Among the mechanical factors which determine resistance to flow are the length and total cross-sectional area of the conduits, i e ,

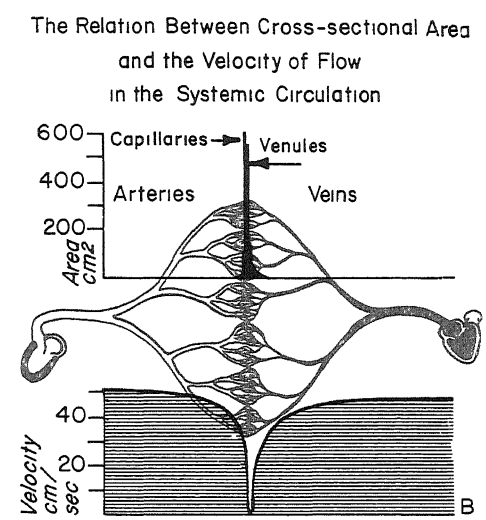
$$\text{Resistance} \propto \frac{\text{Length}}{\text{Cross-section area}} \quad \text{or} \quad R \propto \frac{L}{A}$$

Thus, widening of the vascular bed decreases resistance in segments of comparable length

The *equation of continuity* of flow states that velocity of flow (v) times the cross sectional area (A) of a vessel must be constant at all serial segments in the circuit, e g , in the simplest case, i e ,



$$v_a \times A_a \quad v_b \times A_b, \text{ etc}$$



Thus, flow velocity is inversely proportional to total cross-section of the system,

$$v \alpha 1/A$$

These simple relations explain the characteristics of pressure and flow through the system depicted in Figures 3 2 and 3 7 In the complexly branching vascular system with pulsatile flow, these relations are not necessarily preserved at all sites and instants of time, but the concept holds as an appropriate generalization

Various functional types of vessels can be identified in accordance with pressure, flow, and volume distribution (see also p 3-164), e g high pressure vessels arteries, low pressure vessels veins, capillaries, pulmonary vessels, capacitance vessels veins, and resistance vessels. small arteries and arterioles chiefly,

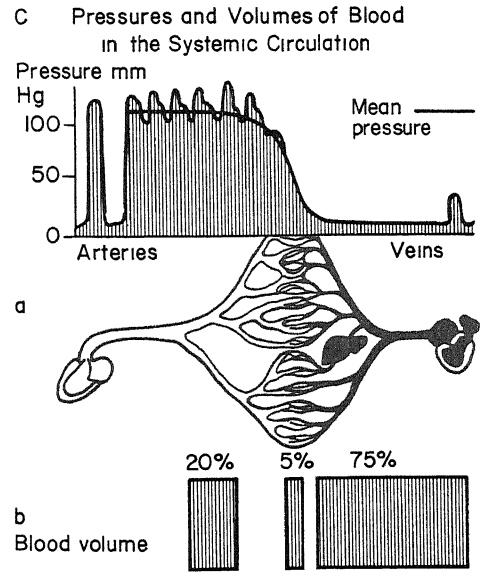


Fig 3 2 *A* The volume flow per unit time through each segment of the circulation must equal that entering and leaving the system despite great differences in cross sectional area *B* The cross-sectional areas of various segments of the circulation computed from a 13-kg dog are graphed above velocity of blood flow to show their inverse relationship Flow through the capillaries averages about 0 07 cm /sec *C* Approximate pressures and volumes throughout the circulation are depicted schematically Pressure is high and pulsatile in the arteries falls rapidly across the resistance vessels and the pulsation is damped out in the capillaries and veins Pressure is low and nonpulsatile in most capillaries and veins The blood volumes depicted are approximations (Redrawn from Rushmer 1961)

also capillaries and smallest venules Volume flow ($\dot{V}$) remains constant through each segment of the circulatory bed (Fig 3 2*A*) while mean pressure (P) decreases progressively (Figs 3 2*C* and 3 7) Pressure gradients (ΔP) are not uniform By scanning the pressure curves in Figures 3 2*C* and 3 7, the location of points of high resistance (R) can be found where pressure drop (ΔP) is greatest Resistance to flow is determined by the viscosity of the fluid and geometry of the tubular system Assuming viscosity to be constant, the factors determining resistance are length of conduits, their cross-sectional area and whether they are arranged in series or parallel In the case of dichotomously branching arterioles and capillaries, the resistances are in parallel and series The total resistance (R_T) at any segment is the sum of the vessel resistances in that segment The relative contributions can be derived from geometrical data, in Table 3 3, e g , in the case where areas and lengths are equal,

$$R_T \propto (1/\text{No of vessels}) \times (\text{Length/Cross-sectional area})$$

where the vessels are in parallel

Series resistances simply add, e g ,

$$R_T = R_{\text{arteriole}} + R_{\text{capillary}} + R_n$$

or the total resistance can be derived from

$$\dot{V} = \Delta P/R \text{ or } R = \Delta P/\dot{V}$$

While blood volume distributions (Figs 3 2*C* and 3 6, and Table 3 2) are not rigidly fixed, they are ordinarily maintained within fairly narrow limits The volume capacity of the systemic arterial distributing system (high pressure system) is the most limited and least variable, i e , it is least dilatable It contains (Table 3 2) only about 14% of the blood volume The

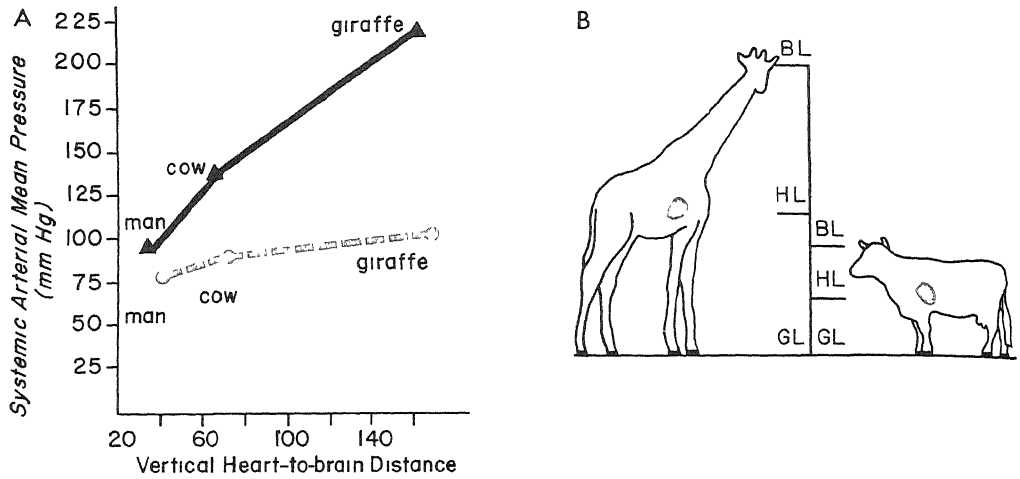

Fig 3 3 *A* mean arterial pressures at the heart level (*solid line*) and brain level (*dashed line*) in man cow and giraffe *B* scale drawing of giraffe and cow indicating relative levels of ground (G L) heart (H L) and brain (B L) (Redrawn from Patterson 1965)

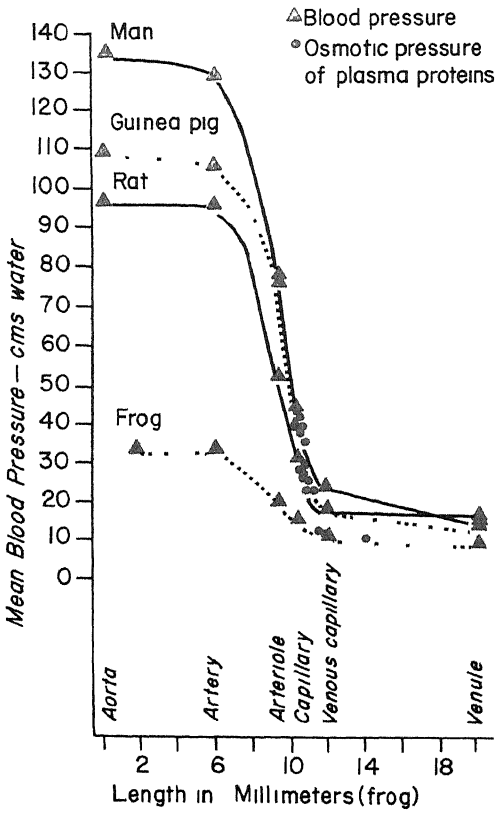

Fig 3 4 The relation between blood pressure gradients capillary blood pressure and osmotic pressure of the plasma proteins in four species (Redrawn from Landis, 1964)

Table 3 1
Relation of colloid osmotic pressure and blood pressure

Animal	Colloid Osmotic Pressure	Blood Pressure
	mm Hg	*mm Hg*
Aplysia	0 02	1 8
Homarus	1 15	8 5
Octopus	3 24	40
"Amphibia"	4 2	50
Oryctogalus	20 2	99
Homo	29 1	120

From Florey, 1966 Data from Florkin and Blum, 1934

remainder is in the heart (about 7%) and the low pressure system (about 79%) Of the latter about 9% is in the pulmonary circuit The low pressure system thus has the greatest capacity and is most dilatable When blood volume is increased as by transfusion, only about 1% is distributed to the high pressure system Thus, the low pressure system serves a reservoir function It is in the low pressure system that receptors for blood volume control are located which are the sensors for fluid volume regulations

The velocity flow (v) varies with the cross-sectional area of the system (Fig 3 2*B*) in accordance with the *equation of continuity* This provides for rapid flows through the relatively narrow distributing arterial and collecting ve-

Regulatory Factors

Complex control arrangements maintain and adjust the distribution of blood pressure, flow, and volume to the various organs within physiological limits

INTRINSIC CONTROL

In the most peripheral part of the circulatory system, through the dimly understood mechanisms of autoregulation, flow is controlled so that with elevation of tissue metabolism flow increases, and vice versa Local cardiovascular control mechanisms govern the caliber of pe-

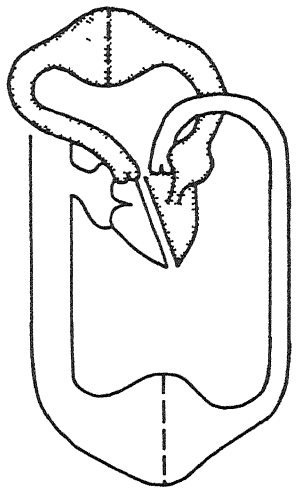

Fig 3 6 Circulation schema depicting blood volume distribution and distensibility of various segments of the circulatory system The shaded segment is the so-called central blood volume region It acts as a filling reservoir for the left ventricle with adjustable volume and compliance This accommodates temporary volume flow changes between the two ventricles and through reflex alterations in vascular compliance determines velocity of flow and pressure transmission across the pulmonary vascular bed In addition this low pressure segment of the circulation contains receptors which sense blood volume changes These initiate reflexes important in fluid volume regulation (From Gauer 1968)

ripheral arteries and thus influence cardiac output They have been shown to operate in the absence of central nervous system and peripheral autonomic innervation (Granger and Guyton, 1969) These controls provide a fundamental regulation which maintains homeostatic stability In individual organs autoregulatory responses occur within 1 to 3 min , while in the whole body their onset is delayed 3 min , or more and requires up to 50 min or more for completion Superimposed on this is reflex regulation (e g , baroreceptor reflexes) which is rapid (appearing within time units of less than 1 min) and long-term adjustments requiring days or weeks (e g , alterations in blood and other fluid compartment volumes)

The basic function of circulation being regulated is the filtration-diffusion process at the exchange vessels all regulations serve to maintain this at the appropriate level set by tissue metabolic needs

Accordingly, a logical place to begin in considering circulatory control is with the microcirculation, where fluid exchanges between blood and tissue fluids occur

Autoregulation Autoregulation is the term applied to blood flow changes in tissue and organs produced by local (or intrinsic) control mechanisms The organ or tissue tends to minimize the effect of changes in perfusion pressure on flow, thus holding flow relatively constant, when pressure is the only variable changed On the other hand, blood flow will increase with elevation of metabolic activity, even though the perfusion pressure remains constant These relations are schematized in Figure 3 8

Autoregulation has been demonstrated in the circulations of the brain, heart, kidney, liver, intestine, and muscle It probably occurs in most, if not all, tissues However, attempts to demonstrate autoregulation in the cutaneous or pulmonary circulations have failed These are called *passive vascular beds* In them there is little intrinsic tendency for flow to be kept constant when arterial pressure is altered, or to

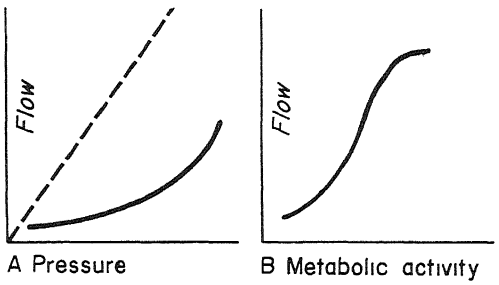

Fig 3 8 *A* The broken line depicts a linear relationship between pressure and flow as would be seen when a Newtonion fluid perfuses a rigid tube system The solid line depicts the pressure-flow relationships when a tissue with constant metabolic activity is perfused at increasing pressures *B* A hypothetical relationship between the level of metabolic activity and flow at constant perfusion pressure is depicted

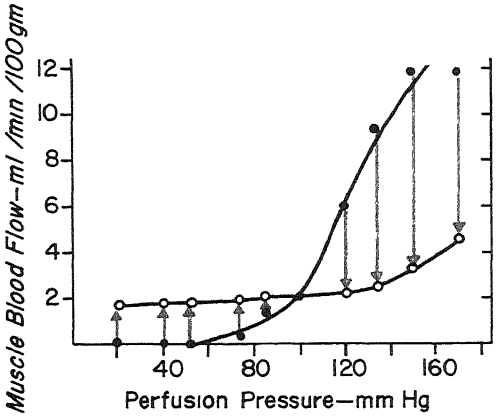

Fig 3 9 Pressure-flow relationships in the skeletal muscle vascular bed of the dog The closed circles represent the flow rates first measured when pressure was changed abruptly from the control level of 100 mm Hg the open circles are the steady-state flows finally attained at the new perfusion pressure The two lines intersect at the control pressure point (From Berne and Levy 1967)

maintain any other variable in the face of tissue metabolic changes

In Figure 3 9, pressure-flow relations are graphed from observations on an isolated skeletal muscle preparation in the resting state Note that the immediate effect of increase in pressure was elevation of flow, which then after 30 to 60 sec , returned toward the control level

Since autoregulation occurs in denervated tissues, reflexes are not necessarily involved However, in the intact animal reflex and hormonal control mechanisms may override local regulation in a particular organ. Several factors have been suggested to account for local circulatory control Among these are. contractile response of vascular smooth muscle to increased tension, variations in amounts of vasodilator metabolites, variations in oxygen tension, and changes in tissue pressure Other possible mechanisms are discussed on p 3–168 In any case, autoregulation is clearly an important local regulatory factor accounting for blood flow distribution consonant with tissue needs Through the mechanisms of autoregulation, nutrient flow and capillary pressure are regulated within physiological limits

In experimental dog preparations in which all nervous control of circulation has been removed by destroying the central nervous system, the vascular system as a whole exhibits substantial, slowly developing autoregulatory responses over periods of 20 to 90 min These responses could develop further with time (Granger and Guyton, 1969) This finding suggests that whole body autoregulation is a deliberately acting control mechanism which ranks along with ner-

vous and humoral control of cardiac output and peripheral resistance in regulating blood pressure

EXTRINSIC CONTROL

Local adjustments of blood flow by intrinsic regulation depend on maintenance of adequate blood pressure within the distributing arteries The mechanical relationships of flow, pressure and resistance in the systemic arterial circulation are, as given before

$$\dot{V}_{as} \quad \Delta P_{as}/R_{as}$$

where $\dot{V}_{as}$ is systemic arterial flow, ΔP_{as}, systemic arterial pressure gradient, and R_{as}, systemic arterial resistance It is clear that when vessels dilate locally and resistance (R_{as}) is lowered, adjustments must occur in flow ($\dot{V}_{as}$) and pressure (P_{as}) All tissues require that a certain pressure be maintained for their autoregulatory mechanism to be effective This is provided for by extrinsic regulatory systems which govern heart rate, blood vessel caliber, and blood volume The components of these extrinsic control systems can be classified as follows effectors heart muscle, vascular smooth muscle, endocrine secretory cells, regulators nerve impulses, hormones, vasoactive substances, sensors nerve receptors, and transmitters nerves, blood stream

A simplified mechanical analog for certain aspects of blood pressure control is the fluid tank with fluid level control (Fig 3 10) The fluid level variable (h, height) is kept constant by a mechanical link, L, which adjusts a valve, a, in accordance with the effect of pressure (height × gravitational acceleration, hg) on an expansible syphon, S The valve, a, regulates flow in, $\dot{V}_i$ Flow out, $\dot{V}_o$, is determined by the fluid level, h

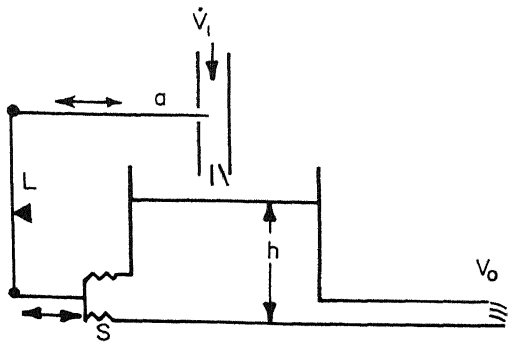

Fig 3 10 Tank with level control

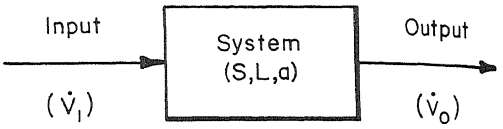

Fig 3 11 Input-output system

This is an *input-output system* with negative *feedback control* An increase in pressure (hg) leads to a decrease in inflow, $\dot{V}_i$

In this system, input and output will be related in accordance with the characteristics of the negative feedback mechanical components S, L, and a (Fig 3 11)

Often, in biology the components of control systems and their interactions are only vaguely understood As a first approximation it is useful to study merely the relationship between the input and output of a given variable, without analyzing the components of the system responsible for the relationship Such a relationship between input and output is called a *transfer function* (Fig 3 12) In some cases the transfer function can be represented by a mathematical equation, in others, only by a table of observed values or a set of postulates or rules [1]

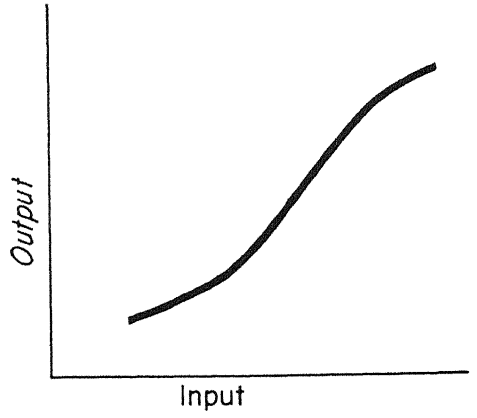

Fig 3 12 Transfer function

The regulation of circulation has as its chief function the maintenance of an adequate *flow* of blood to all organs Given a constant pressure in the distributing arteries, flow can be altered to suit tissue metabolic needs by local

[1] The term 'transfer function' is not used here and subsequently in accordance with its mathematical definition in which for any linear component or any linear system it designates the 'Laplace transform of the output divided by the Laplace transform of the input with zero initial conditions assumed (Riggs, 1970)

adjustment of peripheral resistance However, an increase in flow to one organ would tend to decrease flow to another insofar as a fall in pressure were allowed to occur This is prevented by *sensors* which monitor blood pressure These are mechanoreceptors (stretch receptors) which are activated by changes in arterial pressure and are thus known as *pressoreceptors* or *baroreceptors* Located in the walls of blood vessels (e g , carotid sinus, aortic arch), they indirectly help govern blood flow by detecting changes in blood pressure These are the sensory elements of a negative feedback loop which helps maintain the constancy of blood pressure The *effector* organs are the heart and peripheral arterioles whose level of activity is regulated by *transmitters*, nerve impulses, and humoral agents Thus there is a *controlling system* made up of *regulators* (nervous system, endocrine organs) and a *controlled system* (heart and blood vessels) which govern a *regulated variable* (blood pressure)

These elements of the cardiovascular control system can be formulated as a block diagram in which the regulators are designated *controlling system* and the effectors, *controlled system* (Fig 3 13)

In such a system, certain elements can be examined separately to establish their relations (*transfer functions*) For example, one of the ways the baroreceptors affect blood pressure is through altering heart rate, which, in turn, increases or decreases cardiac output ($\dot{V}$) Thus, heart rate (frequency, F) is related to blood pressure in a baroreceptor (e g , carotid sinus pressure, P_{cs}) somewhat as in Figure 3 14

In curve A, heart rate is plotted as a function (dependent variable) of carotid sinus pressure Represented in curve B is the fact that heart

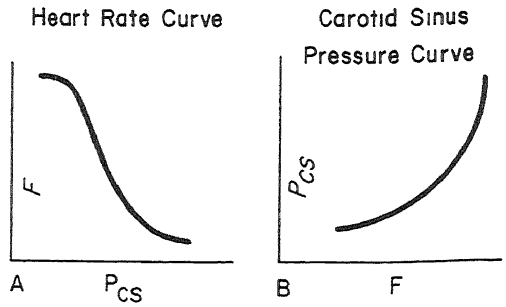

Fig 3 14 Relation of heart rate F and carotid sinus pressure P_{cs} (These and other similar curves are drawn to show the sign of the slope their shape has no mathematical validity)

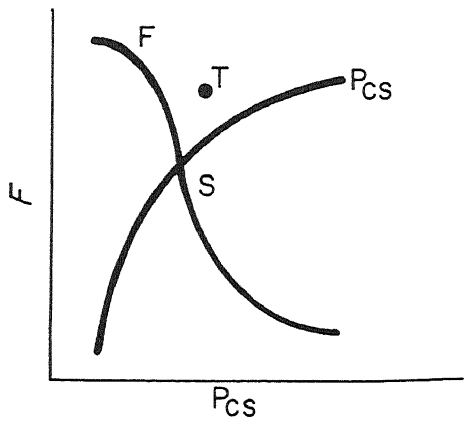

Fig 3 15 Determination of equilibrium (steady-state *S*) values of heart rate F and carotid sinus pressure P_{cs}

rate, as one determinant of blood pressure influences carotid sinus pressure in a predictable way Note that in each graph of a transfer function the input (independent) variable appears on the abscissa, the output (dependent) variable on the ordinate These two graphs illustrate interdependent variables, a common situation in biological control systems How these relations interact to help maintain the blood pressure within certain limits can be appreciated by plotting them on the same graph In this plot the graph B for carotid sinus pressure as the dependent variable is rotated 90° and the carotid sinus pressure ordinate reversed The resulting graph shows an intersection, S, of the curves in A and B (Fig 3 15)

The point of intersection of the two transfer function curves represents the steady-state heart rate and carotid sinus pressure when the system is at rest or undisturbed If some transient influence (e g , exercise, excitement) dis-

places the heart rate and carotid sinus pressure curve point of intersection, say to point T, the two curves will return toward their original positions until they intersect at S, the resting steady-state position or point of equilibrium

The transfer functions depicted in Figures 3 14 and 3 15 show only the influence of carotid sinus pressure on heart rate and heart rate on carotid sinus pressure However, both these variables are subject to other influences These influences can alter the transfer function of either dependent variable Suppose that the sensitivity of the receptor nerve terminals in the carotid sinus were increased by a drug Then its transfer function would be shifted to the right as indicated by the dotted line in Figure 3 16

Thus, for a given carotid sinus pressure, the heart rate would be lower and the equilibrium point would be shifted to the right, a condition which would permit the blood pressure at rest to remain lower than before administration of the drug Should some factor inhibit the heart rate, its curve would shift to the left and the point of intersection change accordingly (Fig 3 17)

A slightly more complex example of control can be illustrated by diagramming two factors known to modify the pumping action of the left side of the heart The basic model is that of a three variable system in which two independent variables, x and y, alter dependent variable z (Fig 3 18)

Cardiac output (left ventricle volume flow, $\dot{V}_{LV}$) is a product of the amount of blood ex-

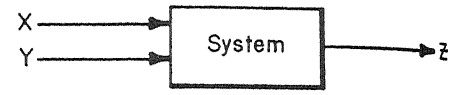

Fig 3 18 A three variable system

pelled with each heart beat (stroke volume, Vs), times the heart rate (frequency, F)

$$\dot{V}_{LV} = F\ Vs$$

Two independent variables which modify left ventricular output are the input pressure in the left atrium (P_{LA}) and the output pressure load (aortic pressure, P_{Ao}) These are related by transfer functions as in Figure 3 19

The intersection of these two curves represents a steady-state condition, s, for given values of P_{LA} and P_{Ao} which determine $\dot{V}_{LV}$ (Fig 3 20)

The two independent variables, P_{LA} and P_{Ao} can be diagrammed as a three variable system with two feedback loops, which act upon a controlling system (nerves, hormones, intrinsic ventricular muscle factors) to regulate a controlled system (left ventricle) such that its output tends to remain stable (Fig 3 21)

By experimentally holding one of these independent variables constant and altering the other, their individual roles in governing $\dot{V}_{LV}$ can be determined Results of such experiments in dogs are shown with a three-dimensional plot in Figure 3 22 In this figure it can be seen that at low left atrial pressures (P_{LA}) an increase in aortic pressure (P_{Ao}) has little effect on $\dot{V}_{LV}$ until high aortic pressures are attained. At high left atrial pressures, the influence of increased aortic pressures is greater Similarly, at high aortic pressures, decreases in left atrial pressures have little effect until low atrial pressures are reached However, at low aortic pressures, the influence of increasing left atrial pressure (P_{LA}) on $\dot{V}_{LV}$ is much greater

Thus far only control arrangements governing cardiac action have been considered Resistance (R_{as}) to flow out of the arterial system ($\dot{V}_o$) is also regulated in a similar way to

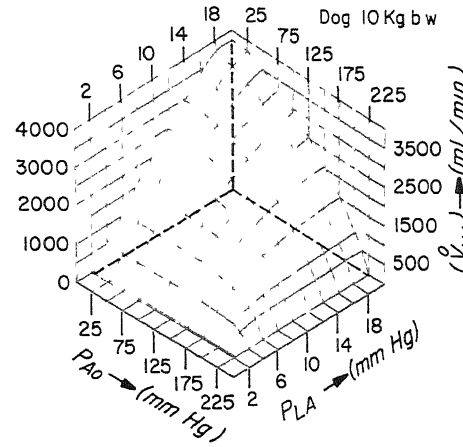

Fig 3 22 A three dimensional plot of mean aortic pressure (P_{Ao}) mean left atrial pressure (P_{LA}) and cardiac output ($\dot{V}_{LV}$) (From Milhorn 1966 by K Sagawa)

oppose changes in blood pressure Constriction and dilatation of arterioles, causing alterations in resistance, occur in concert with cardiac output changes to maintain homeostasis of blood pressure Intrinsic factors within the tissues adjust arteriolar caliber to permit flow changes appropriate to tissue metabolic needs Feedback control loops involving the baroreceptor sensors also act through nerves and hormones to produce vasoconstriction or vasodilatation in various tissues, as required to maintain blood pressure and adequate flow

Although the chief requirement of these control systems is to maintain an adequate *flow* of blood, the main sensors detect pressure changes Flow receptors are not known in the circulatory system

The controls described thus far act rapidly to effect their adjustments in a short period of time i e , *short-term* regulation Such adjust-

ments are effected within time intervals of seconds, minutes, or, at most, a few hours

Long-term regulation is also present, effected through mechanisms which govern body fluid volume, vascular tone, and vascular capacity These in turn alter blood pressure, cardiac output, and vascular resistance, producing or opposing sustained deviations in pressure and flow distribution Long-term adjustments require days or weeks and thus operate slowly

Functional Characteristics of the Systemic Circulation

VOLUME FLOW

The anatomical complexity of the circulation may obscure some basic facts which have been stressed The volume flow of blood through any part of the circulation must equal that flowing through any other part There may be regional shifts of flow so that some arteries or capillaries carry more or less flow than in other arteries or capillaries, or there may be a small difference in the blood volumes put out by the two ventricles, but the former does not affect the relative total flow through the capillaries and arteries while the latter can only exist momentarily for a few heart beats, else the organism dies

BLOOD CONTENT

The blood content of different areas is not constant but is continuously changing and is available for redistribution to other vascular areas where it may be needed The volume in any one compartment depends not only upon the basic anatomical size of the bed but upon dynamic changes induced by passive and active changes in capacity and content, i e , distensibility

Basic control. Blood storage can be on a long term basis (blood reservoir) or it can change rapidly during a cardiac cycle (compression chamber). Both are dependent on the blood content of the cardiac cavities and of the vessels at zero internal pressure and on their distensibility, i e , change of diameter and length with change of internal pressure, in turn, the basic distensibility of the cavities is governed by the myocardial resistance to stretch For example, the distensibility of a heart cavity actively changes if, for the same resting size or volume, the pressure within the cavity is altered The distensibility of the ventricles can be grossly altered by nervous, humoral, and other influences The distensibility of the vessels is governed by their content of elastic and collagen tissue and smooth muscle (Fig 3 23) All varieties of blood vessels except the arterioles, capillaries, and venules, have a prominent component of elastic tissue, and in some vessels such as the aorta, as much as 40% by weight is elastic tissue The elastic fibers with their great range of extensibility before their elastic limit is reached, produce maintenance tension without energy expenditure against the normal blood pressure In the wall of every type of blood vessel except the capillary, there are white collagenous fibers in a matrix penetrating between the other elements The collagenous fibers act in a similar way to the elastic fibers but, because of the architecture of the wall, are stretched only at higher than normal blood pressure and have a protective supporting role (Fig 3 23) If, however, the vessels reacted in a purely passive way based on their content of collagen and elastic fibers, their internal pressure would be determined only by the volume of contained blood and, at any constant mean pressure the mean volume of blood within them would also not change However, many types of vessel contain much smooth muscle which does not contribute significantly to the elastic tension of the wall Its function is to produce active tension under vasomotor stimulation or local action of various chemicals (vasodilator and vasoconstrictor substances and oxygen lack) and so change the size of the lumen Such vascular tone adjustment is seen in most vascular areas It counteracts distensibility by inducing smooth muscle reaction which, at times, is strong enough to induce a net decrease in vascular lumina in the presence of an elevated pressure Such activation will, of course, change completely the pressure-volume relationship in a vascular bed or area

Aorta and its Arterial Branches. The pressure-volume relationship or distensibility of the isolated aorta has been exhaustively studied in vitro The distensibility varies widely in different aortas in the same age group (Fig. 3 24) There is no statistically significant correlation

between age and absolute distensibility However, aortic size or capacity increases considerably with age so that the average diameter of the aorta may exceed that of the sum of its branches and the contained volume at a diastolic pressure of 80 mm Hg may almost double This shift toward larger volumes with increasing age indicates that the enlarged aorta does not now need to expand as much to accomodate the same systolic ejection The distensibility of an isolated aortic segment studied in vivo and in vitro differs mildly during its inflation and deflation, the resulting curves forming a loop (Fig 3 25) This is presumably because of hysteresis of the elastic fibers

Although such studies aid in orientation, there is no guarantee that the characteristics of the aorta or, indeed, any vessel postmortem apply to conditions in the intact normal animal or man Since the systemic arterial system contains only about 14% of the total blood in the systemic circulation, even if smooth muscle contraction reduced its volume by 25% (or 175 ml) its function as a reservoir would be small Actually, during systole and cardiac ejection, much of the pressure and flow are transferred immediately to the periphery However, the aorta and some of its immediate branches belong to the elastic type of arteries, i e , elastic tissue is abundant and muscle fibers are relatively scarce Because of their large distensibility, the walls of these large central arteries act as compression chambers which serve to buffer the more peripheral branches from too sudden an increase in pressure and flow The volume of blood suddenly injected into the aorta by the powerful ventricular action is only partly moved forward, a considerable portion is stored locally by the successive expansion of the large vessels Although earlier work indicated that there is no radial expansion of the aorta beyond the arch, later work using cinematographic

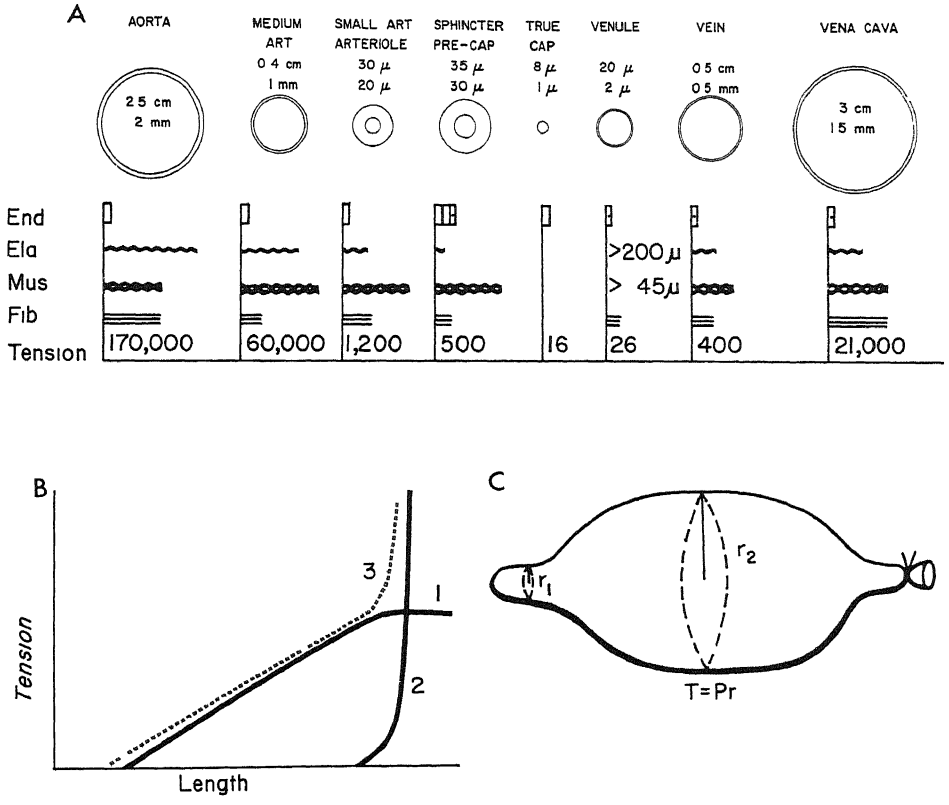

Fig 3 23 Illustrated are the lumen diameters wall thickness relative amounts of different tissues and wall tensions in the various blood vessels *Lower left* Tension-length diagrams of elastic *1* and collagen fibers *2*) presented alone and in combination *3*) *Lower right* balloon demonstrating pressure-tension relation The pressure (*P*) within the balloon is equally transmitted to all parts of the contained air (Pascal s law) and the tension (*T*) in the balloon varies with the radius (*r*) in that portion Laplace s Law (Modified after Burton 1954 and Wolf 1952)

films at 1500 frames/sec showed dilation of the thoracic aorta during systole of 15 to 20% of its diastolic diameter which corresponds to a 30 to 40% increase in volume per unit length of the artery, radial enlargement of the more distal aorta was somewhat less. Thus it is estimated that up to one-half of the pressure and flow discharged during systole is stored here and that this moves forward during diastole through the elastic recoil of the arterial walls. This enables a portion of the blood to run off into the capillaries during diastole and not during systole.

Whether active changes in aortic distensibility normally occur is only incompletely investigated. Simultaneous measurements have been made of phasic aortic blood pressure by an appropriate pressure manometer and of changing aortic circumference during a cardiac cycle. In the open-chest dog or man the latter is obtained by noting the movement of a pair of recording mechanical calipers placed around the aorta. In the unanesthetized dog, aortic circumference is detected by measuring the changing resistance in a mercury-filled rubber tube wrapped around it. In the open-chest dog, when the arterial blood pressure is elevated to a high level by mechanical constriction of the aorta, the size of the aorta during diastole initially increases but then decreases in the presence of an elevated internal pressure, and at the same time, its distensibility increases, i.e., the pulse pressure becomes larger. A large intra-arterial injection of adrenaline constricts an aortic segment being perfused in vivo so that it may contain less than half the volume of the normal aorta in the low pressure range, while in the high pressure range the volumes are almost equal, i.e., the constricted aorta now has a much greater distensibility than the normal aorta. These changes are presumably related to active changes in the smooth muscle which is abundant in these vessel walls. However, these experiments must be interpreted cautiously, for preliminary measurements in intact unanesthetized dogs have shown an intimate relation between the aortic pressure and aortic circumference. Thus, the actual amount of and the significance of active alteration of aortic size under changing physiological states is not known.

The more peripheral arteries such as the carotid, brachial, and femoral and their branches, are predominantly muscular types of arteries

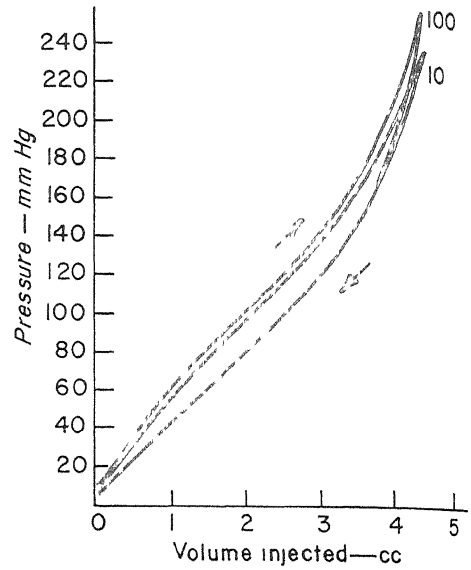

Fig. 3.25. Pressure volume diagrams obtained from an isolated segment of thoracic aorta by injections and withdrawals (*arrows*) at rate of 10 and 100 ml of blood per minute (Alexander 1954a)

containing circularly arranged smooth muscle fibers in large numbers which, by their shortening, can reduce the lumen of these vessels considerably Such a set-up obviously permits adaptation or adjustment of this distributing system to accommodate changing volumes of circulating blood This is initiated by heat, cold, trauma, and many other physiological events In the latter instance, pressure-volume curves done in situ on small (1 2 mm or less internal diameter) and very muscular arterial segments of the intestine showed that with elevation of the aortic distending pressure, directly or through an increased portal venous pressure, the segment diameter may actually decrease Since intra-arterial procaine did not block the response and since the vessel constriction was abolished after ischemia, papaverine or cyanide, an active response of the arterial smooth muscle wall (and probably of myogenic origin), is suggested which is caused by the elevated wall tension

It can also be demonstrated that the femoral artery dilates in response to contraction of the peripheral muscles This persists with local nerve section, occurs only on the stimulated (active muscle) side, and is abolished by local procaine or cutting of the artery distal to the point of measurement of femoral artery volume Therefore, the response is by way of a conducting system in the arterial wall The velocity of such peripheral conduction is 10 cm/sec , and therefore, the conducting elements are probably the smooth muscle of the media of the vessel wall

Arterioles The arterioles contain the smallest blood volume of the cardiovascular system, but the pressure and flow in the circulatory system are more sensitive to minute changes in blood content of the arterioles than to that of any other part of the circulatory system The arterioles are the final or end branches of the distributing system and operate as stopcocks which control the run-off of blood from the arterial system into the capillaries The caliber of these vessels is controlled by the state of contraction of their circularly disposed and strongly developed smooth muscle fibers The latter are regulated by local metabolic process and by blood borne substances They are also supplied with vasomotor fibers which are controlled by centers in the spinal cord and medulla Their distensibility other than through myogenic change has not been determined.

Capillaries The blood content of the capillaries (300 ml) is also very small The arteries, even as far as the commencement of the true capillaries, are impervious The total filtering surface by the capillary endothelium in the adult human body amounts to about 6300 m ^{2} (68,000 ft ^{2}) The summed areas of the capillary walls in all regions could be imagined, therefore, as constituting an endothelial membrane over 12 miles long and a foot wide, yet so thin that when tightly rolled, it would form a cylinder of about the thickness of a lead pencil

The capillary wall proper is composed of a single layer of endothelial cells and is about the most tenuous structure conceivable (Fig 3 26) It does not exceed half a micron in thickness The endothelial cells which are flat are joined at their fringes by a so-called "intercellular cement" which fills in between adjacent cells The cellular area makes up more than 99% of the total area across which exchange takes place, the small nonliving zone (cement) less than 1% The cement substance which binds the endothelial cells at their edges is being continuously washed away and renewed again by the endothelial cells Its basic structure is a porous network of a complex cement substance, presumably a calcium proteinate At one time it was thought to be hyaluronic acid, but this idea is no longer held Superimposed on this network, either by electrical, chemical, or surface tension forces, is a large adsorbed molecular component of protein which lines the inner surface and plugs most of the large pores in the cement, considerably reducing the perviousness of the structure The capillary endothelial tube is enclosed and supported by a delicate sheath or membrane of fine fibrils derived from or closely related to the surrounding connective tissue The intervening space between capillary and this membrane contains a freely moving fluid Surrounding this in the interstitial spaces

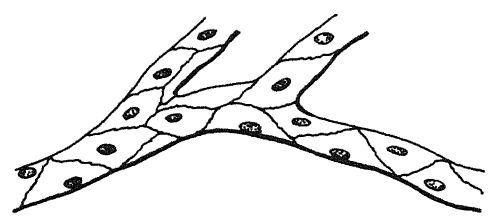

Fig 3 26 Section of capillary wall stained with silver nitrate to demonstrate the intercellular cement Nuclei of the cells stained with hematoxylin

is the so-called tissue fluid which is of a gel-like consistency

It is still debatable whether the bulk of exchange occurs across the entire surface area or is restricted for most molecules to the pervious intercellular cement Ions and small molecules diffuse across the capillary wall at such an incredibly fast rate (at least 100% exchange within 1 min) that it has been suggested that the whole capillary wall is permeable to these substances The penetration, however of capillary walls by water and dissolved substances appears to take place solely by processes which require no energy transformation by the capillary endothelial cells From this has arisen a general belief that the capillary walls, or specifically the intercellular cement, is pierced with numerous ultramicroscopic openings or pores with an average diameter of about 30 Å which are generally too small to allow the passage of plasma protein molecules, but are of sufficient size and number to account for the observed rates of passage of water and nonprotein constituents of the plasma Considerable evidence has been adduced that lipid soluble molecules, such as oxygen and carbon dioxide, can penetrate rapidly the plasma membranes of the capillary endothelial cells and are not restricted to the aqueous intercellular spaces Finally, the evidence is fairly clear that penetration of large molecular aggregates and formed elements, such as the red and white cells, occurs through the intercellular portion of the wall The presence of vesicles in capillary endothelial cells which can take up tagged protein molecules, suggests that a process analogous to pinocytosis plays a role in the transport of large molecules across the endothelium Capillary permeability is by no means uniform throughout the body For example, skeletal muscle capillaries are about 100-fold less permeable to water than the glomerular capillaries

The functional anatomy of the capillaries has been worked out for some cold-blooded animals, for the rat and dog mesentery through microscopic observations of the in vivo vessels, and for the myocardium by both anatomical and microscopic observations (Fig 3 5) Briefly, blood flows generally from the arterioles directly into a metarteriole, and then into capillaries The metarterioles lead directly into channels which are main thoroughfares from the capillary bed to the venules The true capillaries concerned with interchange between blood and tissues are interanastomosing side branches of the main channels through the bed At the ostia of each capillary is a small precapillary sphincter of smooth muscle which is controlled by nerves presumably from the sympathetic nervous system, in the same manner that these nerves control the arterioles and metarterioles In the body, the metarterioles and their precapillary sphincters undergo periodic contractions at intervals of 15 sec to 3 min When the tissue is in a resting state, the constrictor phase of this rhythm predominates and the precapillary sphincters may be completely closed When the tissue becomes active, the dilator phase of the metarterioles predominates and the precapillary sphincters are open Thus, in skeletal muscle, it is believed that the increase in blood flow with exercise comes in large measure from this opening up of large numbers of additional capillaries It is believed that the factors that affect the degree of constriction and relaxation of the metarterioles and the precapillary sphincters during vasomotion are the same factors that affect arteriolar diameters These are the nervous and hormonal stimuli and local conditions in the tissues Thus, sympathetic stimuli and epinephrine in the blood intensify the constrictor phase of vasomotion in most areas of the body in the same manner that these two constrict the arterioles On the other hand, vasodilator substances decrease the vasoconstrictor phase The significance and value of this arrangement generally to capillary beds and to overall circulatory dynamics remains to be established

Although controversy has raged for many years, at present it is believed that change in capillary diameter is on a purely passive basis, i e , by change in intracapillary pressure or in extravascular tissue pressure, supposedly, the active changes in capacity previously described by many workers is probably due to the activation of smooth muscle whose presence was unsuspected at that time in the metarterioles and precapillary sphincters

Capillary Exchanges. The hydrostatic and osmotic forces causing fluid exchanges across the capillary membrane are discussed on p 3-148, and in chapter 12 of section 4 They account for the net exchange, the "bulk flow", in which noncolloidal plasma constituents move in and out of the capillary together The concept, known in classical forms as the Starling hypothesis, supposes that filtration occurs

at the arteriolar ends of capillaries and absorption at the venular ends While this relationship may occur in a given capillary, a decrease in precapillary resistance may increase pressure and flow so that filtration takes place along the entire length of a given capillary Conversely, the capillary pressure may be reduced below that of colloid osmotic pressure so that the vessel acts entirely as an absorbing unit

Such bulk flow explains fluid shifts between the plasma and extracellular compartments However, it contributes little to the actual rate of exchange of materials between plasma and interstitial fluid Diffusion is the prime determinant of transcapillary exchanges and for a given solute may proceed along a concentration gradient in a direction opposite to net bulk flow

Veins Since the systemic veins contain such a large proportion of total blood volume, they must function as blood reservoirs The responses by which they may counteract distending forces and thus prevent excessive pooling of blood have been of great interest and have been documented in animals and human experiments As the venules merge to form larger veins, they acquire a layer of connective tissue and then distinct muscle fibers These vessels have a larger blood content than the corresponding arteries Their walls are also much thinner and contain less elastic tissue but have a rather well-developed muscular coat When the volume of blood in a normally partially collapsed vein is augmented, the intravascular pressure barely increases until the vein becomes round and has a certain degree of fullness The volume increase up to this point is similar to the filling of a collapsible tube without distending the walls True distension now occurs when further volume increments lead to an elevation of intravascular pressure (Fig 3 27) Veins excised or within the organism have a very low distensibility when the increase in volume is rather rapid With prolonged elevation of intravenous pressure, there is a delayed compliance or passive yielding of the venous walls which is attributed to the viscoelastic properties of the smooth musculature Thus, although initially the low distensibility of veins may prevent blood pooling, the delayed compliance favors it It is estimated that the ability of the venous system to take up blood is at least 100 times that of the whole circulatory system Thus, if 1000 ml of blood is transfused in a human, about 990 ml will reside in the extra-arterial or low pressure system, and 10 ml in the arterial system

The diameter of these venous capacitance vessels may be changed either passively by external forces (gravity, respiration, or pressure breathing) or actively by contraction or relaxation of their walls There is considerable evidence to indicate that the venous system (including the pulmonary system) behaves somewhat like an elastic bag For example, change in posture has no particular effect on their state of contraction when human subjects are bled or transfused with about 500 ml of blood the pressures in the central veins, the pulmonary artery, and left atrium rise and fall in parallel as the blood volume is changed by bleeding or transfusion (Fig 3 28)

While this leads to the conclusion that the venous system operates in a passive manner, it must also be emphasized that this may be true only if the induced changes in central blood volume are moderate or gradual and not in the nature of emergency reactions It is easy to demonstrate that a fixed pressure-volume relationship need not apply to the veins and venules for they are the most sensitive of all vessels to all types of mechanical, chemical, and temperature impacts For example, the trauma attendant to dissection or to needle insertion may completely close a medium-sized vein In addition, they are supplied with vasomotor nerves through the action of which the distensibility and capacity of the venous system can be actively and greatly changed This provides a means by which the volume of the venous system can change within wide limits without significant corresponding changes in venous

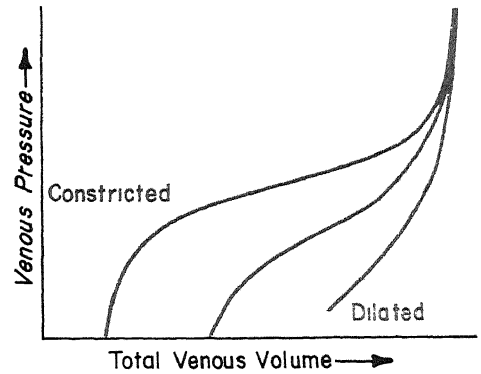

Fig 3 27 Venous distensibility patterns with different degrees of vasomotor tone (Alexander 1954b)

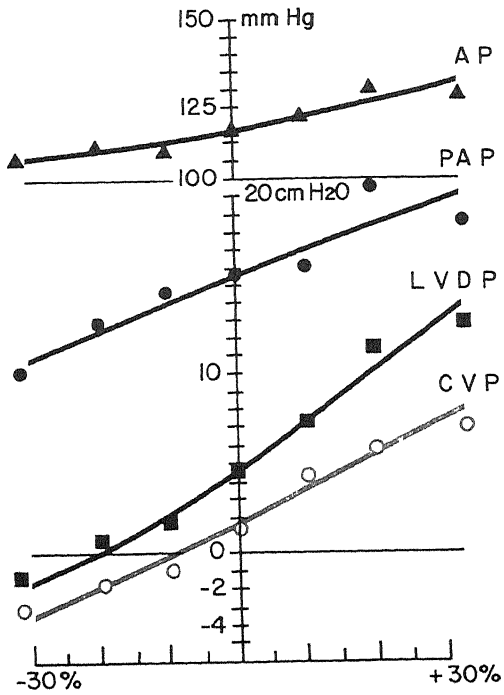

Fig 3 28 Effects of changing total blood volume (by transfusion (+) or bleeding ( )) upon aortic (A P) pulmonary artery (P A P) left ventricular diastolic (L V D P) and central venous pressures (C V P) (Gauer and associates 1956)

pressure Such innervation has been demonstrated for the vena cava and veins of the hind limb and mesentery in animals Active contraction or relaxation of the venous smooth muscle (venoconstriction or dilation) can be elicited by activation of local stretch receptors in the venous walls, and reflexly by activation of the baroreceptors (stretch receptors) in other veins and in the aorta and carotid arteries, by hypoxic stimulation of the carotid chemoreceptors, and by direct local action of adrenergic or cholinergic substances (Fig 3 27) The reflex venoconstriction produced by carotid artery occlusion in dogs can be abolished by the administration or reserpine or guanethidine, suggesting that these reflexes are mediated through the sympathetic nervous system Reflex venomotor activity has also been measured in normal subjects by means of pressures developed within isolated segments of superficial veins An arm superficial vein segment without tributaries is temporarily isolated by applying pressure at the segment ends so that the volume is held constant and vein contraction can be reflected by an increase in pressure which is recorded continuously by an indwelling needle connected to a pressure manometer Changing from the supine to the erect posture results in venoconstriction, as indicated by an increase of the venous pressure within the isolated segment, on resuming the supine position venodilatation occurs Reduction of the circulating blood volume by means of phlebotomy also produces an increase of the venous tone Strong contractions are caused by the Valsalva maneuver, cold, exercise, and hyperventilation Persons with postural hypotension or with absent circulatory reflexes (as in tabes dorsalis) show little or no segment or central venous response to these stimuli, indicating impaired reflex venomotor activity Although the entire venous bed may be regarded as a large variable blood depot, the central systemic veins constitute the most important part of this depot for supplying the right heart It is estimated from observations in dogs that the pressure-volume curve of the venae cavae in the intact living dog can be varied by 15 to 20 times and with only a small effect on venous pressure This means that translocation of large volumes of blood to the pulmonary and systemic arterial circuit is easily effected

VELOCITY CHANGES

In Different Vessels (Fig 3 2B) Just as the cross-sectional area varies greatly in different parts of the cardiovascular system, so does the velocity of blood flow Since the velocity of flow is inversely proportional to the cross-sectional area of the vessel through which it flows, velocity will be maximal in regions of the circulation with the smallest total cross-sectional area Hence, the blood velocity in the aorta is the most rapid of that in any part of the body, but even here the average velocity of about 40 cm /sec , is low In the capillaries, it is least, at about 0 07 cm/sec This slow rate of passage in the peripheral capillaries, of course, provides time for the exchange of materials across the capillary membranes or walls After passing into the veins, the blood again accelerates as the cross-sectional area progressively decreases However, since the caliber of the veins is larger than that of the corresponding arteries, the velocity of venous blood flow never becomes equal to that of the arterial blood and generally equals about one-fourth of that in the arteries For example, the flow of blood along the two venae cavae which together have a cross-sec-

tional area some four times as great as that of the aorta, is only about 8 to 10 cm /sec under resting conditions

Although the average blood velocity is low the peak velocity of blood flow may be high since this changes greatly from moment to moment during each heart beat in the systemic arterial system In the ascending aorta near the aortic valves, the peak velocity during systole may be 120 cm /sec , during most of diastole, the velocity may approximate zero Further down the thoracic aorta and in the abdominal aorta, the small backflow present in the ascending aorta at time of closure of aortic valves is greatly accentuated and extended, while forward flow during diastole is increased In the major aortic branches these violent fluctuations of velocity, although somehwat damped, are largely retained However, except for the coronary, femoral, and axillary arteries, backflow disappears, and the flow curve is often patterned after its corresponding pressure pulse At the capillary level, these fluctuations in velocity are pretty well removed so that a smooth rate of flow is attained In the venules and as the veins become larger, fluctuations or variations in the velocity of flow again reappear In the venae cavae near the right atrium, blood velocity may become much greater during ventricular systole than during its diastole, indicating that contraction of the myocardium itself draws blood toward the heart, not to be confused with *vis a fronte* or cardiac suction (see p 3-103) During inspiration, the whole flow curve in the venae cavae is greatly elevated

Across a Blood Vessel Finally, the velocity of flow will vary in different portions of the cross-sectional area of a blood vessel, especially in the larger vessels (Fig 3 29) In the larger vessels there is a cylindrical layer of blood which adheres to the vessel wall and wets it Inside this motionless layer is another cylindrical fluid layer which flows and rubs against it, and inside this there is another flowing faster, and so on, until the central axial core of blood is reached which has the maximum velocity In arterioles and vessels of quite narrow caliber, red cells are concentrated pretty much in the axial part of the blood stream so that plasma flows along the walls As a result, the red cells move faster than plasma by a significant amount, and hence, the hematocrit in capillaries is somewhat less than that of the larger vessels The effect of this is, of course, to change the distribution of the velocity in the various parts of a cross-section of such a vessel

The flow of blood is laminar or streamlined in most portions of the circulatory tree When the velocity of flow is increased above some critical level turbulence develops

Reynolds' or Random Turbulence The factors determining whether flow is laminar or turbulent include the average velocity of flow, $\bar{v}$ (cm /sec) the vessel diameter, D (cm), the density of the fluid, ρ (about 1 05 g /cm ^{3} for blood) and the viscosity of the fluid, η (about 0 035 to 0 05 poise for blood) The conditions required for laminar flow to become turbulent can be defined when a dimensionless quantity known as *Reynolds' number*, N_R, exceeds a critical value in accordance with the following relation

$$\text{Revnolds' number} = N_R = \bar{v}\, D\rho/\eta$$

The critical value of Reynolds' number for blood flowing through rigid tubes is approximately 2000 In man this value is not exceeded in most parts of the circulation (see Table 3 4), except in the aorta and pulmonary artery where values of 3600 to 5800 or higher may be reached (Schultz et al , 1969) High rates of flow (as in exercise) or decreases in viscosity (e g , in anemia) favor turbulent flow, since cardiac murmurs may be heard over these large vessels during systole in high flow states or anemia, they have been attributed to turbulence However, it is doubted that random turbulent flow can produce sufficient acoustic energy to be audible at the thoracic surface

Aeolian Tones or Fluttering Turbulence and Vortex Formation The forces which produced the musical tones of ancient wind harps of the Greeks probably account for murmur production (Bruns, 1959) As fluid flows past an obstruction or through a stenotic area, vortices or

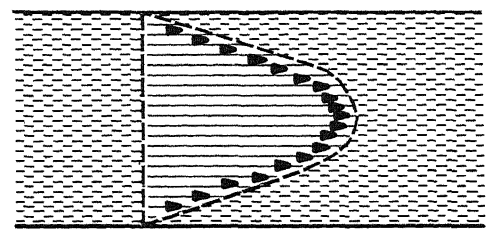

Fig 3 29 Schematic representation of the variable velocity of blood flow in vessels Flow is fastest in the central axial stream and progressively decreases to zero at the vessel wall

swirls are formed which pass downstream as a fluctuating wake Such periodic wake fluctuations generate vibrations in the audible frequency range This kind of turbulence, rather than the random turbulence of Reynolds', probably accounts for most cardiovascular murmurs

PRESSURE CHANGES

Kinetic and Potential Energy Lateral and End Pressure Of the energy developed by the left ventricle, more than 98% is normally in the form of potential energy, 1% or less as kinetic energy When the left ventricle pumps out blood, it increases the radius and length of the aorta and its large branches to store potential energy as tension in the arterial walls Because of the motion (velocity) of the blood during ejection, a certain amount of kinetic energy is also transferred to the blood During exercise with a very large cardiac output or in the presence of aortic stenosis, as much as 10 to 50% of the energy expended by the heart is used for increasing blood velocity Ultimately, however, most of the potential energy is changed to kinetic energy to produce flow through vascular elements, and then is finally dissipated as heat through friction The kinetic energy of flow can have a real effect on intravascular pressure This can be demonstrated by inserting into the flowing bloodstream small catheters or cannulas connected to pressure manometers (Fig 3 30) With the catheter opening pointing upstream, end pressure or potential energy is measured, with the opening at right angles to direction of flow, *lateral* pressure or the pressure actually pressing on the vessel is measured In the vessels of humans, end pressure and lateral pressure are almost equal except in the aorta and its immediate branches in which the kinetic energy is sufficiently high from prevailing blood velocity to cause the lateral pressure to be significantly lower, i e , lateral pressure is inversely proportional to the blood velocity (Bernoulli effect) At rest, the average aortic lateral pressure is about 1 mm less than the end pressure, with exercise, the difference might be 15 mm Hg If one is recording phasic aortic pressure throughout the cardiac cycle, then with exercise the lateral pressure might be 40 mm Hg less than the end pressure during the period of rapid blood ejection (first third of systole) Ultimately, most of the potential energy is converted into kinetic energy in producing flow In this exchange no energy is lost However, as

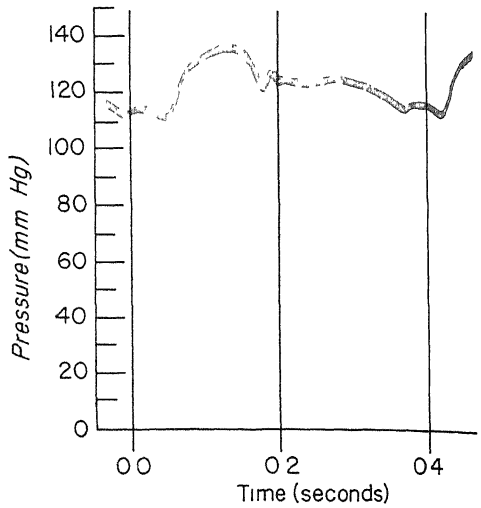

Fig 3 30 Reproduction from original record of lateral upstream and downstream phasic pressure patterns taken at the subclavian level in the aorta of a large open chest dog by means of three strain gauges adjusted to identical zeros and sensitivities The patterns and pressure values of the three curves are almost identical at systolic pressure 139 mm Hg diastolic pressure 115 mm Hg heart rate 150 min

blood progresses from the aorta to the atrium, the intravascular pressure decreases to very low values This permanent loss of energy or pressure arises from fluid friction developed within the vessels with gradual change of energy into heat

In different vessels (Fig 3 2C) Pressure in the aortic arch reaches a maximum during mid systole, and a minimum at the end of diastole The numerical difference between these pressures is called the "pulse pressure " Similarly, pressures in the thoracic and abdominal aorta and their major branches, i e , the carotid, the radial, and especially the femoral, show that the values for the systolic pressure increase and those for diastolic pressure decrease, i e , pulse pressure increases In still smaller arteries, the pulse pressure progressively diminishes, systolic pressure falling more than diastolic However, this does not represent a frictional loss of energy but merely a replacement or shift in the temporal relations of pressure during a cardiac cycle, since the mean pressure, for example, in the femoral arteries is close to that in the aorta

As the arteries divide and subdivide, the caliber of the individual vessels diminishes and the pressure gradients become correspondingly steeper, particularly in the arterioles and capillaries Not only is the pressure gradient steeper,

but the oscillations of pressure during a cardiac cycle are reduced to a minimum at the time the arterioles are reached At the arterioles there is a pronounced decrease in pressure gradient, a second abrupt decrease in the capillaries with almost no residual pressure fluctuations A more gradual pressure decline occurs in the venules and veins until a negative pressure is actually reached in the central veins owing to the effect of the subatmospheric pressure within the thorax

Functional Characteristics of the Pulmonary Circulation

In many respects the pulmonary vascular bed (pulmonary artery through pulmonary veins) is similar to the systemic circuit but certain differences deserve emphasis The pulmonary circulation is a low resistance circuit, arterioles being essentially absent, the pulmonary vessels supply only one type of tissue (alveoli) so vasomotor requirements are low, pulmonary blood volume is less than that in the systemic circuit, extravascular conditions (within the thoracic cage) are fairly uniform (Fig 3 31)

The main pulmonary artery and its branches are structurally similar and of about the same or slightly larger diameter than the aorta, but their walls are one-third the thickness and their branches are much shorter and of very small capacity Small arteries in both systems have thick muscular walls Arteries less than 0 1 mm in diameter are endothelial tubes without muscle There are no vessels corresponding to arterioles, i e , no small bore high resistance vessels The capillaries are somewhat larger, appear to take off very densely from the above endothelial tubes, and have multiple anastomoses There are numerous AV shunts The pulmonary veins are short and contain less blood than the systemic veins

The pulmonary artery and pulmonary bed in general are many times more distensible than the systemic portion of the arterial circuit and probably represent the most distensible part of the low pressure system Simultaneous pressure and diameter measurements of the main pulmonary artery in living, thoracotomized dogs show a linear relationship over relatively wide ranges of pressure up to 50 cm water The pressure and diameter pulse contours are almost identical, indicating minimal inertance and viscous resistance of the vessel wall In vivo pressure-volume curves of the entire pulmonary vascular bed and of the pulmonary veins (and left atrium) have pretty much the shape of venous pressure volume curves in the relaxed state (Fig 3 31) The blood volume of the pulmonary system is only about 10% of the total blood volume of which about 60 to 80 ml is in the capillaries, and the rest is in the major arteries and veins Since the pulmonary vessels are a low pressure distensible system, a minute increase in outflow pressure at the left ventricle or an increase in pressure at the right ventricle results in a sizeable accumulation of blood in the lungs Thus, the blood volume of the pulmonary vascular bed has an important reservoir function and is about the most important depot for supplying the left heart

The pulmonary circulation has been considered as a variable blood reservoir which serves to supply the left ventricle with a steady supply of blood, thus buffering changes in venous return to the right heart It was believed to function more or less passively to shifts in blood volume caused by systemic venoconstriction, changes in blood volume and variations in ventilation This is an oversimplication (Heinemann and Fishman, 1969) The pulmonary circulation is under sympathetic control and as sympathetic tone increases, the compliance of

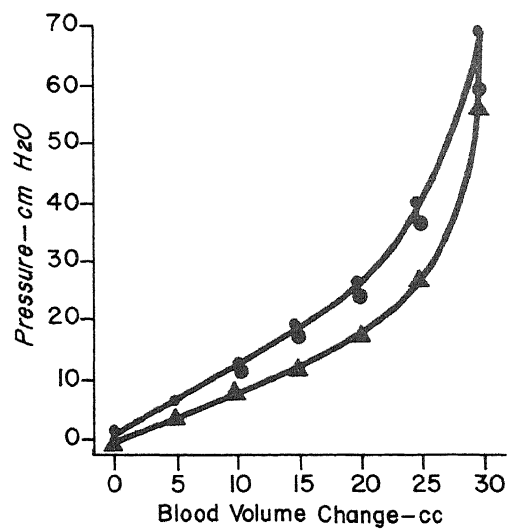

Fig 3 31 Pressure volume relationship of the pulmonary vascular bed Injections and withdrawals made at 10-sec intervals Dots pressures immediately after end of each injection Closed circles pressures 5 sec after end of each injection Triangles pressures immediately after each withdrawal From Sarnoff and Berglund 1952)

the pulmonary vessels decreases This improves pulsatile blood flow transmission from right to left ventricle (see p 3-125) Changes in tone of the pulmonary vascular tree, thus, play a role in maintaining appropriate delivery of blood to the left ventricle and are probably more important than reservoir function in rapid circulatory regulations In pathological conditions, the blood reservoir function is obvious Thus in left heart failure pulmonary blood volume increases, while it diminishes in hypovolemic shock

Since the stroke volume and mean velocity of flow are almost identical in the aorta and pulmonary artery, the kinetic energies of the two bloods are the same, but because the potential energy imparted to the blood by the right ventricle is much less, the kinetic factor is a greater proportion of the energy output of the right ventricle Phasic variations in blood flow velocity are possibly even more marked in the pulmonary artery than in the aorta In contrast to the systemic circulation, a markedly pulsatile flow is retained in the pulmonary capillary bed during rest and after exercise During systole, blood is accelerated in the right ventricle and pulmonary artery by contraction of the right ventricle The blood gains kinetic energy or energy of motion As blood distends the arterial tree, the latter acquires potential energy (elastic and hydrostatic) At the same time, energy is partially dissipated by resistance to systolic flow in the small vessels During diastole the potential energy in the arterial tree is partly lost in hysteresis, and the remainder is dissipated in elastic recoil as blood flows through the resistance of the small vessels By the end of diastole, the pressures in the vascular bed are almost equilibrated and capillary flow practically ceases

The resistance to blood flow in the pulmonary circulation is about one-thirteenth that of the systemic circulation This is because there are no high resistance arterioles, the pulmonary capillaries are large and very numerous, the pulmonary vessels are so easily distended passively, and large portions of the pulmonary bed are only partially used normally The pressure pulsation in the pulmonary artery of 22/8 (mean 13 mm Hg) is fairly well maintained in the capillary bed and pulmonary veins since the capillary flow is so pulsatile during a cardiac cycle However, the capillary pressure has not been directly measured Phasic pressures taken indirectly through a catheter passed through the pulmonary artery until it is "wedged" in its small branches have been assumed to represent "capillary" or left atrial pressures since the blood obtained through the catheter is well oxygenated However, what such recorded phasic pressure curves represent has never been clearly defined The pressure gradient through the pulmonary bed is quite small Its highest pressure (pulmonary artery 13 mm Hg mean) drops to about 7 mm Hg in the left ventricle at the end of diastole and at the site of outflow from the pulmonary circuit This pressure gradient of about 6 to 7 mm Hg causes to flow through the pulmonary circuit the same volume of blood as flows through the systemic system with a pressure gradient of about 90 mm Hg

The capillary pressure in the pulmonary circulation is far lower than in most parts of the systemic circulation (e g , 7 mm Hg) while the plasma colloidal osmotic pressure is at its usual value (e g , 30 mm Hg) This has led to the postulate, supported by some experimental evidence, that a large negative interstitial space pressure (e g , −15 mm Hg) must prevail to account for pulmonary capillary exchanges (Guyton, 1969)

In addition to its function in blood gas exchange and as a blood volume reservoir, the pulmonary circulation serves to filter the systemic venous blood Small foreign particles, blood clots and other types of emboli are trapped in the lungs when they are removed by proteolytic enzymes and phagocytosis Since the pulmonary arterial system and bronchial arterial system share a common capillary network, embolization of a small pulmonary artery does not ordinarily abolish the blood supply through alveolar membranes Thus, the affected lung tissue survives until the embolus is removed When large emboli occlude major arteries, the bronchial circulation is inadequate to prevent necrosis Since most emboli enter the systemic venous system, the filtering function of the pulmonary circulation protects such vital organs as the brain, heart, and kidneys from embolic infarction White blood cells and platelets are also removed from the blood in the pulmonary circulation as are erythrocytes after incompatible blood transfusions

Interrelation between Pressure, Flow and Resistance

Hemodynamics is the study of the forces which cause, alter, and regulate the flow of blood through the body

A simple association of pressure and flow can obviously serve as an index of total peripheral resistance (TPR) to flow in the cardiovascular system, thus

$$\frac{\text{(Aortic Pressure}}{\text{(Aortic flow}} \text{ or } \frac{\text{Pulmonary artery pressure)}}{\text{Pulmonary artery flow)}}$$

or to local resistance in single bed or organ, for example

$$\frac{\text{(Renal artery pressure)}}{\text{(Renal artery flow)}}$$

Such measurements and calculations have been used extensively in recent years in clinical and experimental investigation and, especially in the aorta, to separate the resistance changes due to central or cardiac factors from those due to peripheral factors The architecture of the whole circulatory distributing system is such that the organs are supplied through many parallel shunts In this the total peripheral resistance (TPR) is

$$(1/\text{TPR}) = (1/r1) + (1/r2) + (1/r3) \quad (1/r^n)$$

but since the aorta supplies all the regions with pressure and flow, TPR can be calculated as mean aortic pressure divided by cardiac output (see p 3–192) A little reflection will indicate, however, that the resistance to flow can arise from active changes in the smooth muscle of the particular vascular bed in question, or it could be related to passive changes in the geometry of the same vascular bed due to internal and external variations of the pressure The above approach does not permit separation and quantitation of active and passive changes in vessel size which is essential to the proper understanding of pressure and flow relations In a modified form, some physical laws derived from hydrodynamics have application to the flow of blood, and they will be considered next

POISEUILLE'S LAW

Generally stated, the volume (F) of blood flowing through a circulating system increases with the perfusing pressure (P) and decreases with the resistance (R) to flow as indicated by the equation $F = P/R$ This is Poiseuille's experimental law which is expressed in more detail as

$$F = (P_1 - P_2)\ \pi r^4/8L\upsilon$$

in which F is flow per unit of time, P_1 is pressure at an upstream point in the tube, P_2 is the pressure at a downstream point in the tube, π is 3 1416, r is the tube radius, L is tube length, υ is fluid viscosity Poiseuille's experiments were based upon measurements of streamlined flow (nonturbulent) in nondistensible tubes with Newtonian fluids at constant temperature This means that flow is augmented by an increase in any factor in the numerator and decreased by any factor in the denominator Thus, flow would decrease by one-half if tube length is doubled or if blood became twice as viscous Blood is caused to flow from one point to another in a tube by the difference of pressure between such points This means that doubling the pressure gradient ($P_1 - P_2$) along the tube will double the flow Change of radius is much more effective in changing flow, for doubling the radius will increase flow 16 times

The resistance to flow, defined as the ratio of the driving force to the flow, is obtained by a rearrangement of the above formula in which

$$R = (P_1 - P_2)/F = 8L\upsilon/\pi r^4$$

Resistance to flow is made up of two distinct factors These are the viscosity (υ) or inner friction of the fluid and the geometry of the tube

$$(8L)/(\pi r^4)$$

which is made up of the radius and length Thus the terms on the right of the foregoing equation represent the frictional load affecting liquid flow through a straight, rigid, narrow tube In his system, the resistance was constant since both the viscosity and the geometry of the tube were unchanged and did not change with rate of flow or pressure A plot of flow versus pressure gave a straight line through the origin, and one of resistance vs pressure a horizontal straight line (Fig 3 32)

APPLICATION OF POISEUILLE'S LAW TO THE CIRCULATION

The applicability of this law in toto to the circulation depends upon whether resistance is independent of pressure and flow In the circulatory system peripheral resistance is a measure of the totality of all factors affecting blood flow. These include change (decrease) in apparent blood viscosity (which is known to occur with increase in perfusion pressure, occasioned by the movement of the red cells to form a central axial rod) the existence of streamlined vs turbulent flow, the length of vessels and the cross-sectional areas of the blood vessels The latter

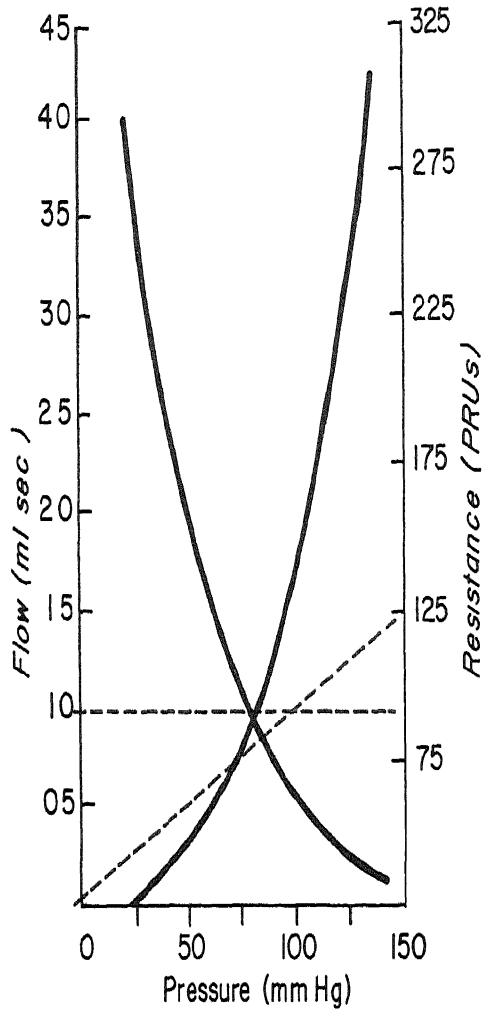

Fig 3 32 The relationships of flow pressure and resistance in nondistensible tubes using Newtonian fluids (*dotted lines*) at constant temperature (Poiseuille s law) and blood in vessels (*solid lines*) See text for details

is determined by the extravascular pressure provided by surrounding tissue, by mechanical dilation with rising perfusion pressure, by opening of new capillaries and vessels with change in metabolism and with rising perfusion pressure, and by active changes in the state of contraction of the muscular walls through vasomotor nerves, humoral substances and metabolic products

The flow-pressure curves obtained with blood in vascular beds (Fig 3 32) are quite different from those of the artificial system used in Poiseuille's experiments The chief differences are the curves do not pass through the origin, and flow is insignificant until a critical level of pressure is attained (called by Burton the critical closing pressure) The curves for dilated vessels are almost linear, but with increasing tone the curves become sigmoid and then convex to the flow axis At sufficiently high pressures, the curves tend to become straight lines pointing toward the origin The resistance is almost constant at high pressure but rises as the pressure is reduced to reach very high values near the critical closing pressure Such deviations could arise if *1)* the geometric factor of Poiseuille's law is not constant but varies with the distensibility of the blood vessels, and *2)* blood has anomalous viscosity so that the viscosity factor of Poiseuille's equation varies with the rate of flow and, hence, the driving pressure While experimental evaluation is difficult, it does appear that vessel distensibility is the major factor responsible for the deviation of in vivo pressure-flow curves from Poiseuille's law This in turn is related to the active tension or contraction of smooth muscle in the vessel walls and to the combined effects of elastic and collagenous fibers in the architecture of the vessels

2 / THE HEART: GROSS STRUCTURE; MYOCARDIAL CELLS

Weighing some 330 g and about the size of a large man's fist, the heart is a four-chambered double pump Each 24 hr it contracts more than 100,000 times, pumping over 60 barrels (7200 liters) of blood

Gross Structure

Some of the important structural features of the heart are depicted in Figure 3 33*A* The fibrous skeleton (Fig 3 33*B*, *C*) is a dense connective tissue framework separating the muscular layers of the atria from those of the ventricles It forms the annuli fibrosi, or fibrous rings, which surround the orifices of the aorta, pulmonary artery, and the atrioventricular valves These rings provide firm attachment sites for the valves of the heart and for the insertion of the cardiac muscles

THE ATRIA

The atria are relatively thin-walled structures which act as receiving chambers for the venous blood returning to the heart The myocardium is disposed in two sheets A superficial or oblique sheet continues over both atria Internal to this are deeper layers, one for each atrium, in which the fiber bundles are arranged more or less at right angles with the superficial bundles Certain features of the atria which are of physiological significance are depicted in Figure 3 34

Three functions are subserved by the atria (Mitchell and Shapiro, 1969) *1*) elastic reservoir and conduit from the venous bed to the ventricle, *2*) booster pump action, enhancing ventricular filling and maintaining low mean atrial pressure, *3*) atrioventricular valve closure before ventricular systole Following atrial contraction, which increases ventricular pressure, pressure in the relaxing atria declines The resultant ventriculo-atrial pressure gradient aids or actually effects atrioventricular valve closure (Patterson et al , 1965)

The pumping function of the atria is relatively unimportant at slow heart rates The ventricles fill, for the most part during the period when atria and ventricles are quiescent and venous blood flows into the heart as into a common chamber At the very end of this period, the atria contract and increase ventricular filling In normal subjects atrial contraction increases cardiac output from 15 to 20% and from 20 to 30% in patients with certain heart diseases (Benchimol, 1969) (see also p 3-104)

THE VENTRICLES

As can be seen from Table 3 5, the ventricular myocardial mass makes up most of the heart weight Four major bands of muscle may be identified by dissection (Fig 3 35) *1*) the superficial sino spiral (with origin and insertion at the tricuspid valve ring), *2*) the superficial bulbo spiral (with origin and insertion at the mitral valve ring), *3*) deep sino spiral muscles which encircle both the ventricles, *4*) deep bulbo spiral muscle fibers which encircle only the left ventricle

The deep muscle fibers spiral very gradually so that they actually act as circular constrictor muscle fibers Although these muscular bands may be dissection artifacts, the transition of fiber direction from counterclockwise to clockwise across the ventricular wall is clear (Grant, 1965)

When the ventricles contract during the so-called isovolumetric contraction period, the chambers are closed and no reduction in heart volume occurs until the pressure is great enough to open the valves leading to the pulmonary artery and aorta During this period, the heart changes in shape from an ovoid to a more spherical form Then, as blood is ejected into the aorta and pulmonary artery, the transverse diameter decreases and the base of the heart moves downward, shortening the distance from base to apex Since the spiral muscles

Body weight	54 7 kg
Heart weight	297 g
Heart weight as percentage of body weight	0 54%
Left ventricle	85 5 g
Right ventricle	49 7 g
Interventricular septum	63 6 g
Left atrium	17 0 g
Right atrium	12 5 g
Interatrial septum	9 5 g

After Bargmann, 1963

turn in opposite directions, there is little rotation of the heart with contraction, save for a slight turning to the right

Thus, the volume of the left ventricle is reduced by a decrease in the transverse diameter caused by shortening of the constrictor fibers and shortening of the base-apex diameter The left ventricle can be thought of as a cylinder which displaces volume by decreasing in height and by reducing its diameter This latter effect is particularly effective owing to the constrictor effect of the deep muscular band

The right ventricle is much thinner walled than the left ventricle (see Table 3 5) Its free wall is moved toward the interventricular septum by contraction of the spiral muscles If the entire free wall of the right ventricle is rendered inactive by cauterization, some reduction in volume will still take place during systole As the constrictor muscles of the left ventricle contract, the curvature of the septum is increased, pulling the free right ventricular wall toward the septum This process is called *left ventricular aid* (See page 3-99)

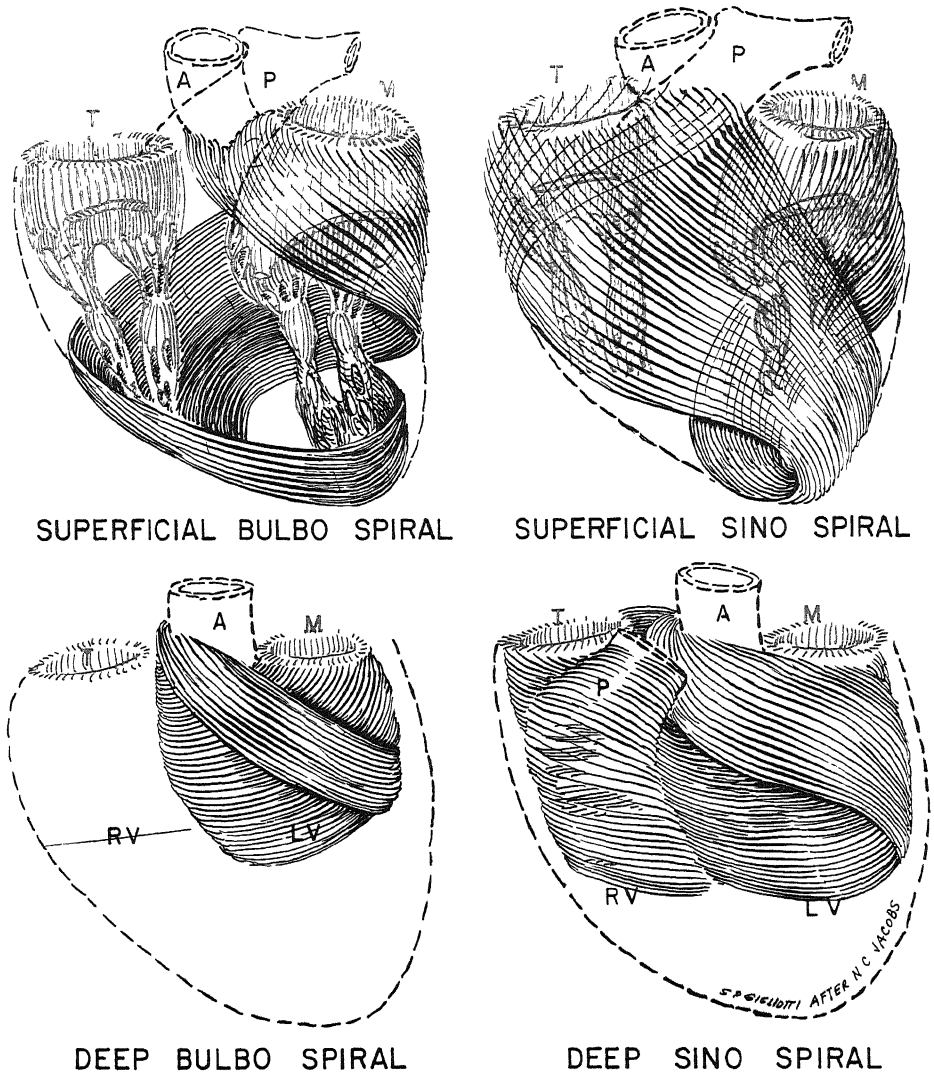

Fig 3 35 Demonstration of the superficial and deep ventricular myocardial bundles (Robb and Robb 1942)

ROLE OF THE PERICARDIUM

The pericardium is a double-walled sac containing a few cubic centimeters of serous fluid which gives a smooth lubricated surface for the heart's movements Although its potential volume is larger than that occupied by the normal heart in diastole, still, after moderate enlargement of the contained heart, the intrapericardial sac pressure rises greatly with small volume influence Thus, in the case of left ventricular stress and enlargement, the pericardium restrains diastolic expansion, especially of the right ventricle, and, therefore, limits right ventricular work This protects the left ventricle from overload and the pulmonary circulation from congestion The pericardium also protects against tricuspid or mitral valve regurgitation at high ventricular filling pressures The value of these mechanisms is probably limited to situations involving acute changes in heart volume, when cardiac enlargement develops more gradually, the pericardium follows suit and stretches to accommodate the larger contents Congenital lack of a pericardium is not uncommon in animals and humans who live to a ripe old age without evidence of cardiac distress

Myocardial Cells

Functionally, there are two general types of myocardial cells cells specialized for impulse formation and conduction, and cells specialized for contraction Cardiac tissue is composed of discrete cells, each bounded by an intact plasma membrane However, these anatomically distinct cells form a functional syncytium because of the presence of "tight" junctions characterized by low electrical resistance (see intercalated discs) These allow the passage of certain ions and perhaps small molecules from cell to cell

The cells specialized for pacemaking and conduction functions are capable of generating spontaneous rhythmic electrical potentials Those specialized for contraction remain at rest until stimulated by a conducted impulse which has arisen elsewhere

The individual myocardial cells in all mammals (mouse through whale) are about the same size (10 to 15 μ in diameter) Thus, the hearts of larger species are composed of many more cells than those of smaller species (Sommer and Johnson, 1970)

PACEMAKER AND CONDUCTING CELLS

Three types of cells specialized for impulse formation and rapid conduction have been described (James and Sherf, 1968) P cells, transitional cells, and Purkinje cells

The *P cells* have been so named because *1)* they are pale, *2)* they are primitive in internal structure compared to the more highly differentiated contractile cells, and *3)* pacemaking appears to be their primary function They are located in the sinoatrial and in the atrioventricular nodes These cells, on cross-section, are oval or rounded, in contrast to the elongated shape of other myocardial cells, and their surface is smooth They measure 5 to 10 μ in greatest diameter and contain relatively few intracellular organelles

Transitional cells are slender and elongated They are both shorter and narrower than other myocardial cells Their internal complexity is intermediate between the P cells and the contractile myocardial cells They appear to form the only connection between P cells of the sinoatrial node and the remainder of the heart

The *Purkinje cells* measure from 10 to 30 μ in cross-section and 20 to 50 μ in length They are shorter and broader than working myocardial cells and more commonly joined end to end, rather than side to side

CONTRACTILE OR WORKING MYOCARDIAL CELLS

These form the bulk of cardiac cells and are highly organized for their contractile function For the most part they are joined longitudinally in series with multiple cells forming the so-called myocardial "fibers" seen under the light microscope These "fibers" are in turn arranged parallel to one another In contrast to skeletal muscle, they have many lateral and end to side connections joining the separate plasma membranes of each cell Unlike the sparse linear myofibrils of Purkinje cells and the sparse and randomly distributed myofibrils of P cells, the myofibrils of working myocardial cells are densely packed Individual cells are some 10 to 20 μ in diameter and 50 to 100 μ in length

Working myocardial cells are architecturally similar to skeletal muscle cells but exhibit a number of important functional and structural differences The major morphologic features are diagrammed in Figure 3 36

Fiber, Fibril, and Filament. The myocardial cell is a specialized striated muscle cell containing a centrally located nucleus, a continuous limiting plasma membrane (the sarcolemma), and numerous contractile myofibrils which are separated by varying amounts of sarcoplasm A mucopolysaccharide-rich basement membrane invests the sarcolemma of each cell The intercalated discs join individual cells end to end The term *fiber* is sometimes used to designate an individual myocardial cell but is more commonly applied to a series of cells joined end to end which thus form a long fiber The fibers are separated from one another by intercellular spaces containing collagen, fibroblasts, and capillaries Individual cells frequently branch to interdigitate with adjacent fibers, forming a continuous network of cells Groups of muscle fibers are invested by sheaths of connective tissue separating them into long bundles Individual bundles also interconnect with other bundles The muscle fibers within a given bundle are parallel, but adjacent bundles may be oblique or transverse to one another The cells contain longitudinally arranged myofibrils which extend their full length and insert into the cytoplasmic surface of the intercalated discs These multiple parallel myofibrils are cross-banded and each is divided into a series of repeating units, the sarcomeres, the fundamental structural and functional units of

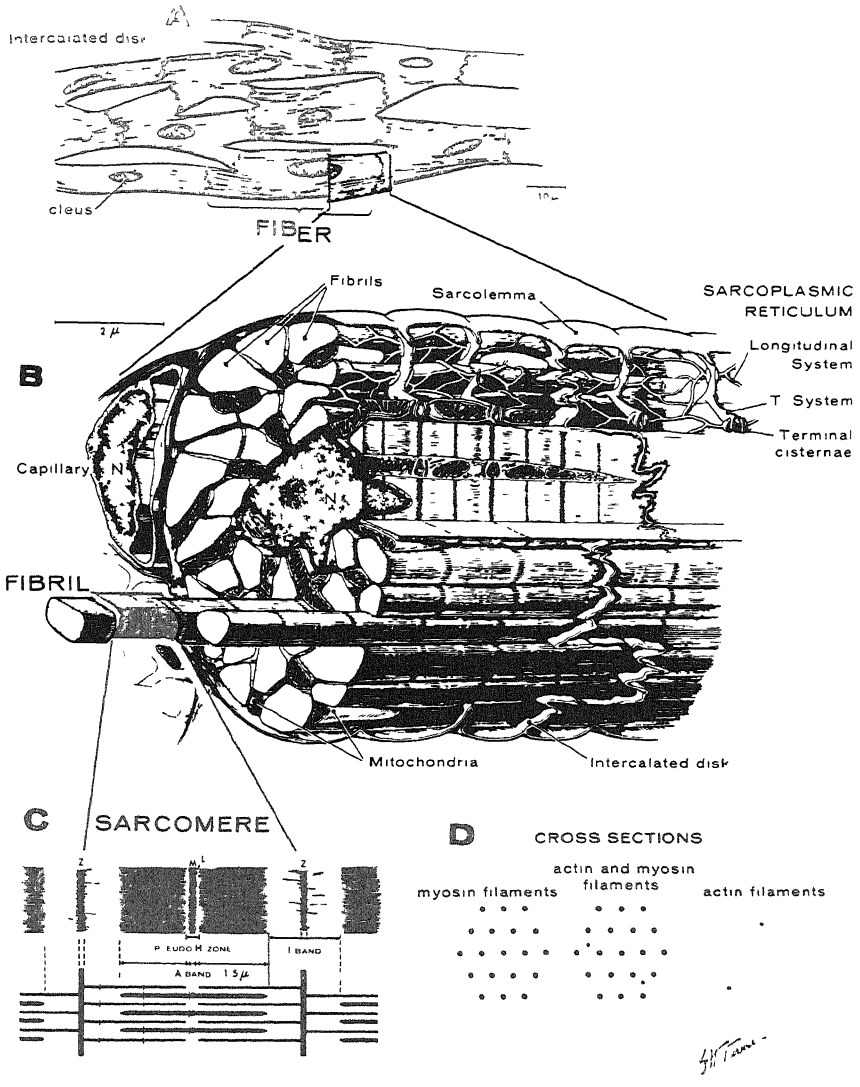

Fig 3 36 Structure of the myocardium as seen with light (*upper*) and electron (*lower*) microscopy In the diagram of a sarcomere the various structural features seen on longitudinal section are identified The sarcomere is delimited by two dark Z lines The I band is a region on either side of the Z line containing only thin actin filaments These extend into the lateral portions of the A band where they interdigitate with the thicker myosin filaments At the center of the A band is a dark line the M line flanked by two lighter areas the L lines This M-L complex is called the pseudo-H zone When the actin filaments do not penetrate as far as the M line the band where there is no overlapping of the actin and myosin filaments is designated the H zone This zone is seen only when the sarcomere length exceeds 2 2 μ (From Braunwald et al 1967)

contraction These sarcomeres make up about one half of the cell mass and are aligned in transverse register, i e , the ends of the sarcomeres in adjacent fibrils are next to one another and are of the same length It is this arrangement which gives the fiber its banded or striated appearance under the light microscope The sarcomeres, in turn, are composed of filaments (myofilaments) consisting of strands of contractile proteins

The individual sarcomere is composed of a number of proteins, some as yet incompletely characterized The two primary and best defined components of the sarcomere are actin and myosin The sarcomere is delimited at either end by an amorphous, dark transverse

septum called the Z line The area between two Z lines is composed of interdigitated thick and thin myofilaments which overlap in such a way as to produce the alternating light and dark transverse bands The distance between two Z lines varies between 1 5 and 2 2 μ, depending on the overall muscle length At the center of the sarcomere, a broad dark band of constant width (1 5 μ), called the A band, is found This is formed by parallel ranks of thick (100 Å) myosin filaments which are located in the central portion of each sarcomere On either side of the A band are two lighter bands, termed the I bands, which are of variable width These are formed by longitudinally oriented parallel ranks of thin (50 Å) actin filaments which extend from each Z line toward the center of the sarcomere Where they meet the myosin filaments of the dense A band, the two types of filaments are interdigitated for a variable length depending upon the state of contraction In the midportion of the A band, where there is no overlapping of thin and thick filaments, a lighter H zone occurs The central portion of the A band is bisected by a dark line, the M line, which is flanked by two lighter areas, the L lines This central area of the A band is called the M-L complex or pseudo-H zone Thus, the sarcomere consists of an orderly array of partially overlapping rodlike myofilaments These myofilaments are of fixed length but the sarcomere may change its length during contraction and relaxation through an interaction of the actin and myosin filaments These slide past one another producing a greater or lesser degree of overlapping

The myofilaments are made up of aggregates of contractile proteins Actin is composed of two linear chains of globular sub-units wound around the other in a helical arrangement (see Fig 3 37) The myosin units are held together by a lateral arrangement of cross linkages which make up the centrally located M band Each myosin subunit is rod shaped with a globular enlargement at one end They are lined up in the myosin filament with the globular portions clustered at either end and the rods occupying the central part of the filament (Fig 3.37) The globular ends of the myosin molecules consist of the more rapidly sedimenting heavy meromyosin which contains both the ATPase and actin-binding sites of myosin These rounded subunits of heavy meromyosin are thus arranged at either end of the thick

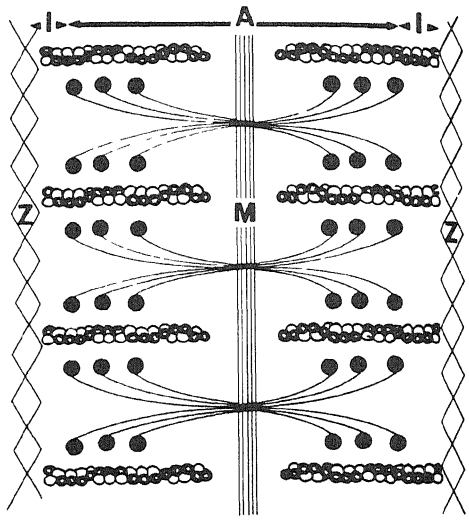

Fig 3 37 Diagram representing the arrangement of actin and myosin in the sarcomere The Z bands probably are made up of a lattice like arrangement of tropomyosin The subunits of actin are globular and linked in two strands which form a double helix In cross-sections at each pitch of this helix is seen the globular end of a myosin filament consisting of heavy meromyosin The subunits comprising each myosin filament are lined up with the globular portions clustered at either end and the rods occupying the central part of the filament Cross bridge formation during contraction probably occurs at these sites The M band at the center of each sarcomere is a system of cross links which fix the myosin units in position (Redrawn from Legato 1969)

myosin filament such that one projects as a cross-bridge just under each pitch of the actin helix Cross-bridge formation occurs at these active sites of the two filaments, and sequential making and breaking of these interconnections produces the sliding of actin along myosin which occurs in muscular contraction When heavy meromyosin is applied to isolated actin filaments they become aligned in a reproducible configuration indicating that both actin and myosin filaments have polarity In sarcomeres it is thought that the actin filaments are so arranged that the polarity of the filaments is reversed on either side of the Z band This orientation would give direction for cross-bridge formation between the myofilaments so that the actin strands at either end of the sarcomere can only move toward one another This arrangement permits shortening of the sarcomere when sequential making and breaking of cross linkages occurs during contraction

Since it has been observed that both the thick and thin contractile filaments of the sar-

comere are constant in length at rest and during contraction, these interdigitating filaments must slide over one another when shortening and lengthening occurs During contraction the actin filaments travel farther into the A band The A band remains constant in length while the I bands become shorter as the Z lines move toward one another

In vivo, the mechanisms involved in excitation and contraction require the presence of at least two other proteins called modulatory proteins (tropomyosin and troponin) The functions of these proteins will be discussed later under the heading "Contractile Proteins"

Intercalated Discs. Adjacent cells in a series are joined by specialized, paired membrane junctions, the intercalated discs The transverse portions of these discs are at right angles to the muscle fibers They are located at the ends of cells and always at the level of a Z line These cell boundaries follow a zigzag path neighboring transverse segments are often connected by a longitudinal segment which runs the length of a sarcomere to the next Z line, thus forming steps between certain cells The intercalated discs constitute structural cell boundaries so that the myocardium is not a true anatomical syncytium However, since there is low electrical impedance between the cells (Weidmann, 1966) and the attachments at the intercalated discs are firm, the myocardium functions as a syncytium both mechanically and electrically

Cell Junctions. Three types of junctional specializations form the intercalated disc (McNutt, 1970) *1) The Macula Adherens or Desmosomes* These are dense, paired sarcoplasmic bodies found opposed on either side of the intercalated disc, not in relation to myofibrils They seem to form an area of strong adhesion between the adjacent cells *2) The Fascia Adherens* This structure is generally larger than the macula adherens and occupies the major part of the transverse segments of the intercalated disc The thin actin filaments of the I band insert into the fascia adherens The thin myofilaments do not appear to insert into the maculae adherentes The fascia adherens appears to provide adhesion between adjacent cells and a locus for insertion of myofilaments on either side of the intercalated disc Thus, together with the maculae adherentes, these structures provide for mechanical attachment of adjacent cells, allowing the transmission of contractile force from cell to cell *3) Nexus* Nexuses or "tight junctions" are generally found in the lateral portions of the disc No filaments insert into them and they seem to be out of the direct line of tension exerted by myofilaments The plasma membrane of one cell comes into contact with that of the adjoining cell at the nexus Nexuses appear to serve as efficient low-resistance pathways for electrical conduction between the cells

Mitochondria. The mitochondria or sarcosomes are remarkably numerous, making up from 25 to 30% of the myocardium They are the major sites of oxidative phosphorylation, in which energy provided from substrate oxidation is converted to adenosine triphosphate, the source of energy for cell function

Sarcoplasmic Reticulum. The sarcoplasmic reticulum of cardiac muscle differs from that of skeletal muscle in several ways The two systems are compared diagrammatically in Figure 3 38 The first element, termed a *transverse component* or *T system*, consists of relatively thick-walled transverse tubules formed by invaginations of the sarcolemma which extend into the myocardial fiber Invaginations of the sarcolemma, continuous with the T system, are seen located at the level of the Z line Although the T tubules are usually found at the level of the Z lines, T tubules may be disoriented to run longitudinally in the fibers (Tice, 1967) Thus, the membrane forming the T tubule is continuous with the sarcolemma and the lumen of the tubule is in direct connection with the extracellular space The second component is termed the *longitudinal system* or *L system* It consists of a series of anastomosing thin-walled tubules which invest the sarcomere These tubules form a complex reticulum of anastomosing intracellular channels having no direct contact with the cell exterior It will be noted in Figure 3 38 that the T tubes of cardiac cells are considerably larger than those found in skeletal muscle and their relationship to the longitudinal tubular system is dissimilar The relationship between the T and L systems in cardiac and skeletal muscle is depicted in Figure 3 39 The cardiac sarcotubules form a less constant and predictable pattern than those of skeletal muscle The latter form repeating units which are contained between two Z bands of a single sarcomere and have a fenestrated cistern at the central portion in the region of the M band (Fig 3 38*B*) Car-

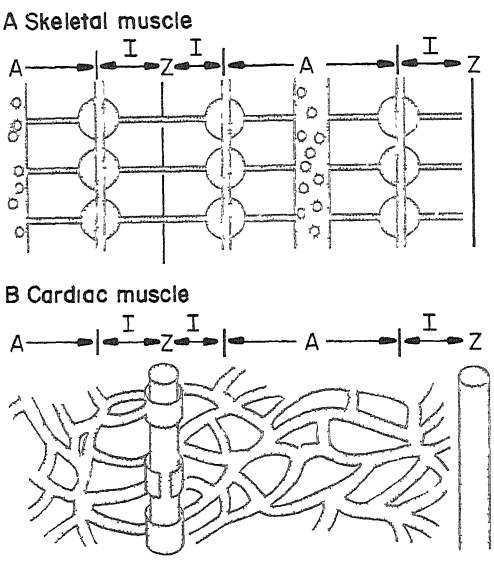

Fig 3 38 Diagrams of the tubular systems in skeletal (*A*) and cardiac (*B*) muscle In cardiac muscle the T-tubules are larger than in skeletal muscle and the lateral sacs differ in shape and wrap partly around the T-tubule The fenestrated central cistern at the M band of skeletal muscle is absent in cardiac muscle and the branching of the longitudinal tubules is more irregular (Redrawn from Legato 1969)

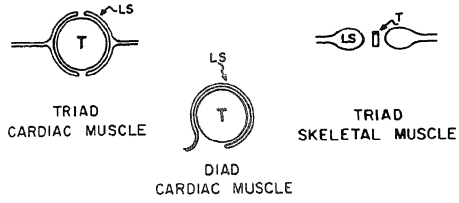

Fig 3 39 Diagrammatic concepts of triadic and diadic relationships in cardiac and skeletal muscle sarcomeres (Redrawn from Legato 1969)

diac muscle sarcoplasmic reticulum has no predictable central modification and one or more tubules often pass over the Z band into the next sarcomere Skeletal muscle sarcotubules end in a terminal dilatation, the lateral sac, whereas in the myocardium the longitudinal tubules usually divide into two arms which are wrapped around the transverse tubules The reticular tubules from adjacent sarcomeres thus flank a large central tubule forming the so-called *triad* In some cases only one lateral sarcotubule is apposed to the T vesicle forming a *diad*

The T system is thought to play a role in two important functions the conduction of excitatory electrical impulses from the cell surface membranes into the depths of the cell to the contactile system and in the distribution of substrates to the cell interior and the removal of metabolic end products The longitudinal system is thought to function in the storage, release, and uptake of calcium ions which are responsible for initiating myofibril contraction and relaxation The juxtaposition of the T system with the L system has suggested the hypothesis that the depolarizing impulse travels along the transverse tubule from the outer cell membrane, triggering release of calcium from stores within the longitudinal tubular system The calcium then diffuses into the myofibril, activating contraction Sarcoplasmic reticulum fragments are known to accumulate calcium in vitro It is thought that they do this during contraction, thus lowering the ionic calcium available to act on myosin filaments, hence leading to relaxation

In summary, the myocardial cell consists of four major functional elements a contractile element, the myofilament, an intracellular nutritive and energy producing organelle, the mitochondrion, an electrolyte transport system, the sarcoplasmic reticulum, and an organizer, the nucleus

CONTRACTILE PROTEINS

Four major contractile proteins have been extracted from myofibrils of cardiac muscle myosin, actin, tropomyosin, and troponin (Katz, 1970) There is considerable evidence that other proteins, as yet unidentified, are present in the contractile apparatus of cardiac muscle However, only the four proteins mentioned have clear roles in the contractile process Troponin may consist of two distinct proteins The approximate concentrations of these major contractile proteins in the myocardium are given in Table 3 6

Contractile proteins of the heart convert the

chemical energy of substrate metabolism into the mechanical energy of contraction Adjustments of cardiac contractile strength result from changes in the interactions between the contractile proteins induced by physical and chemical factors The heart normally behaves as a syncytium, responding to a single stimulus with activation of all myocardial fibers In contrast to skeletal muscle, myocardial contraction cannot be altered by variations in the number of motor units activated nor by incomplete or complete summation (tetanus) dependent upon nerve impulse frequency Tension development and shortening of myocardial fibers are dependent on two factors the resting length of the sarcomeres (the Frank-Starling mechanism) and changes in the chemical environment of the proteins during contraction The length dependent changes are related to physical alterations in the positions of the contractile proteins within the sarcomere at the onset of systole Changes in the chemical environment, such as alterations in the concentration of calcium ions or catecholamines, can alter tension development in the absence of changes in sarcomere length

Myosin is the chief constituent of the thick filament of striated muscle, both cardiac and skeletal Two high-molecular weight components having different sedimentation velocities can be identified by the analytical ultracentrifugation These two components have been designated meromyosins The more rapidly sedimenting heavy meromyosin possesses both ATPase activity and the ability to bind actin Light meromyosin, the less rapidly sedimenting component, possesses neither ATPase nor actin binding activities Heavy meromyosin is the only myofibrillar protein which, under ordinary physiological conditions, is an active ATPase The ATPase activity of cardiac myosin is similar to that of red skeletal muscle myosin and both are less active than that of white skeletal muscle myosin The units of heavy meromyosin are arranged at either end of the myosin filaments and project laterally to form the cross-bridges which are visible under the electronmicroscope The rod-shaped portion of these myosin subunits consists of the lighter meromyosin which occupies the central part of the filament

Actin is the major protein of the thin filaments It exists in two states G-actin (G = globular) is the monomer which is stable in solutions of low ionic strength, and F-actin (F = fibrous) is a polymer of G-actin monomeres which is formed on addition of salts Tropomyosin makes up about 10 to 12% of the myofibrillar protein of cardiac muscle It resembles the structure of the Z line in muscle but the location of tropomyosin has not been conclusively demonstrated, although it appears to be located in the thin filaments (actin filaments) It plays a role in modulating the interaction between actin and myosin

Troponin sensitizes the interaction between actin and myosin to the effect of the calcium ion released during excitation-contraction coupling Like tropomyosin, it is believed to be associated with the thin (actin) filaments of cardiac muscle

Unpublished experiments by R E Davies and A Delluva have shown that, in the turtle heart, ATP is used for contraction Thus, the enzymatic activity of myosin is central to the conversion of chemical energy to mechanical energy during muscle contraction, since ATP is the immediate source for the chemical energy utilized in contraction Calcium ions strongly stimulate while magnesium ions inhibit the ATPase activity of cardiac myosin If both magnesium and calcium salts are present together, the inhibitory effects of the magnesium predominate, so that magnesium ions strongly inhibit the calcium activated ATPase activity of cardiac myosin

MODULATORY PROTEINS

Tropomyosin and Troponin. In vitro combinations of purified cardiac actins and myosins possess the contractile properties of myofibrils They hydrolyze ATP and can undergo physicochemical changes in vitro which probably represent the contractile process of living muscle However, the mechanisms representing the final stages in excitation-contraction coupling require the presence of tropomyosin and troponin in the actomyosin gel

The presence of troponin and tropomyosin is necessary for the sensitization of reconstituted actomyosin to the physiological actions of calcium ions The most significant action of tropomyosin is the inhibition of the interaction between actin and myosin

Troponin and Sensitization of Actomyosin to Calcium. Calcium sensitization of actomyosin requires the presence of both troponin

and tropomyosin and neither protein itself possesses this activity The sensitization of actomyosin to calcium ions appears to result from a primary interaction of the tropomyosin-troponin complex with actin in which troponin strengthens the binding of tropomyosin to F-actin Troponin has now been identified as the calcium receptive protein in cardiac muscle

In addition to the four contractile proteins mentioned in the foregoing, several other proteins and protein complexes have been prepared from muscle Two of these, α-actinin and β-actinin, appear to play a role in the structural interactions of the thin filaments and the Z line in sarcomeres, rather than modulating actin-myosin interaction Both are postulated to be involved in some way with the determination of myofilament length and sarcomere structure and possibly play a role in the production of new sarcomere units (Legato, 1970)

DIFFERENTIATION

The adult myocardium, while consisting mainly of cardiac muscle cells, is a heterogeneous tissue containing many other cell types, e g , Purkinje fibers of the specialized conduction tissue, fibroblasts, nerve fibers, phagocytes, vascular endothelium and smooth muscle cells, squamous or low cuboidal cells of the epicardial epithelial sheet, and endothelial cells of the endocardium

The developing myocardium is derived from embryonic splanchnic mesoderm and, initially, consists entirely of developing striated muscle cells Thus, it is originally an epithelial tissue, containing only developing myocytes Following development of the epicardium and endocardium, mesenchymal cells appear These nonmuscular components are probably fibroblasts derived from the endocardium or epicardium

Early cardiac myocytes contain few fibrils and large amounts of cytoplasm More fibrils form as development proceeds, the cytoplasm decreases and the fibrils become aligned in parallel pattern The term myoblast designates presumptive muscle cells as yet morphologically undifferentiated, i e , cells which have not yet acquired myofibrils Once myofibrils are present, the cells are termed myocytes The fibril to cytoplasm ratio of cardiac myocytes increases during embryogenesis until the myofibrils occupy most of the cell volume These early myocytes are epithelial cells on the basis of their ultrastructure and organization Large amounts of glandular endoplasmic reticulum are seen within the cytoplasm Such endoplasmic reticulum is largely responsible for the production of protein destined for extracellular use, and it has been suggested that these cells have a secretory or glandular function Thus, in the young heart wall, the myocardium may be described as a contractile glandular epithelium The glandular endoplasmic reticulum diminishes as the myocytes mature However, a little later, the secretory function is again evident in some ventricular myocytes in the form of dense particles within the Golgi lamellas, suggesting that this cell type may retain a secretory function throughout life (see p 3–115)

At the time of the first heart beat (in the chick embryo), well-developed fibrils containing organized myofilaments and Z bands are present

The myofibrils in early cardiac myocytes are randomly oriented Later, by an unknown mechanism, they align themselves in parallel along the same axis In well organized cells, the Z lines are at right angles to the bundles of myofibrils and the latter insert with an angle of approximately 90° into the intercalated discs These early changes are illustrated in Fig 3 40

Development of Specialized Pacemaking and Conducting Fibers. Little evidence is available on the embryological development of the specialized pacemaking and conduction tissue (sinoatrial node, atrioventricular node, bundle of His, and Purkinje network) of the adult heart (Lieberman, 1970) Morphological findings and physiological evidence (transmembrane potential characteristics) support the hypothesis that remnants of the sinus venosus and primitive atrial canal (atrioventricular ring) are the precursors of the adult sinoatrial junction, atrioventricular node, and bundle of His The Purkinje network is thought to originate from strands of primordial myocardial tissue pulled out into fascicles by the growing ventricular wall However, corroborative structure-function studies to establish the origin of the His-Purkinje system are lacking

Nonmuscular Components of Cardiac Tissue. Initially, the myocardium is a pure population of muscle cells The nonmuscular components arise from other sources The appearance of the epicardium and endocardium is associated with the entry of nonmuscular elements, such as fibroblasts, into the myocardial

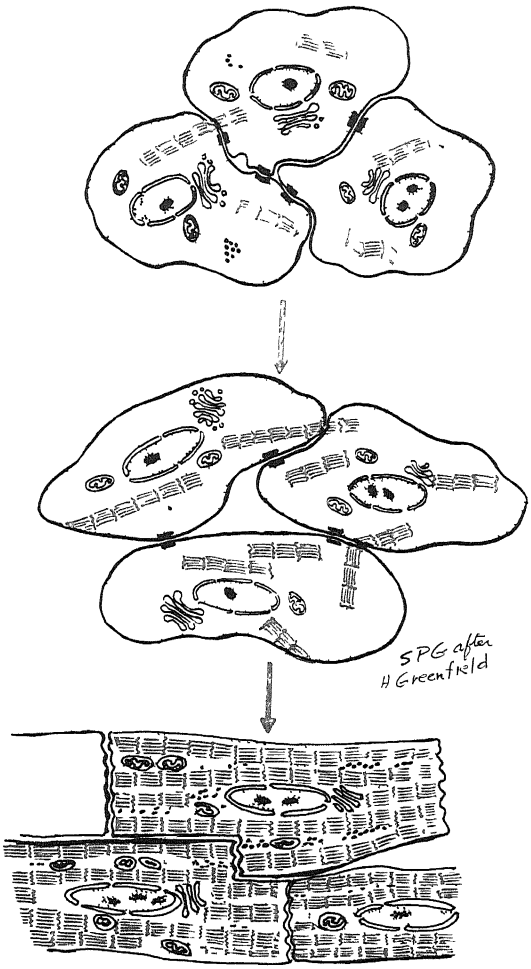

Fig 3 40 Differentiation of cardiac myocytes Three stages in early development of myocardial cells are diagrammed As maturation proceeds the cells become less rounded the number of fibrils increases and their alignment becomes more regular Then more and more myofibrils appear and intercalated discs form and are oriented at right angles to the fibrils The sarcoplasm is crowded out by the myofibrils becoming restricted to the region at the nuclear poles Mitochondria line up in rows between the fibrils and desmosomes appear at lateral cell borders (Redrawn from Manasek 1970)

tissue, apparently, they are derived from the endocardium and epicardium.

Properties of Myocardial Cells

CONDUCTIVITY

Myocardial cells possess the functional characteristic of conductivity, i e , they are capable of transmitting action potentials Although individual cells are separated by plasma membranes, the impulse can pass from cell to cell, presumably through the specialized junctions known as "tight junctions" or nexuses (q v)

CONTRACTION

The only important function of the heart is that of a muscular pump Contraction of the myocardium differs from that of skeletal muscle in several respects as follows *1*) the individual cells, while anatomically discrete, transmit impulses across the cell boundaries and thus behave as a functional syncytium A stimulus above threshold thus initiates a transmitted impulse which excites all myocardial fibers, producing an "all-or-nothing" response of the entire myocardium *2*) The active state (q v), and duration of contraction are longer *3*) The refractory period is longer and myocardial cells can neither be summated temporally nor tetanized *4*) The rate of force development during contraction is slower and velocity of shortening is slower *5*) The maximum tension developed per unit of cross-section of muscle is only $\frac{1}{3}$ to $\frac{1}{2}$ that of skeletal muscle

The physiological features distinguishing cardiac from red and white skeletal muscle are outlined in Table 3 7 Tension development in skeletal muscle is regulated by the frequency of motor nerve impulses (temporal summation, tetanus) and by variations in the number of muscle units activated during a single contraction Cardiac muscle is not organized on a muscle unit basis (nor are individual muscle fibers directly innervated), and behaves as a physiological syncytium so that all myocardial cells are activated during each contraction in an "all-or-none" fashion Further, under physiological conditions, myocardial cells cannot be summated temporally nor can they develop tetanic contraction

When compared with certain types of smooth muscle on the one hand and red and white skeletal muscle on the other, myocardial cells have structural and functional features more closely allied to those of smooth muscle and red skeletal muscle than to white skeletal muscle Smooth muscle cells are relatively poor in myofibrils, are often arranged as a syncytium and contract slowly. Similarly, red skeletal muscle is richer in sarcoplasm than white skeletal muscle and contracts more slowly than the latter Cardiac muscle, like certain types of smooth muscle, is arranged as a functional syncytium and is rich in mitochondria like red

Table 3 7
Regulation of contraction in cardiac and skeletal muscles

Mechanism	Cardiac Muscle	Red and White Skeletal Muscle
Ability to summate responses to rapidly delivered stimuli	None	Marked
Ability to vary the number of active muscle fibers	None	Marked
Ability to alter contractility	Marked	Little
Ability to alter contractile response by changing of initial fiber length	Present functions at short sarcomere lengths	Present functions at long and short sarcomere lengths

From Katz 1967

skeletal muscle The abundant mitochondria of both red skeletal muscle and cardiac muscle regenerate ATP by oxidation of fats and, to a lesser extent, carbohydrates There is much less reliance on phosphagen stores (creatine phosphate) White skeletal muscle regenerates ATP through the less efficient pathways of anaerobic glycolysis, utilizing as its major energy source creatine phosphate These various features which smooth muscle and red striated skeletal muscle share with cardiac muscle correlate with functional similarities, e g , smooth muscle, red striated muscle, and cardiac muscle contract more slowly and engage in more sustained activity than white skeletal muscle

Cardiac contraction or systole results from the aggregate shrinking of individual sarcomeres In accordance with the sliding-filament concept of Huxley, the thin actin filaments, which are anchored in the substance of the Z line at either end of the sarcomere and interdigitate with the thicker myosin filaments, move toward one another during contraction Neither the thick nor the thin filaments shorten during contraction

EXCITATION AND THE MEMBRANE SYSTEM OF CARDIAC CELLS

As in all excitable cells, excitation is mediated in myocardial cells by depolarization of cell membranes (sarcolemma) The sarcolemma in turn gives rise to the intercalated disc and the transverse tubular system The intercalated disc is made up of multiple convolutions formed of adjacent sarcolemmal membranes The transverse tubular system consists of sarcolemmal invaginations which extend from the cell surface throughout the entire thickness of the myofibril

The intercalated discs contain tight junctions of low electrical resistance, which permit rapid transmission of depolarizing impulses from cell to adjacent cell The transverse tubular network extends the extra cellular compartment to all levels of the myocardial cell, shortening diffusion distance from cell exterior to structures in the cell interior Depolarization and repolarization can occur in intimate association to intracellular structures Thus, the transverse tubular system is considered an active part of the myocardial cell membrane providing for the transmission of excitation throughout the fiber and a potential pathway for the diffusion and exchange of substances between the intra- and extracellular spaces The longitudinal sarcoplasmic tubular system, on the other hand, does not open to the cell exterior At the level of the I band and Z line the tubules and expanded ends of the intracellular longitudinal tubular system form intimate contacts as described in the foregoing

EXCITATION-CONTRACTION COUPLING

Ionic calcium appears to be the link between excitation and contraction The subcellular sarcoplasmic reticulum is known to accumulate, store, and release calcium within the muscle cell This tubular network envelops the entire circumference of the myofibril and extends throughout the sarcomere

The lateral sacs of the longitudinal sarcoplasmic tubular system are found in close association with the transverse tubules (diads and triads), along the sarcoplasmic membrane at the outer cell surface, and all along the course of the intercalated disc Electron microscopic studies have shown that the lateral sacs are storage depots for calcium It is hypothesized

that membrane depolarization in all of these areas releases calcium ions from lateral sacs, thus freeing them for interaction with the contractile proteins

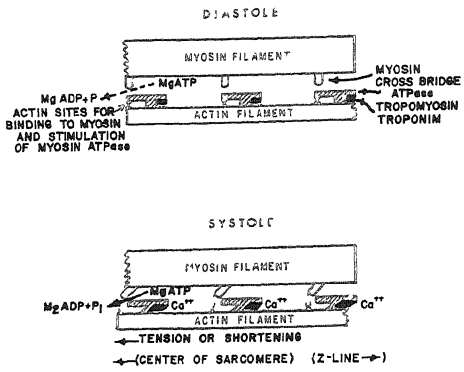
In white skeletal muscle it is generally agreed that the source of calcium ions mediating excitation contraction coupling lies within the muscle cell, associated with the sarcoplasmic reticulum In the resting state, this system sequesters (binds) calcium within the cell but outside the region occupied by the contractile proteins Upon excitation, this calcium is released into the cell interior and becomes available for binding to troponin In skeletal muscle it is unlikely that an influx of calcium at the cell surface membrane during depolarization could contribute importantly to excitation-contraction coupling because the interval between excitation and contraction is too brief to permit calcium to diffuse to the troponin calcium binding sites In the myocardium, in which the cells are smaller, the development of the active state (q v) is slower and the action potential longer It is not possible to exclude calcium influx from the surface membrane as a source of calcium ions for excitation contraction coupling Very likely, net calcium fluxes maintained over a long period of time are responsible for some of the changes in myocardial contractility Further, phasic calcium movements across the sarcolemma likely cause beat-to-beat changes in intracellular calcium ion concentration responsible for excitation-contraction coupling The existence of the system of intracellular vesicles and tubules in cardiac muscle similar to the sarcoplasmic reticulum of white skeletal muscle implicates these structures in the release of calcium ions for excitation contraction coupling in the heart However, the sarcoplasmic reticulum in cardiac muscle is relatively sparse as compared with white skeletal muscle Further, less calcium is accumulated by cardiac muscle after glycerol extraction than is the case in skeletal muscle and less calcium-sequestering activity is present in cardiac microsomes than in skeletal microsomes Thus, changes in transcellular calcium flux, as well as release of calcium from the sarcoplasmic reticulum, appear to have a role in excitation contraction coupling

The amount of calcium released from the sarcoplasmic reticulum during any given contraction may determine the proportion of troponin molecules receiving calcium ion and thus govern the strength of myocardial contraction Transcellular calcium flux appears to play a role in determining contractility by this mechanism However, it is not clear whether calcium exchanges across the cell surface act during each contractile cycle or determine, on a long-term basis, the amount of membrane-bound calcium that may be released during each systole

In heart muscle, calcium deprivation does not abolish the action potential but does abolish contraction In skeletal muscle, absence of calcium prevents both electrical and mechanical response to stimulation Thus, calcium is required in skeletal muscle for action potential generation In resting skeletal muscle, almost all calcium is sequestered in the reticulum and the concentration of calcium in the sarcoplasm is almost zero In skeletal muscle, the calcium involved in contraction comes from the lateral sacs of the sarcoplasmic reticulum An influx of calcium from the extracellular medium is unimportant In heart muscle, however, part of the calcium involved in the contractile response comes from a superficial layer or from the extracellular medium while the remainder is from an intracellular site, probably the sarcoplasmic reticulum

Less calcium uptake activity is present in the cardiac microsomal (mitochondrial) fraction than in skeletal muscle microsomes However, this capacity is more than sufficient to consider mitochondria as a source for adequate calcium release to saturate all calcium-binding sites that control the actin-myosin interaction Whether the calcium affinity of cardiac microsomes is sufficient to bind calcium rapidly enough to account for the rapid calcium removal causing relaxation is uncertain It is possible that mitochondria, which have been shown to have a capacity to take up calcium, may play a role in the relaxation process However, the evidence that uptake and release of calcium by myocardial mitochondria play a significant role in cardiac excitation-contraction coupling is not conclusive

How calcium ions cause sarcomeric shortening is somewhat speculative Katz (1970), has proposed a model which defines the interactions between the four proteins myosin, actin, tropomyosin, and troponin (Fig 3 41) The interaction between actin and myosin is regulated by the amount of ionic calcium made available for binding to troponin The calcium



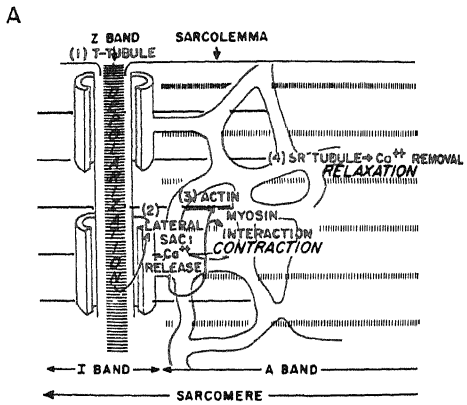


Fig 3 41 Possible interactions between the two contractile proteins actin and myosin and the two modulatory proteins tropomyosin and troponin *Upper* in the resting state (diastole) tropomyosin is depicted as the interaction inhibitor *Lower* during systole addition of calcium abolishes inhibition of the actin myosin interaction by the tropomyosin-troponin complex This appears to result from binding of calcium to troponin and an action of troponin and tropomyosin together Release of inhibitory action of modulatory proteins permits the ATPase stimulating and physicochemical interactions between actin and myosin to proceed The active state is established and the muscle shortens Maximal shortening velocity (V_{max}) appears to be governed by the rate at which actin-activated myosin cross-bridges hydrolyze ATP Maximum tension (P_0) seems to be determined by the number of interacting sites between actin and myosin (Redrawn from Katz 1970)

acts to release an inhibitory action of the tropomyosin-troponin complex upon reactive sites on the actin molecule The latter is then able to interact with myosin It is assumed that the initial action of calcium is to induce a conformational change in the troponin molecule This, in turn, leads to a reversal of the inhibitory action of tropomyosin, possibly through a troponin-tropomyosin interaction Thus, calcium permits release of the inhibitory action of the modulatory proteins, allowing the ATPase-stimulating and physicochemical interactions between actin and myosin to occur These events establish the active contractile state required for muscle shortening This speculative explanation is schematized in Figure 3 41

The contractile event depends on the presence of calcium and relaxation upon its removal When calcium ions are removed from the area of the myofilaments, cross-bridge formation between actin and myosin ceases and the sarcomere returns to its resting length Thus, the sarcoplasmic reticulum with its ability to bind, transport, and resequester calcium in an inactive site (lateral sac) is considered the sub-cellular system which produces contraction, regulates tension, and achieves relaxation These various functions are summarized in Figure 3 42*A* and *B*

In summary, it is thought that the depolarizing impulse travels along the sarcolemma and is propagated throughout the cell via the T tubular network Depolarization of the membranes of the lateral sacs associated with T tubules and those beneath the sarcolemma results in calcium ion release Calcium ions induce interaction between actin and myosin and contraction results Relaxation is the result of

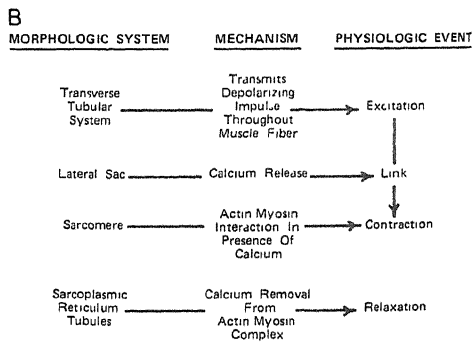

Fig 3 42 *A* Subcellular systems involved in excitation-contraction coupling and relaxation The depolarizing impulse travels over the sarcomeric membrane and along the T-tubule membrane into the depths of the cell Depolarization causes calcium ion release from storage depots of the lateral sacs Calcium ions bind with troponin of the tropomyosin-troponin complex and somehow abolish the inhibitory effect of these modulatory proteins on the interaction between actin and myosin and contraction occurs Relaxation occurs when this freed calcium is removed by being taken up again by the lateral sacs ***B***, the events of excitation contraction coupling are summarized in this table (Redrawn and modified from Legato 1969)

sarcotubular removal of calcium from the area of the myofilaments

ACTIVE STATE

The active state represents a capacity of the contractile element to shorten and do work but not the transformation of this into external mechanical performance (Holland and Sabatini-Smith, 1969) The mechanical output of a strip of cardiac muscle during a single contraction is only an indirect representation of the degree of activity of the contractile component itself The external manifestation of activity is dependent on the stretching of the series component and is delayed Hill used the term "active state" to designate the degree of activity of the contractile unit It may be expressed as a maximal isometric tension that the contractile unit is able to develop or just bear without lengthening at a given moment To measure the active state, recording must be arranged such that no movement of the series elastic element occurs Then the capacity to shorten and do work is translated into mechanical performance Study of the active state in cardiac muscle depends on indirect methods such as the "quick release" method of Jewell and Wilkie (1958) The shortening velocity of the contractile unit at various moments after stimulation can be determined by this method The speed of shortening at any given moment is proportional to the ability of the contractile unit to develop tension

The active state is much longer in the heart than in the skeletal muscle In rabbit papillary muscle (at a contraction frequency of 30 beats/min at 30° C), the intensity of the active state is maximal about 60 msec after stimulation, and activity begins to decline at about 100 msec The active state has diminished to approximately 80% of the peak value at the time of the maximal isometric tension (Holland and Sabatini-Smith, 1969)

An inotropic change of the myocardium may be achieved by an alteration of either two parameters of the active state its intensity or its duration A reduction of the duration of the active state will decrease the height of the contraction by giving the contractile unit less time to stress the series elastic component Thus, decreased or increased duration of active state results in reduction or lengthening, respectively, of the time to peak tension A change in intensity of the active state will produce a symmetrical alteration in the height of the isometric contraction curve

METABOLISM AND ENERGETICS

Under normal circumstances, myocardial cells operate almost exclusively on an aerobic metabolic system which provides the constant supply of high-energy phosphate bonds for mechanical and chemical work

In Table 3 8 are listed various metabolic substrates together with their percentage contribution to myocardial oxygen usage Under normal conditions the major fuel for cardiac metabolism is free fatty acids Glucose and lactate are also important contributors while amino acids, ketones, and pyruvate make lesser contributions

Olson and Piatnek (1959) divided myocardial metabolic processes into three phases (see Fig 3 43) energy liberation, energy conservation, and energy utilization

1) *Energy liberation* or production is the conversion of the energy of substrates (e g , fatty acids, glucose, lactate) into the energy of the high-energy phosphate compounds, adenosine triphosphate (ATP) and creatine phosphate (CP)

2) *Energy conservation* or storage is the steady state concentration of ATP and CP in the heart

3) *Energy utilization* is the rate and efficiency of conversion of this chemical energy to the mechanical energy (work) of cardiac contraction The major intermediary metabolic pathways of myocardial cells are diagrammed in Figure 3 44 Note that the mitochondria (sarcosomes) are the sites of the major aerobic or oxidative processes upon which the heart

Table 3 8
Percentage contribution of various metabolic substrates to total myocardial oxygen usage

Carbohydrate		Noncarbohydrate	
Glucose	17 90%	Fatty acids	67 0%
Pyruvate	0 54%	Amino acids	5 6%
Lactate	16 46%	Ketones	4 3%
Total	34 90%[a]	Total	76 9%[a]

[a] The total is more than 100% because some of the substrates removed from the blood, in amount measured by the arteriovenous differences, were stored by the heart or not completely metabolized

From Bing, 1955

depends primarily for energy Myocardial cells differ from white skeletal muscle cells in having a much higher concentration of mitochondria In some myocardial cells the mass of mitochondria equals that of the myofibrils

In white skeletal muscle the major metabolic pathways are anaerobic while in red skeletal and cardiac muscle they are aerobic, thus accounting for the high concentration of mitochondria in the latter muscle types

In cardiac muscle during the energy liberation phase, the major myocardial substrates (see Table 3 8) are metabolized to the two-carbon molecule, acetyl-coenzyme A, which enters the citric acid (Krebs) cycle in the mitochondria Then follows the step-wise release of carbon-hydrogen bond energy

In the second, or energy conservation phase, the energy release through hydrogen or its electron is transferred into the bonding energy of the high-energy phosphate bond (~P) through oxidative phosphorylation This process occurs in the mitochondria also The result of oxidative phosphorylation in the mitochondria is the formation of creatine phosphate (CP), adenosine monophosphate (AMP), adenosine diphosphate (ADP), and adenosine triphosphate (ATP)

The third, or energy utilization phase, occurs when ATP is hydrolyzed by adenosine triphosphatase to ADP and inorganic phosphate (P_i) at the time of muscular contraction ATP is the immediate source of energy for muscular contraction and other chemical cellular processes such as modifying substrates, producing glycogen, synthesizing lipids and proteins, and maintaining ionic concentration gradients across the cell membrane The relationships between these biochemical events, myocardial contraction, and cellular maintenance are diagrammed in Figure 3 45 The physicochemical interaction of actin and myosin utilizes ATP The latter is then replenished from high phosphate bonds from creatine phosphate (CP) or from the electron transport chain The increased amounts of adenosine diphosphate (ADP) and inorganic phosphate (P_i) resulting from muscular contraction act to stimulate oxidative phosphorylation, the citric acid cycle and glycolysis This increases high-energy phosphate bond production High levels of ATP depress these processes Thus, the relative levels of ADP and P_i on the one hand and ATP on the other serve as a regulatory feed-back control governing aerobic mitochondrial processes leading to the production of high-energy compounds Creatine phosphate (CP) functions as a small but immediately available source of high-energy phosphate bonds

To understand the dependence of cardiac

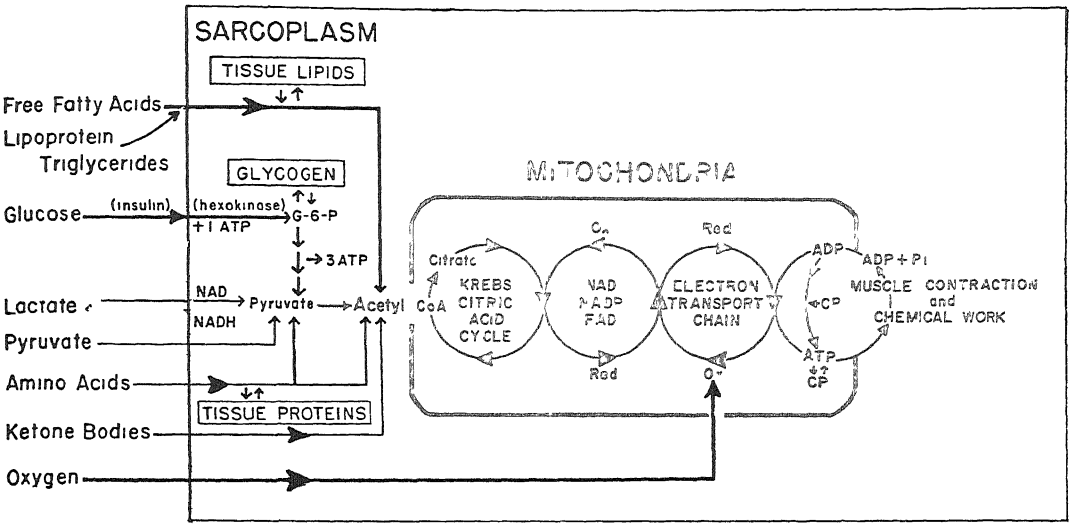

Fig 3 44 Schematic diagram of a myocardial cell illustrating the major pathways of cardiac metabolism Most substrates are taken up more or less in proportion to their arterial concentration above their extraction threshold The major reactions of glycolysis which are anerobic take place in the sarcoplasm (cytoplasm) The mitochondria are responsible for the major aerobic or oxidative processes including the oxidation of free fatty acids (FFA) the citric acid cycle which utilizes acetyl Coenzyme A (acetyl CoA) from many sources and the complex respiratory chain or electron transport chain (ETC) which oxidizes reduced flavin and adenine coenzymes formed in the citric acid cycle The process of oxidative phosphorylation results in the formulation of adenosine triphosphate (ATP) and creatine phosphate (CP) ATP is the immediate source of energy for muscular contraction and for many chemical reactions while CP serves as a reservoir of high energy phosphate bonds FFA are metabolized predominantly in the mitochondria to acetyl CoA which enters the citric acid cycle The contribution of lipoprotein triglycerides to the fatty acids metabolized by the heart is uncertain Glucose is transported across the cell membrane under the control of insulin and is then phosphorlyated in the cytoplasm by hexokinase to glucose-6-phosphate (G-6-P) a reaction which utilizes one high energy bond from ATP In the subsequent steps in the metabolism of G-6-P to pyruvate each molecule of G-6-P yields 4 high energy phosphate bonds however one of these is used in the important and rate-limiting phos phorylation of fructose-6-phosphate to fructose-1 6-diphosphate by phosphofructokinase Lactate is normally taken up and converted to pyruvate which is then converted to acetyl-CoA to enter the citric acid cycle The enzyme phosphorylase which exists in two forms catalyses the reaction glycogen + $P_i \rightarrow$glucose-1-phosphate which is then changed to G-6-P to enter the glycolytic pathway Hypoxia inhibits many mitochondrial functions including the ETC and the citric acid cycle, with a resultant decrease in CP and ATP Hypoxia also stimulates glycogenolysis glycolysis and uptake of glucose Excess pyruvate produced during hypoxia is released by the heart as lactate The metabolism of large amounts of FFA or ketone bodies increases the intracellular concentration of citrate which inhibits phosphofructokinase and therefore glycolysis and the uptake of glucose Abbreviations NAD nicotinamide-adenine dinucleotide NADH reduced nicotinamide-adenine dinucleotide, NADP nicotinamide-adenine dinucleotide phosphate FAD flavin-adenine dinucleotide Red reduction Ox oxidation (From Schlant 1970)

muscle on the continual oxygen supply, it is useful to compare the patterns of energy production and utilization with those of red and white skeletal muscle (Katz, 1970) The heart, like red skeletal muscle is organized to maintain its work over long periods of time without rest, both of these types of muscle rely upon oxidative metabolism for ATP regeneration and have little ability to function anaerobically or to incur oxygen debt This is in contrast to white skeletal muscle which is organized for brief bursts of intense activity followed by periods of relaxation The substrates, metabolites, pathways of intermediary metabolism, and intracellular energy reserves of the two types of muscle are strikingly different (Table 3 9) Cardiac muscle derives its energy mainly from oxidative metabolism It contains large numbers of mitochondria which are rich in the enzymes of the citric acid cycle and oxidative phosphorylation The myoglobin content is large, favoring oxygen diffusion into the fiber In white skeletal muscle the chief source of energy comes from the metabolism of carbohydrates (glycogen, glucose) During activity, these substrates are not oxidized to carbon dioxide and water Rather, lactic acid is produced and an oxygen debt develops The enzymes catalyzing aerobic glucose utilization and anaerobic glycolysis are more abundant in

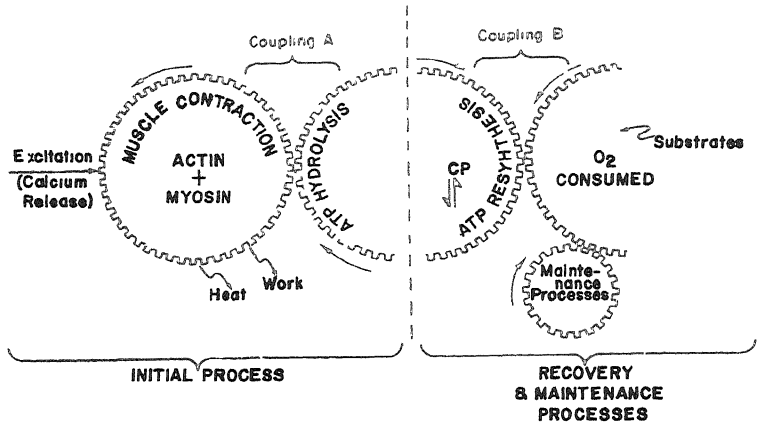

Fig 3 45 Diagram of mechanochemical coupling in cardiac muscle The interaction of actin and myosin during contraction is initiated by Ca^{++} release (left hand panel initial process) and utilizes ATP through Coupling A Oxidative phosphorlyation provides for the formation of creatine phosphate (CP) and adenosine triphosphate (ATP) CP serving as a reservoir for high energy phosphate bonds available for ATP resynthesis Oxygen utilization is related to CP and ATP synthesis through Coupling B Oxygen is also consumed in various cellular maintenance processes (Redrawn from Braunwald et al 1967)

Table 3 9
Energy sources for contraction of red and white skeletal and cardiac muscle

Energy Source	White Skeletal Muscle	Red Skeletal and Cardiac Muscle
Major substrates	Carbohydrate	Lipid
Major metabolic pathways	Anaerobic	Aerobic
Major products of metabolism	Lactic acid	CO_2 and H_2O
Oxygen debt on activity	Significant	Minor
Reserve of phosphate bond energy (phosphocreatine)	Significant	Minor
Ability to function in the absence of oxygen	Good	Poor

From Katz, 1967

white skeletal muscle Cardiac muscle is richer in enzymes providing for the oxidative metabolism of pyruvate, succinate, and acetoacetate The heart is specialized metabolically to function aerobically, requiring a continual oxygen supply and large numbers of mitochondria White skeletal muscle can contract in the absence of oxygen, utilizing anaerobic carbohydrate metabolism and its large phosphocreatine reserve However, it needs a recovery period during which its glycogen and creatine-phosphate reserves are replenished by oxidation of lactic acid. Only under anaerobic conditions does the heart utilize glycolysis and deplete its slender creatinephosphate reserve Thus, the heart, like red skeletal muscle, depends upon oxidative metabolism for ATP regeneration and requires a steady supply of oxygen

The energy utilization phase of cardiac and red skeletal muscle also differs characteristically from white skeletal muscle The ATPase activity of myosins from the former is less active than that of white skeletal myosin The maximal shortening velocities of both red skeletal and cardiac muscles are slower than that of white skeletal muscle, presumably because shortening velocity may be determined by the rate of ATP hydrolysis by the contractile proteins. The relatively lower tensions developed by cardiac muscle, as contrasted with white

skeletal muscle, may be attributed in part to the larger number of mitochondria in myocardial cells These, by taking up considerable intracellular space, reduce the amount of contractile protein present per unit volume of myocardial tissue

REGENERATION

There is no unequivocal evidence that adult myocardial cells can divide (Grove et al , 1969) This is in contrast to the differentiating embryonic cells which can multiply by cellular division Embryonic and early postnatal growth of the heart is accomplished by hyperplasia of myocardial cells It appears that any subsequent myocardial enlargement can only be accomplished by hypertrophy of the individual myocardial cells through enlargement and multiplication of intracellular structures (mitochondria, myofilaments) This absence of the capacity for hyperplasia and regeneration remains somewhat controversial since there are indirect evidences that the number of myocardial cells may increase during hypertrophy in the adult individual (Linzbach, 1960, Beznak, 1969) From tissue culture studies of myocardial cells it is known that, in contrast to skeletal muscle, both contractile and undifferentiated cells can divide In developing skeletal muscle, once the cell begins contractile activity, mitotic cell divisions and DNA synthesis cease Whether or not undifferentiated stem cells (myoblasts) may remain in the myocardium and form new cells under appropriate stimuli, and whether hyperplasia through cell division or activation of latent myoblasts can occur in early life (e g , hypertrophy accompanying congenital heart disease) is unknown However, at present the concensus is that ordinarily an increase in myocardial mass can be accomplished in the adult only through enlargement of cardiac cells already formed

DILATATION

The term cardiac dilatation refers to increased capacity of the heart chambers Alterations in cardiac volume occur within physiological limits as part of the mechanism for changing cardiac output Enlargement of cardiac chambers beyond physiological limits occurs both acutely and chronically in various abnormal states

Three factors are involved in acute dilatation sarcomere lengthening, "fiber slippage," and stratification change Two of these factors are represented schematically in Figure 3 46 In acute dilatation, sarcomeres longer then 2 2 μ appear, and in electron micrographs, an H zone (Fig 3 36 page 3-29), normally absent in cardiac sarcomeres, can be seen (Fig 3 46*B*) "Fiber

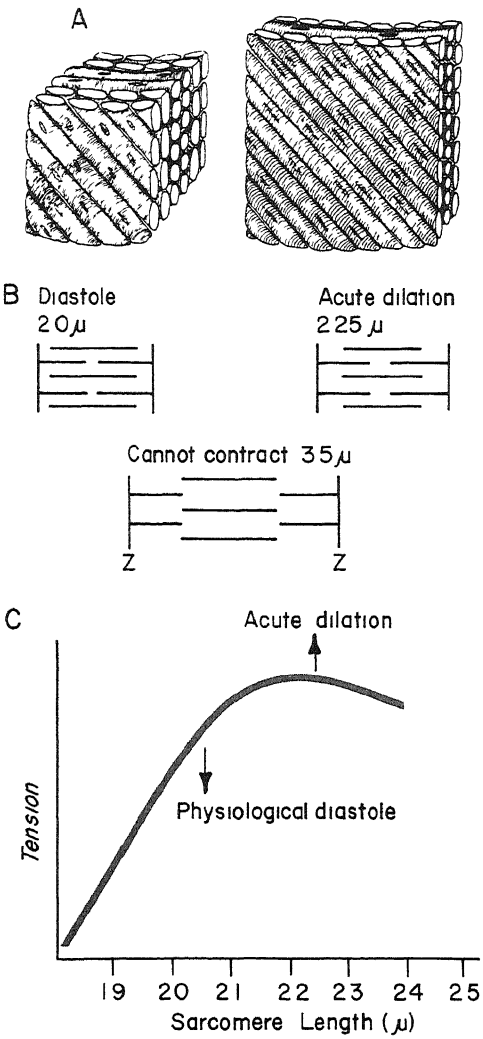

Fig 3 46 ***A,*** schemata of stratification change The same part of the right ventricular wall is represented in normal state and with marked dilatation ***B,*** schematic representation of sarcomeres in different states of stretch showing the relations of the thin and thick filaments ***C,*** Length tension diagram of an isolated papillary muscle showing the sarcomere lengths for physiological diastole and acute dilatation (Redrawn from Hort 1968)

slippage" means that individual fibers slide past one another in different directions longitudinally A change in stratification of fibers is believed to account for dilatation in a direction at right angles to myocardial fibers In this process there is a rearrangement of fibers from adjacent layers of myocardium As the myocardium is stretched, the individual fibers become thinner and fibers from adjacent layers slip between one another This increases the number of fibers within a single layer and decreases the number of layers across the myocardial wall In this way, wall thickness is reduced and surface area increased The term *plastic dilatation* has been applied to longitudinal "slippage" and lateral rearrangement of myocardial fibers

Dilatation, which increases sarcomere length and increases the internal diameter of cardiac chambers, has two functional implications Increasing sarcomere length, within limits, increases the contractile strength of myocardial fibers (Frank-Starling relationship, pp 3-88 and 3-119) An increase in chamber diameter increases the wall tension for a given intracardiac pressure in accordance with the Laplace relation (Tension = Pressure $\times$ π radius^2, see page 3-92 and Fig 3 96) Physiologically, increased stretch results in increased wall tension but, at the same time, force of contraction is increased However, if the sarcomeres are stretched too far, contractile strength decreases and the heart still must operate at an increased wall tension for a given level of intracardiac pressure Studies on experimental animals in which acute cardiac dilatation has been induced (e g , acute asphyxia) indicate that sarcomere stretch beyond physiological limits does not ordinarily occur (Fig 3 46) The increase in sarcomere length which does take place cannot account fully for the degree of observed dilatation, so that fiber "slippage" and stratification change must play a significant role It does not appear that the sarcomeres become stretched to the point that this factor alone can account for contractile weakness nor that individual sarcomeres are stretched to the point that they cannot contract at all However, sarcomere length is increased to the point that there is little reserve for increase in contractile strength through the Frank-Starling mechanism

In chronic dilatation it has been shown experimentally that fiber "slippage" and stratification change as well as moderate increase in sarcomere length occur, as in acute dilatation However, in chronically dilated human hearts, Linzbach and Kyrieleis (1968), did not find any increase in sarcomere length Additionally, there is the possibility (unproven) that new sarcomeres may be synthesized in series to lengthen cardiac fibers Dehiscences or separations of fibers at intercalated discs have been found by electron microscopy in tissue from the auricular appendages of chronically dilated human hearts (Poche, 1969), and increased number of sarcomeres per fiber have been identified in hypertrophied hearts (Laks et al , 1969)

In summary, acute and chronic dilatation result from "slippage" and stratification change of fibers primarily Sarcomere length is increased moderately, at most, or, as some studies have shown, not at all Because of the increased diameter, the heart must operate at increased wall tension for a given intracardiac pressure Insofar as sarcomere lengthening occurs, the reserve for increased contractile force with increased sarcomere length is compromised (Linzbach and Kyrieleis, 1968, Hort, 1968)

HYPERTROPHY

When the heart is subject to mechanical overload, either through disease states, long-term heavy physical work, or experimental intervention, increase in myocardial mass results The normal heart in human adults ranges from approximately 250 to 350 g in weight Those in athletes or laborers may reach 500 g , but in diseased hearts weights of 500 to 1000 g or even more are seen The principal, or perhaps the exclusive, adaptive change occurring in these conditions is hypertrophy of the individual myocardial fibers, accompanied by an increase in other tissue elements (connective tissue, vasculature) It has been found through light and electron microscopic studies of hypertrophied cardiac tissue that the myocardial cells are increased in diameter and length For example, the average diameter of the normal human heart myocardial cell is 15 μ while in hypertrophied hearts fibers from 25 to 30 μ are found The increase in cell length is the result of adding more sarcomeres to the cell rather then the result of stretching of the sarcomeres (Laks et al , 1969) The locus for addition of sarcomeres may be at the intercalated discs, but this speculation requires further evidence

Legato (1970) has provided electronmicroscopic evidence suggesting that the Z line substance is essential for new sarcomere production In myocardial tissue from adult human hearts, newborn puppy hearts, and in rat ventricular cells grown in tissue culture proliferations of the Z line were observed In certain of the masses of Z substance, some of which had reached a width of 1 5 to 2 0 μ, filaments embedded in an amorphous matrix were observed These findings led to the postulate that the Z substance may serve as a source or template for the production of new sarcomeres in the developing or enlarging cardiac cell The increase in diameter is accomplished by the addition of more myofibrils The ratio of the volume of mitochondria to the volume of myofibrils increases slightly at first, but later returns to normal (Meerson, 1969)

With normal growth of the heart during maturation, the individual myocardial cells do not multiply but become thicker and longer In infants there is one capillary for every four or five myocardial fibers, while in the adult heart the ratio is 1 1 (Linzbach, 1960) In the presence of hypertrophy the adult ratio remains The idea that *capillary inadequacy* is a cause of hypoxia in hypertrophied hearts does not appear valid In marked hypertrophy (heart weights exceeding 500 g) the ratio between coronary artery and coronary ostia diameters decreases This may restrict myocardial perfusion in hypertrophy

Number of Cells There is no crucial evidence for an increase in numbers of myocardial cells, although some investigators suggest that this too may occur, especially in extreme myocardial hypertrophy (Beznak, 1969, Linzbach, 1960) Myocardial cells which have been induced to hypertrophy by experimentally produced mechanical cardiac overload are known to return to their original size when the cardiac workload is returned to normal (Beznak, 1969) Further, if the work of the heart is reduced below normal, myocardial cells will grow smaller (atrophy) Clearly, the myocardial cell possesses the ability to increase or decrease myofibrillar mass in response to altered workload This, in turn, must be accomplished by alterations in protein synthesis which are somehow linked to changes in the level of contractile function In Figure 3 47 each line schematically represents various interrelations between basic myocardial processes The relations

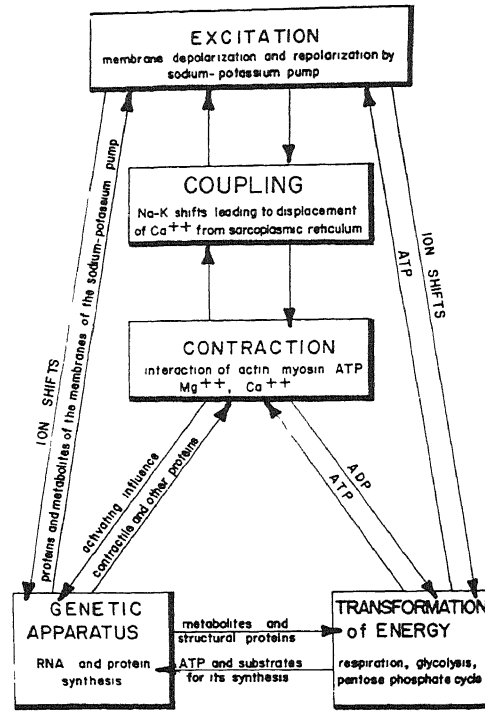

Fig 3 47 The interrelations of various fundamental myocardial processes (Redrawn from Meerson 1969)

between excitation, excitation-contraction coupling, contraction, and energy transformation have already been discussed To these fundamental myocardial cellular processes must be added that of protein synthesis, which is controlled by the genetic apparatus of the nucleus The possible regulatory mechanisms implied as affecting the genetic apparatus are hypothetical

As with other living cells, cardiac fibers maintain a state of dynamic equilibrium between synthesis and breakdown of cellular elements For example, myofibrillar and mitochondrial proteins of rat heart muscle turn over with half-lives of ten to twelve, and five to six days, respectively (Rabinowitz and Zak, 1972) The other intracellular organelles and membranes (e g , sarcoplasmic reticulum) are maintained by continual replacement or renewal of structural proteins This process is under the control of the genetic apparatus in the nucleus (and also in part in the mitochondria) and involves nuclear DNA and the sarcoplasmic RNA system Thus, the cellular structures are maintained at a given level, dependent on the balance struck between the

forces of synthesis and destruction In the case of cellular hypertrophy involving marked increase in contractile proteins, synthesis must be increased so that contractile protein production exceeds loss For this to occur, the genetic apparatus must respond appropriately to variations in the demand on cells for contractile function, and to changes in the rate of breakdown of cellular structures (so-called "wear and tear" of cell structures) The mechanism linking the DNA-RNA system to cardiac activity is obscure However, for hypertrophy to follow increased functional demand on the heart, it is clear that a mechanism must exist which regulates protein synthesis in accordance with contractile function Thus, intensification of the contractile process not only steps up metabolic energy transformations but also has an activating influence on the level of activity of the genetic apparatus

In Figure 3 48, a speculative schema on the pathogenesis of cardiac hypertrophy is illustrated

Workload Cardiac hypertrophy occurs when the workload of the heart is increased abnormally The heart responds by what Meerson (1969) terms compensatory hyperfunction Physiologically, two different types of compensatory hyperfunction are postulated isotonic hyperfunction and isometric hyperfunction Isotonic hyperfunction results when there is an increased blood inflow to the heart as in valvular insufficiency, arteriovenous fistulas, anemia, etc Isometric hyperfunction occurs in valvular stenosis or systemic or pulmonary hypertension Clinically, hypertrophy is also found in the hearts of patients with myocardial or coronary artery disease, accompanied by cardiac dilatation In these cases, a primary increase in workload has not occurred However, wall tension has increased in accordance with the Laplace relationship (q v) Accordingly, a greater radius of a cardiac chamber resulting from dilatation will increase contractile tension and provide a stimulus to hypertrophy Badeer (1968) points out that in all three conditions the mechanical stimuli for hypertrophy require an increased energy expenditure per unit mass of myocardium per beat In Figure 3 48, increased contractile stress per unit cross-sectional area is depicted as an initial change resulting in augmented energy expenditure per beat and stimulation of the genetic DNA-RNA system Hypertrophy results and, as represented in the left hand series of boxes, may be followed by compensation in which a steady state is produced with normal energy expenditure and maintenance of a normal concentration of contractile elements This is considered a stable state of

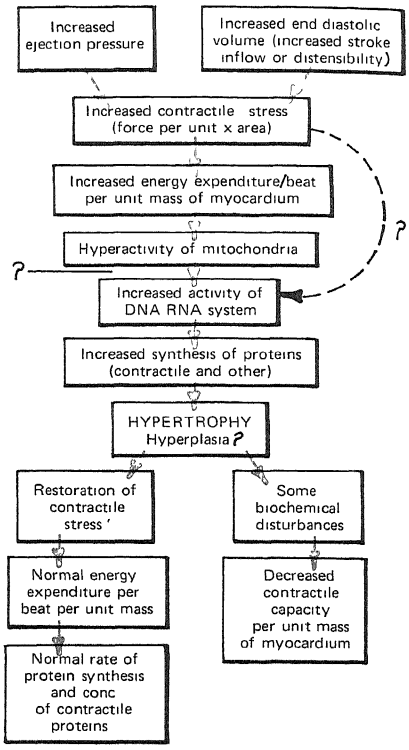

Fig 3 48 The pathogenesis of cardiac hypertrophy (Redrawn from Badeer 1968)

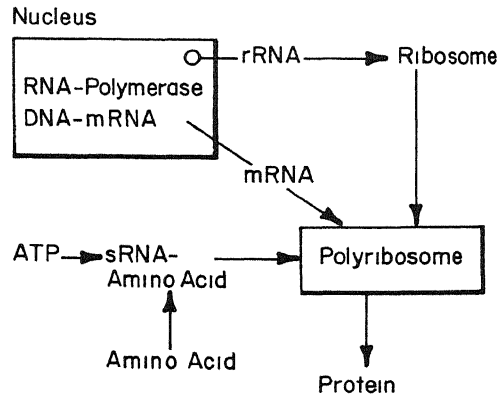

Fig 3 49 Schema of protein synthesis regulation Hemodynamic overload of the heart stimulates nuclear and nucleolar RNA synthesis initiating the hypertrophic process (Redrawn from Scheuer, 1970)

hypertrophy and hyperfunction However, as shown on the right hand side, hypertrophy may fail to restore the functional capacity of the myocardium so that its contractile performance per unit mass may be decreased Decrease in maximum shortening velocity and tension development has been demonstrated in myocardial tissue from non-failing hypertrophied hearts (Spann et al , 1967) This will ultimately lead to congestive heart failure

Protein Synthesis The mechanism of protein synthesis is shown in Figure 3 49 This is under control of the DNA-RNA system and involves three types of RNA ribosomal RNA (rRNA), messenger (mRNA), and transferring (soluble or sRNA) In accordance with present views, ribonucleic acid (RNA) formation occurs in the nucleus and protein synthesis in the ribosomes DNA-dependent messenger RNA (mRNA) synthesis is controlled by the enzyme RNA polymerase Messenger RNA transfers the genetic information from the nuclear DNA to the ribosomes and RNA acts as a template for the synthesis of cellular proteins from amino acids An aggregate of ribosomes, polyribosome, assembles amino acids linked to sRNA into proteins Ribosomal RNA is repeatedly programmed by messenger RNA from the nucleus The amino acids are activated by ATP and transferred to the ribosomes by transferring RNA The ribosomes contain the necessary enzymes, ions, and high energy phosphate for this synthetic process Thus, nuclear DNA regulates protein synthesis through its control of RNA manufacture In myocardial hypertrophy, increased synthetic rates for mRNA, nuclear RNA, mitochondrial RNA, and microsomal, mitochondrial, and cytoplasmic protein occur Increased amino acid incorporation into protein is found as early as three hours after a pressure load is imposed on the isolated heart In microsomal protein, synthetic rates increase as early as 1 hour after an increased cardiac load is applied Various hormones which support protein synthesis play a role in cardiac hypertrophy Growth hormone must be administered in hypophysectomized animals with aortic constriction if hypertrophy is to occur Thyroid stimulating hormone potentiates the effect of growth hormone Adrenalectomy decreases the heart weight in normal animals but does not prevent hypertrophy with an increased cardiac load Insulin and male hormones also influence the hypertrophic response to mechanical overload However, since increased protein synthesis can be demonstrated in overloaded isolated hearts, these hormonal influences are not required for the initiation of the genetic process In rats, digitalis glycosides have been shown capable of protecting against the development of ventricular hypertrophy caused by chronic systolic overload induced by aortic constriction (Greenspan and Edmonds, 1969) Possibly this effect occurs because the drug prevents ventricular dilatation with the increase in intraventricular pressure

Transmembrane Potential (TMP)

The studies of Weidmann (1951), and Woodbury et al (1951) showed that the potential difference across a limited area of muscle membrane of a single heart fiber could be faithfully recorded in the beating heart by use of an intracellular microelectrode of the type developed by Ling and Gerard (1949) Glass tubes of about 1 mm external diameter are drawn out to an extremely small tip of about 0 2 μ When these are filled with concentrated potassium solution and inserted through the fiber membrane into the sarcoplasm, they can be used to measure the potential difference between the outside and inside of a single fiber in the beating heart By cutting off the tip of the glass capillary electrode and suspending it on a wire, the electrode is free to move up and down Thus artefacts from heart movements are minimized and recordings from human hearts during cardiac surgery have been made Human atrial and ventricular muscles, excised from patients undergoing open-heart surgery, were also studied in vitro Where studied simultaneously, the transmembrane potentials from fibers in the intact heart are qualitatively and quantitatively similar to those recorded from single fibers of isolated preparations of either atria or ventricles Information thus obtained concerning the state of polarization of the muscle membrane serves as a much better basis for correlation with studies of excitability and refractoriness than the less direct and more variable measurements obtained with surface electrode techniques (Fig 3.50)

TYPICAL POTENTIALS

Transmembrane Potentials (TMP) of Ventricle and Atrium. Figure 3 51*A* shows the potential changes that are observed when a capillary microelectrode is inserted into a single fiber of a rhythmically beating ventricle When both the microelectrode and the indifferent electrode are outside the cell, there is no potential difference When, however, the tip of the microelectrode penetrates the membrane of a single myocardial fiber, a sudden potential of 80 to 90 mv is recorded with the inside of the fiber negative to the indifferent electrode This resting potential difference across the muscle membrane remains at the same value as long as the tissue is quiescent Following stimulation, however, there is an extremely rapid phase of depolarization (1 to 2 msec) and change in the membrane potential so that the intracellular microelectrode momentarily becomes positive with respect to the indifferent electrode Therefore, at the peak of the action potential, the membrane is not only depolarized but actually exhibits a reversal of polarity or exhibits overshooting amounting to 15 to 30 mv , and lasting 6 to 15 msec Immediately after this reversal there is a plateau of about 100 msec and then a moderately rapid repolarization of the membrane for 100 to 150 msec , as the resting potential is restored On pulling back the electrode, the potential jumps back to the zero level It is believed that use of an intracellular microelectrode gives a true picture of the time course of depolarization and repolarization in a single cardiac muscle fiber and provides an accurate measurement of the size of transmembrane potentials

Transmembrane potentials recorded from the atria and auricles in the open-chest dog (or from single fibers of isolated preparations) are not significantly different from those of the ventricles except that following depolarization, the atrial records show an immediate slow phase of repolarization without an intervening plateau such as occurs in ventricular muscle (Fig 3 51*B*)

The temporal relationship between the action potential of a single fiber and the local ventricular electrogram of the intact and in situ heart is shown in Figure 3 51*A* The upstroke of the action potential coincides with the R wave of the electrogram, the plateau with the R-T segment, and the phase of repolarization with the T wave The temporal relation between the electrical and mechanical activity is very close

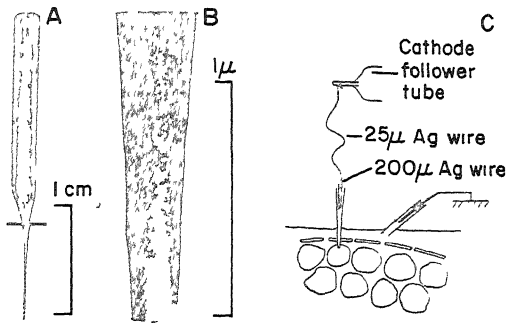

Fig 3 50 Microelectrodes used for determining transmembrane potential in single myocardial fiber as modified by Alexander and Nastuk from Ling and Gerard (1949)

(Fig 3 51*E*) Contraction starts a few milliseconds after depolarization, and tension reaches a peak when the membrane undergoes repolarization The state of contraction is maintained as long as the fiber is depolarized, and relaxation sets in as soon as the resting potential is re-established Under some conditions it has been possible to obtain dissociation between mechanical and electrical events, i e , electrical activity is obtainable when there is no longer a recorded mechanical response

The transmembrane potential and mechanical response of cardiac muscle are very sensitive to certain inorganic ions Changes in concentration of potassium, calcium, and to a lesser extent sodium, have a profound effect on the excitability and contractile response of the mammalian myocardium Magnesium has little action in the presence of normal calcium concentration, but when the latter concentration is decreased both magnesium and strontium have a marked effect on membrane potential

Transmembrane Potentials of Specialized Tissues. Of the three specialized tissues in mammalian heart, i e , the sinatrial node, the atrioventricular (AV) node, and the ventricular conducting system (Purkinje fibers), all have been studied by microelectrode techniques Figure 3 51*C* illustrates the electrical peculiarities of Purkinje fibers in the dog heart In contrast to the constant diastolic membrane potential in atrial and ventricular muscle, there is in the ventricular conducting system a slow depolarization throughout diastole when local electrical activity is induced by a distant pacemaker When pacemaker activity originates in the local area there is, in addition, a slow upward curvature in late diastole which continues until a level of instability is reached and a more rapid depolarization, the action potential, spontaneously begins (Fig 3 51*D*) This peculiarity was first described by Bozler (1943) Pacemaker activity in the sinoatrial and AV junctional tissue, is similar to the above when they act as pacemakers

As to be expected, the electrical properties of the pacemaker region change with factors that alter heart rate Vagus stimulation, acetylcholine, and hypothermia lower heart rate by decreasing the rate of diastolic depolarization and thus lengthening the time taken to reach a critical level at which an action potential is initiated, whereas sympathetic stimulation and epinephrine injection, by inducing a faster rate of

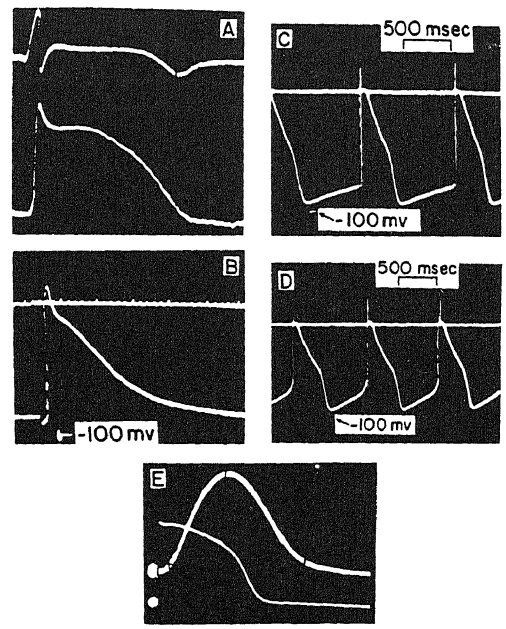

Fig 3 51 *A* Transmembrane action potential of a single ventricular fiber (lower curve) and simultaneous ventriculogram of the intact heart in situ The upstroke of the action potential coincides with the R wave of the electrogram the plateau with the R-T segment and the phase or repolarization with the T wave (After Brooks and associates) *B* Normal transmembrane potential recorded from a single fiber of the intact auricle (After Brooks and associates) *C* Transmembrane action potential of a single Purkinje fiber in a nonpacemaker activity Note slow loss of resting potential during diastole (After Brooks and associates) *D* Spontaneous activity recorded from Purkinje fiber in a pacemaker area Note slow depolarization during diastole and then abrupt onset of spontaneous depolarization (After Brooks and associates) *E* Temporal relation between action potential and mechanical contraction recorded from a papillary muscle (After Dudel and Trautwein 1954)

depolarization with an earlier firing, accelerate heart rate

Transmembrane action potential (TMP) curve during activation from various types of cells are diagrammed in Figure 3 52 Five phases of the action potential are recognized phase 0, an initial rapid depolarization or spike, which overshoots the zero potential by 20 to 30 mv , phase 1, an initial rapid repolarization which returns the TMP toward zero, phase 2, a slow phase of repolarization or plateau, phase 3, a final rapid repolarization which returns the membrane potential to its resting level, phase 4, the resting or diastolic TMP In pacemaker cells the TMP during phase 4 gradually decreases (diastolic depolarization) to a given potential (threshold) at which "all-or-none" depolarization occurs (phase 0)

Threshold Potential (TP). The critical level of cell membrane depolarization (about 55 to 60 mv) at which a propagated impulse is initiated (Fig 3 53) is the *threshold potential* Once this level of depolarization is reached, no greater stimulus is required for the upstroke of the action potential to become self-sustaining The *threshold stimulus* is defined as the magnitude of stimulus required to bring the resting membrane potential to the threshold level Subthreshold stimuli produce only local nonpropagated responses (Fig 3 53) As the resting TMP decreases toward TP excitability increases, i e , less TMP decrease is required to reach TP If the resting TMP becomes sufficiently less than the threshold potential, the cell is not excitable (i e , it cannot initiate a propagated impulse)

The form, duration, resting potential level, and amplitude of action potential are characteristic for the different myocardial cell types (Fig 3 52 *B*, *C*) These differ among mammalian species Those characteristic for man, dog, and rabbit will be described. The SA node pacemaker cells have a relatively low resting potential (Fig 3 52 *B*, *C*, and 3 54), slow phase 0, indistinct phase 1 and phase 2, distinct phase 3 and phase 4 slowly depolarizes Atrial muscle cells lack a distinct phase 2 (plateau) and phase 3 is prolonged Atrioventricular nodal cells may exhibit hyperpolarization at the end of phase 3 and phase 1 is not distinct Purkinje fibers have a distinct phase 1 and phase 2 is relatively long, phase 4 may exhibit spontaneous depolarization.

Most atrial and ventricular cells maintain a

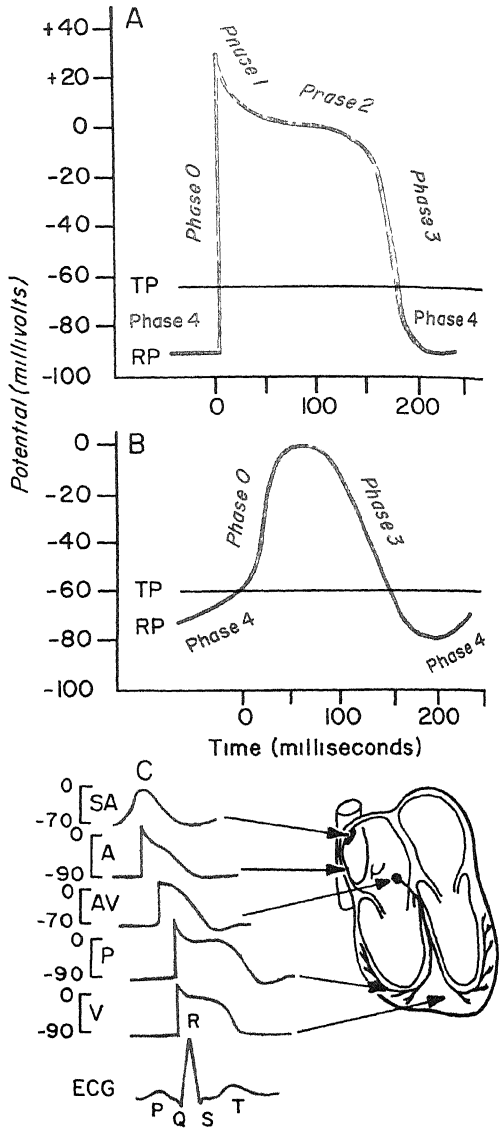

Fig 3 52 Transmembrane potential from a ventricular working or nonpacemaker cell (*A*) and a sinus node pacemaker cell (*B*) with phases labeled *C* illustrates the configurations of TMP from various types of cells from top to bottom sinus node cell, atrial muscle cell, atrioventricular nodal cell, Purkinje cell, ventricular contractile cell (Redrawn from Marriott and Myerburg, 1970)

stable resting membrane potential throughout the phase 4 and are termed *nonpacemaker cells*. Normally, they do not initiate impulses spontaneously

Pacemaker cells are located in the sinoatrial node, in tissues around but not in the atrioventricular node, Purkinje fibers, and atrium (la-

tent atrial pacemakers, some of which, at least, have morphological characteristics of Purkinje cells) These cells have the capacity for progressive diastolic depolarization (phase 4)

MECHANISMS OF TRANSMEMBRANE POTENTIALS

Experimental observations and reasonable assumptions indicate that the ionic theory of Hodgkin and Huxley (1952) for nerve membrane potentials is valid for cardiac cells Myocardial cell membrane permeability and conductance to Na^+, K^+, and Cl^- account for transmembrane potentials

Membrane ionic *permeability* (P_i) is a measure of the ease with which an ion penetrates the membrane when driven by a concentration gradient across the membrane Membrane ionic *conductance* (g_i) is a measure of the ease of penetration of an ion when driven by an electrical force Ion permeability and conductance are related quantities, but not equivalent Their relationship is complicated, depending on such things as the membrane voltage and ionic concentrations on either side of it Ion conductance is the reciprocal of ion electrical resistance in a membrane ($g_i = 1/R$) and is expressed in mhos (ohms spelled backward) It reflects membrane ion permeability

Changes in P_i and g_i determine the membrane's potential (E_m) and flux or current (I_m)

The approximate concentration ratios intracellular extracellular for sodium, potassium, and chloride ions in heart muscle cells are

$$Na^+,\ 1\ 10,\ K^+\ 40\ 1,\ \text{and}\ Cl^-,\ 1\ 30$$

From the Nernst equation (q v) the equilibrium potential for a given ion (E_{ion}) can be calculated if the ionic concentrations inside (i) and outside (o) a cell membrane are known At 37° C

$$E_{(ion)} = 61\ 5 \log (ion)o/(ion)i$$

From typical values of ion concentrations for heart muscle, the estimated equilibrium potentials for Na^+ and K^+ are

$$E_{Na} = +70\ \text{mv}$$

$$E_K = -102\ \text{mv}$$

In Table 3 10 it is seen that the resting membrane potential for various myocardial cells approaches the equilibrium potential of K^+ Potassium ions have been identified as the major ion species responsible for maintaining resting potential That membrane potential (E_m) is not identical with E_K results from the influence of other ions, in particular Na^+ The degree of influence these ions have on resting potentials is determined by their conductance across the membrane To explain why E_m does not equal E_K consider the equation

$$E_m = 61\ 5 \log \frac{[K^+]_o + \alpha[Na^+]_o}{[K^+]_i + \alpha[Na^+]_i}$$

α is a constant expressing the ratio of Na^+

Table 3 10

From Hecht, 1968

[a] MRP, membrane resting potential, AP, action potential, D_{AP}, duration of action potential

[b] The values for D_{AP} depend on temperature and heart rate—some average values are given which show the difference in fiber size and in duration of the action potential in comparison to cardiac tissue

[c] Values for skeletal muscle and nerve fiber are given for comparison note particularly the differences in fiber size and in duration of the action potential in comparison to cardiac tissue

permeability to that of K^+ (P_{Na}/P_K) A small inward flux of Na^+ during rest, would oppose the outward flux of K^+ and reduce E_m, explaining why E_m is less than E_K Since α is thought to be about 0 01 for muscle and nerve, $\alpha[Na^+]_i$ is small compared to $[K^+]_i$ In the physiological range (low $[K^+]_o$ and high $[Na^+]_o$), $\alpha[Na]_o$ becomes a significant factor of the sum $[K^+]_o + [Na^+]_o$ Pacemaker tissues have a lower resting transmembrane potential than working myocardial cells, which could be accounted for by assuming a larger resting Na^+ inward current Cl^- inward flux has the same effect as K^+ outward flux and plays a role with K^+ during repolarization

The distribution of Na^+ and K^+ across the cell membrane is maintained by a metabolically active Na/K membrane pump which derives its energy from organic phosphate metabolism Adenosine triphosphatase (ATPase) located in the cell surface is activated by external K^+ and internal Na^+, i e , the membrane is asymmetrical with respect to Na^+ and K^+ Adenosine triphosphate (ATP) is the immediate source of energy for the pump, which is inactivated by metabolic inhibitors (dinitrophenol, azide, cyanide) and inhibited (although low concentrations can be shown to stimulate) by cardioactive glycosides (ouabain, digoxin) The latter show asymmetry of action too, inhibiting K^+ transport from the outside of the fiber This ATPase is Mg^{++} dependent and inhibited by Ca^{++} at the inner membrane surface

Resting Potential. The maintenance of resting potential is a result of the large ionic concentration gradients across the membrane The voltage and polarity of the resting potential are a consequence of the higher conductance of the resting membrane for K^+ than for Na^+ The resultant membrane potential, E_m, represents the sum of the equilibrium potentials for Na^+ and K^+, $E_{Na} + E_K$ Chloride ions have no effect on resting potential, but contribute to repolarization phases of the action potential Since potassium permeability (P_K) and conductance (g_k) are relatively high in the resting state, the resting membrane potential largely is dependent on K^+ flux

Action Potential. The action potential at a given membrane site results from sequential

changes in membrane ion permeability primarily to Na^+ and K^+, and to some extent to Cl^- The conducted cardiac impulse can be viewed as a traveling wave of ion permeability and conductance changes which transiently reverse membrane polarity The conductance changes for Na^+ and K^+ are graphically represented in Figure 3 54 At the onset of the action potential, membrane P_{Na} increases abruptly Na^+ ions flow down their electrochemical gradient into the cell, producing an action potential spike (phase 0) of about 100 mv There is evidence that Ca^{++} ions may also contribute to this inward current of depolarization During phase 1 g_{Na} decreases from its initial high level and g_K decreases Phase 2 is characterized by low g_K and a moderately high g_{Na} Repolarization occurs when the conductances of K^+ and Na^+ return to their resting levels Cl^- ion inward conductance apparently contributes to phase 3 In nonpacemaker cells TMP remains constant at the resting level during phase 4 This stability is largely the result of a steady g_K

The inward movement of Na^+ and outward movement of K^+ are passive movements requiring no energy, the ions flowing down their respective electrochemical gradients At each activation, minute amounts of Na^+ and K^+ are transferred across the cell membrane The metabolically active Na/K pump mechanism is located in the cell membrane It consumes energy from ATP split by Na/K activated ATPase This process returns K^+ to the cell and extrudes Na^+, against their respective concentration gradients

Pacemaker Potential. Pacemaker cells depolarize progressively during phase 4 (Fig 3 54) If not excited previously by a conducted impulse, they will discharge spontaneously when the threshold potential is reached The chief cause of diastolic depolarization is a time-dependent fall in g_K, i e , g_K decreases with elapsed time K^+ conductance is also decreased somewhat as the membrane potential falls during phase 4 (voltage dependence) This fall in g_K permits the low g_{Na} to become increasingly effective As g_K decreases during diastole, outward movement of Cl^- contributes to diastolic depolarization When the threshold potential is reached, g_{Na} increases suddenly and markedly, producing the spike potential (phase 0)

Refractory States Under physiological conditions, cardiac cells are refractory to further stimulation during most of the action potential period Excitability returns during the repolarization phase and goes through a period of supernormality Various phases of the refractory state are recognized (Fig 3 55)

The *absolute refractory period* (ARP) extends from the onset of the action potential until repolarization has progressed to a TMP of about 55 mv The cell cannot be excited during this period As repolarization continues there is a variable decrease in the stimulus required (threshold) and action potentials vary in rate of rise (phase 0) and amplitude (Fig 3 55) The *relatively refractory period* (RRP) is the interval during which action potential responses with slow phase 0 and submaximal amplitude occur Before a propagated response can occur, there is a period during which a stimulus may produce graded responses in cells which are not conducted The *effective refractory period* (ERP) is this period together with ARP The *total refractory period* (TRP) includes ARP,

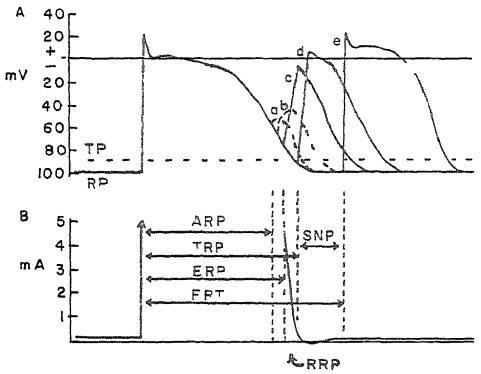

Fig 3 55 *A*, normal transmembrane action potential and responses to series of stimuli applied during and after end of repolarization ***B***, approximate durations of absolute refractory period (ARP) total refractory period (TRP) effective refractory period (ERP) full recovery time (FRT) supernormal period (SNP) and relative refractory period (RRP) In *A* responses shown as dotted lines (*a* and *b*) are graded responses which do not propagate Response (*c*) is earliest propagated response and defines end of effective refractory period Response (*d*) is elicited at the time when transmembrane potential is close to level of threshold potential (TP) and occurs during supernormal period Response (*e*) is elicited after end of repolarization and is normal in terms of rising velocity and amplitude, defining end of full recovery time Changes in threshold shown in ***B*** are related to an arbitrary scale of current strength Curve shows onset of inexcitability coincident with phase 0 of transmembrane action potential gradual decrease in threshold during phase 3 of repolarization and restoration of full excitability after end of phase 3 of transmembrane action potential (Redrawn from Hoffman 1969)

ERP, and RRP The *supernormal period* (SNP) is an interval beginning at about the time the action potential reaches the resting threshold level During this period the stimulus required for response is less than for a resting cell, but the amplitude and rate of rise of the action potential are submaximal *Full recovery time* (FRT) includes all of the foregoing periods up to the time when the resting potential is stable and the rise time, action potential amplitude and duration of the response and excitability are fully restored The term *partial recovery period* is sometimes employed for cardiac tissue or the entire heart to designate the interval during which some cells have recovered fully while others remain in some stage of refractoriness

Conduction Velocity. The rapidity with which the impulse is conducted in a given fiber is a function of the rate of rise and amplitude of the action potential and the fiber diameter The lower the resting potential, the slower is the speed of conduction The larger the fiber diameter, the faster is conduction velocity Sinoatrial and atrioventricular nodal fibers have lower resting potentials than atrial and ventricular cells and are smaller These fibers conduct more slowly

Decremental conduction is said to occur in sinoatrial and atrioventricular nodal tissues, i e , the action potential progressively decreases in rise time, velocity and amplitude, until propagation slows and finally ceases Under certain circumstances (e g , vagal stimulation) decremental conduction may increase in the AV node to the point that the impulse is blocked This may be a mechanism responsible for certain types of SA and AV block and so-called concealed conduction in AV junctional tissues (see under Arrhythmias and Conduction Disturbances)

AUTOMATICITY AND EXCITABILITY (IRRITABILITY)

The term *automaticity* designates the ability of cardiac cells to generate a propagated impulse spontaneously (assume pacemaker function) Normally, as stated earlier, this property is thought to be limited to specialized cells in the SA node, around but not in the AV node, in the atrium, and in the Purkinje system Electrophysiologically, these cells exhibit diastolic depolarization The rate at which diastolic depolarization occurs determines the frequency of spontaneous impulse formation, i e , the steeper the slope of phase 4, the shorter the time interval required for the TMP to reach the threshold potential required for spontaneous depolarization of the membrane When the firing frequency of a cell is increased, its automaticity is said to be increased and vice versa Certain abnormal mechanisms can cause automaticity For example, the drug aconitine causes oscillating afterpotentials to follow phase 3 of the action potential such an oscillatory depolarization can reach TP and initiate an action potential It is speculated that delayed repolarization of a group of cells may set up an excitatory current flow with already repolarized cells, sufficient to cause re-excitation of adjacent cells

In contrast to automaticity, the term *excitability* (or *irritability*) refers to sensitivity to stimulation The strength of stimulus required to bring the resting potential to the threshold for a propagated impulse, is determined by the difference between the existing membrane potential and its threshold potential (TP) If the resting TMP is greater than (i e , more negative) but close to TP, the stimulus needed to initiate an action potential is less than when the resting potential is much more negative than TP On the other hand, cells are refractory to stimulation when TMP is sufficiently less negative than TP (Fig 3 55)

Conduction System

The specialized pacemaking and conducting tissue of the heart consists of the sinoatrial node (SAN), interatrial and internodal conduction pathways, the atrioventricular node (AVN), the bundle of His, the right bundle branch (RBB) and left bundle branch (LBB) of the bundle of His, and the peripheral Purkinje network Ordinarily, pacemaker cells located within the SAN serve to initiate the heart beat From here, the impulse enters the atrial myocardium and follows preferential conduction pathways which conduct the impulse relatively rapidly to the atrioventricular node (internodal tracts) and to the left atrium (Bachmann's bundle) Normally, impulses which reach the ventricle must traverse the atrioventricular node, a region of relatively slow conduction Emerging from the AVN, the impulse reaches the rapidly conducting Purkinje fibers of the bundle of His and travels along the bundle branches to the subendocardial Purkinje fiber

network of the ventricles These structures serve to originate the cardiac impulse for each heartbeat and distribute it throughout the heart They provide for sequential contraction of the atria and ventricles and bring the entire myocardial mass of both ventricles rapidly into coordinated contraction Data on fiber diameters and conduction velocity in the human heart are given in Table 3 11 and the routes of conduction are presented schematically in Figure 3 56

Table 3 11
Fiber diameter and conduction velocity in human hearts

Site	Fiber Diameter	Conduction Velocity
	μ	*m /sec*

AV fibers (about 5 mm long)	3-11	0 05
His bundle branch	9-18	2 0
Ventricular myocardium	10-12	
Subendocardium		1
Subepicardium		0 4-1

From Bauereisen, 1970

THE SINOATRIAL NODE (SAN)

The SAN is imbedded in the right atrial wall at the junction of the superior vena cava and the right atrium This junction appears on the epicardial surface as the *sulcus terminalis*, on the endocardial surface as the *crista terminalis* The SAN is ellipsoid in shape containing rather long thin fibers in which myofibrils are sparse An abundant collagen network interlaces with bundles of nodal fibers James (1970b) distinguishes two types of cells, centrally located P *cells* which may be the normal pacemaker cells and more peripherally located *transitional cells* which serve to connect P cells with adjacent cells of the atrial myocardium and the internodal and interatrial pathways (see p 3-28)

INTERNODAL AND INTERATRIAL PATHWAYS

These are diagrammed in Figure 3 56 Three pathways connecting the SAN to the AVN and one connecting the SAN to the left atrium have been described The anterior internodal tract travels from the left tip of the sinus node a short distance and divides into two branches one branch (Bachmann's bundle) travels along the dorsal aspect of the interatrial band and ramifies over the left atrium The other branch curves downward below the interatrial septum to the region of the AVN, here joining fibers from the other internodal tracts The middle internodal tract (first described by Wenckebach) emerges from the posterodorsal edge of the sinus node, passes behind the superior vena cava to the top of the interatrial septum Here, a few branches pass to the left atrium while the major bundle continues over the interatrial septum to the top of the AVN The posterior internodal tract (Thorel's tract) extends from the posterior end of the sinus node along the *crista terminalis*, through the eustachian

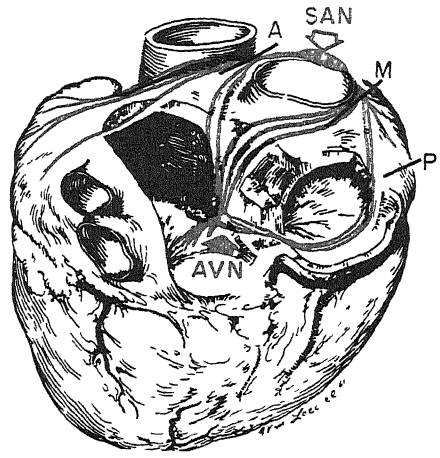

Fig 3 56 Diagram of the internodal pathways of the human heart ***A***, anterior internodal pathway which sends fibers to the AVN and interatrial fibers to the left atrium (Bachmann s bundle) ***M*** middle internodal tract (Wenckebach s tract) ***P***, posterior internodal tract (Thorel s tract) (James 1970a)

ridge to the interatrial septum to join the AVN at its right superior margin

These internodal pathways constitute preferential routes of conduction from the SAN to the AVN and from the SAN to the left atrium Conduction velocity is more rapid in these pathways than in ordinary working atrial myocardium but not as rapid as in the His bundle or its branches The pathways consist of a continuum of myocardial cells made up of a mixture of Purkinje cells and cells indistinguishable from ordinary working myocardium On anatomical grounds, the most direct route for spread of excitation from the SAN to the AVN and left atrium would be through the anterior internodal tract, one branch of which sends

specialized fibers (Bachmann's bundle) into left atrium and the other branch into the AVN Conduction is most rapid in this tract in dogs (Holsinger et al , 1968) Atrial depolarization is accomplished both by radial spread to working myocardial cells from the SAN as well as more rapid transmission over these preferential pathways directed toward the AVN and left atrium The internodal tracts are not ensheathed nor otherwise separated from adjacent myocardial tissue These special pathways provide for rapid spread of excitation throughout both atria and determine its temporal sequence in different parts of the atria There is evidence that specialized atrial cells exhibit elevated resistance to the depressant effects of hyperkalemia and can continue to conduct impulses from the SAN to the AVN when the body of the atrial musculature is inactivated and the P wave of the body surface electrocardiogram absent (Vassalle and Hoffman, 1965, Wagner et al , 1966)

ATRIOVENTRICULAR NODE

The atrioventricular node is located beneath the right atrial endocardium at the base of the interatrial septum just interior to the ostium of the coronary sinus (Fig 3 57) On the atrial side, it receives branches from the internodal tracts as well as from the ordinary atrial musculature and is continuous with the bundle of His on the ventricular side Its fibers, which are smaller than those of atrial muscle, form a pattern of branching and interlacing strands in a connective tissue framework P cells are present within the node especially in its deeper portions, but they are less frequent then in the sinus node The slender transitional cells are the most frequent cell type

CONDUCTION TO VENTRICLE

The Bundle of His At the region of transition between the AVN and bundle of His, the cells gather into more regular fascicles and take on the characteristics of typical Purkinje fibers These fibers of the His bundle then pass from the right atrial endocardial location of the AVN medially and inferiorly along the lower margin of the membranous interventricular septum (Fig 3 57) The His bundle gives rise to a single right bundle branch and multiple left branches, the latter forming a sheet of fibers traveling down the left septal endocardium

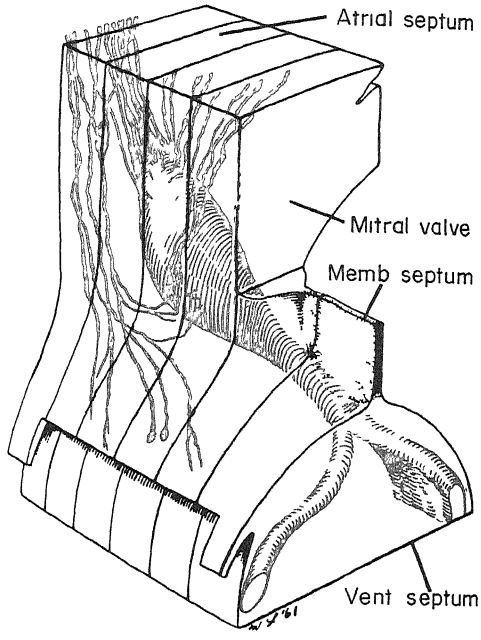

Fig 3 57 Schema of the AV node and His bundle Atrial Septum interatrial septum Vent Septum interventricular septum Memb Septum membranous portion of the interventricular septum Fibers from internodal tracts are shown entering the AV node The bundle of His (not labeled) runs along the lower margin of the membranous interventricular septum It gives rise to a single right branch and then multiple left branches form a vertical sheet down the left septal subendocardium (James 1970a)

The Bundle Branches. The right bundle is given off first as the smaller of the two branches It passes down, subendocardially, the right side of the interventricular septum and, branching, links up with the subendocardial Purkinje network The first functional contact of the right bundle branch with the ventricular myocardium is near the base of the anterior papillary muscle

The left bundle branch continues from the common bundle of His as a broad fascicle which runs subendocardially down the left side of the interventricular septum, dividing into major anterior and posterior divisions before reaching the peripheral Purkinje network In most hearts the left bundle branch makes its first functional contact with the ventricular myocardium on the left endocardial surface of the interventricular septum some distance below the aortic valve

The paraspecific fibers of Mahaim are incon-

stant, but when present are seen as a small bundle of fibers leaving the left bundle branch to enter the upper dorsal parts of the interventricular septum

The Accesory Bundle of Kent Additional communications between atria and ventricle, most frequent in fetal and infantile hearts, may be identified in some adult hearts The most common is the bundle of Kent which extends from the right atrium to the upper parts of the interventricular septum Fascicles of atrial myocardium may also be seen extending through the atrioventricular ring into the base of the atrioventricular valves Purkinje cells are not found in the accessory bundles They are considered by some to serve as atrioventricular conduction routes, by-passing the AVN, which, when active, account for accelerated atrioventricular conduction (Wolff-Parkinson-White syndrome)

The Subendocardial Purkinje Network. The Purkinje network is largely limited to the subendocardium in man These specialized conducting cells of Purkinje penetrate for a short distance into the ventricular myocardium where they merge insensibly with working myocardial cells These fibers are also found in the free-running false tendons in the right and left ventricles

IMPULSE INITIATION

Keith and Flack, 1907, suggested that the SA node embedded in the right atrial wall near the entrance of the superior vena cava is the focus in the mammalian heart from which each heart beat normally starts Evidence of such origin is that *1)* its excision or inactivation causes cessation or slowing of the atrial or ventricular contractions, *2)* temperature change of the node but not of the surrounding tissue changes heart rate, *3)* the node becomes electrically active before any other region of the heart

Although spontaneous and repetitive depolarization arises normally only in this region, there are other areas in which electrical activity can arise under some circumstances and initiate cardiac contraction When the SA node is destroyed or inactivated, the AV junctional tissues often become the site of impulse formation and develop spontaneous depolarization Another area which develops pacemaking activity when the SAN is inactive is in the region of the coronary sinus In turn, in the presence of inactivation of the AV junctional tissue, the ventricles develop a slow rhythm Since both ventricles receive the excitation through natural pathways and contract in a coordinated way, the rhythmical center is the AV bundle If both bundle branches are cut, impulse initiation arises in the ventricular muscle The natural rate of automaticity of these areas is of a descending order of magnitude, the SA node being 70 to 80/min , atria 60/min , AV junctional tissues 40 to 60/min , and ventricles 20 to 40/min It is obvious that normally, the atria, AV junctional tissue, and ventricular tissue cannot set the heart rate because the SA node repolarizes and automatically discharges more rapidly than any of these tissues Hence, an impulse from the SA node will always depolarize these tissues before any could initiate a rhythm On occasion, however, an ectopic focus in the atrium or ventricular muscle can assume a rhythm faster than that of the SA node, and hence, it becomes the pacemaker

SPREAD OF EXCITATION IN HUMAN HEART

The cardiac impulse normally is initiated in sinoatrial node pacemaker cells (Fig 3 52) Thus, the sinus node sets the pace and depolarizes other potential pacemaker cells before they can discharge automatically If the frequency of sinus node cells decreases greatly or they fail to discharge automatically, other slower pacemakers will begin to initiate the heart beat Ectopic foci in the atria or ventricles can develop a faster rhythm than the sinus node cells under certain conditions These sites then determine cardiac rate and rhythm from an abnormal location

Although preferential pathways of conduction have been identified in human and dog hearts, as described in the foregoing, in isolated human hearts spread of excitation proceeded more or less radially from the region of the SA node at a rate of about 1 m /sec (Durrer et al , 1970) Conduction through the atrioventricular node is slow and decremental, requiring 80 to 120 msec Here conduction velocity may be increased by sympathetic stimulation, ordinarily traveling at a velocity of 0 1 to 0 2 m /sec The Purkinje fibers of the bundle of His and bundle branches conduct rapidly at rates of about 2 m /sec , distributing the impulses fairly synchronously to the subendocardium, where conduction velocity is about 1 m /sec Excitation is then conducted from endocardium to epicar-

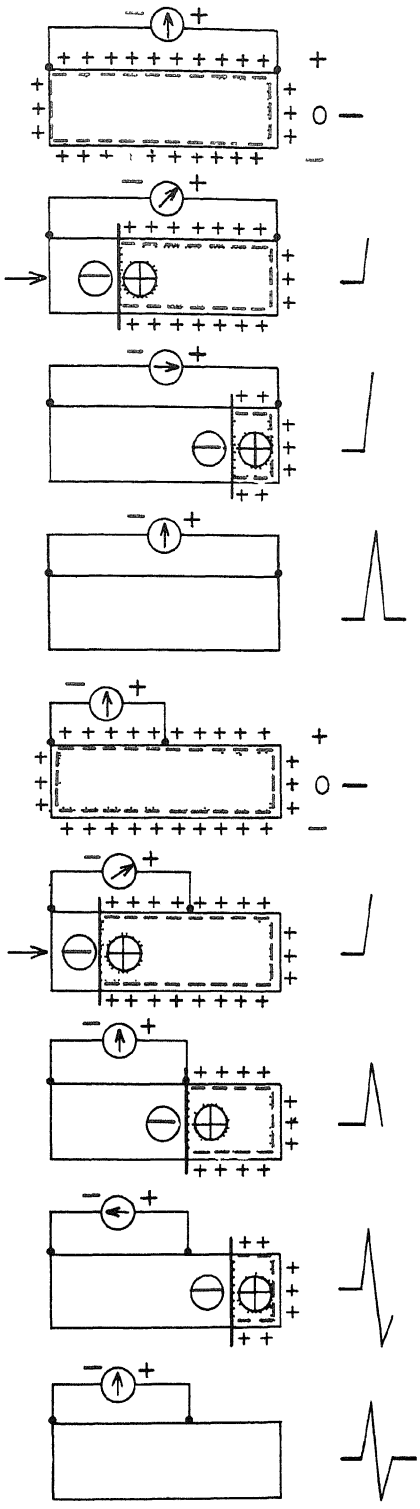
dium Conduction velocities in the human ventricular myocardium of about 0 35 to 0 40 m /sec have been found (Durrer et al , 1970)

During the first 5 msec of ventricular excitation depolarization of the left central interventricular septal region and anterior and posterior paraseptal surfaces begins and these areas become confluent in 15 to 20 msec Subendocardial depolarization in the right ventricle begins near the insertion of the anterior papillary muscle 5 to 10 msec after the onset of ventricular activation Septal activation starts in the middle third of the left side of the interventricular septum and at its lower third near the septal posterior wall junction After 30 msec , a nearly completely confluent front is moving through the left ventricular wall, except at the posterobasal wall, and subepicardial excitation has appeared on the anterior surface of the heart near the atrioventricular sulcus and at anterior and posterior paraseptal areas halfway between apex and base The posterobasal area is the latest to be activated Right ventricular activation, starting at 5 to 10 msec , rapidly invades the septum and adjoining right free walls reaching the subepicardium in 20 msec near the area pretrabecularis Ultimately, the pulmonary conus and posterobasal areas are activated (at 60 to 70 msec) Thus, the general sequence of ventricular activation is *1*) septal excitation proceeding from left to right, *2*) excitation in the upper part of the anterior wall of the left ventricle, proceeding through the free wall, *3*) excitation of the left ventricular posterior wall proceeding in the opposite direction, *4*) excitation traveling through the right ventricular free wall and moving from right to left through the midanterior part of the septum, *5*) completion of activation at the pulmonary conal and posterobasal areas (Durrer et al , 1970)

ELECTROCARDIOGRAPHY

Electrocardiography may be defined as that branch of physiology which is concerned with the recording and analysis of the electrical activity of the heart The electrocardiograph is an instrument which receives the electrical impulses as they vary during the heart cycle and transforms them into a graphic record called the *electrocardiogram*, when recorded from the surface of the body Records obtained directly from cardiac muscle are called *electrograms*

Instrumentation



The first electrocardiogram was obtained in 1887 by Waller who employed a capillary electrometer Einthoven became the real father of electrocardiography when he described the string galvanometer in 1903 This instrument became the standard apparatus for the recording of electrocardiograms until it was largely supplanted by the vacuum tube, amplifier-driven oscillograph in the 1930's This type of instrument was later modified by increasing the amplification sufficiently to drive a mechanical lever arm so that directly written records might be obtained either with an ink writer or a hot stylus applied to specially waxed paper Recently transistorized modifications of the vacuum tube type of oscillographic instrument have come on the market Common to all these instruments is the property of faithfully inscribing the variations of the cardiac voltages on an accurate time scale abscissa

The cathode ray oscilloscope has been employed for specialized research in electrocardiography and recently it has been adapted by means of the sweep circuit to give a constant visual display of the electrocardiographic pattern which can be monitored during surgery or other critical clinical conditions

Depolarization and Repolarization of Cell Aggregates

The electrocardiogram which is recorded from body surface electrodes is the result of a vast number of systematically propagated electrical events taking place in the individual muscle cell fibers of the heart We have seen that the individual myocardial fiber is depolarized and repolarized with large voltage fluctuations across the cell membrane, but with only small potential differences being recorded outside the cell How then does the transmembrane action potential relate to the electrocardiogram recorded from the surface of the heart or from the surface of the body? One simplified approach to understanding the complex phenomena involved will be here presented

It must be remembered first that the depolarization of a portion of a fiber initiates a flow of current from the polarized zone to the depolarized zone. This flow of current propagates the wave of depolarization until the entire tissue is depolarized Since the heart is functionally a syncytium of muscle fibers, if one portion of the

muscle becomes depolarized it will initiate a wave of activation that will eventually depolarize the entire heart That such is indeed the case is shown by the fact that extrasystoles may be produced by touching the epicardium of the exposed heart at surgery or by touching the endocardial surface with a cardiac catheter during diagnostic studies The localized point of depolarization initiated by the mechanical stimulus is propagated to the entire heart muscle

THE ISOLATED MUSCLE STRIP

Depolarization The relationship between the surface electrocardiogram and the spread of depolarization through the muscle is illuminated by experiments on isolated strips of heart muscle Figure 3 58 illustrates the sequence of events when a wave of activation sweeps over a strip of myocardium with electrodes applied directly to its surface On the resting polarized muscle there is no difference of potential since all parts of the surface are equally positive in charge Hence the galvanometer records only a straight line at zero potential When the strip is stimulated at the region of the negative electrode to the left of the drawing, this zone becomes depolarized and is electrically neutral The other end of the strip is now positive with respect to the depolarized zone, and the galvanometer records a positive deflection As the wave of activation approaches the positive electrode more and more positivity is recorded until the muscle strip is completely depolarized, whereupon there is no longer a potential difference, and the recording drops abruptly to the zero line

When the positive electrode is placed in the middle of the strip and the stimulus is applied to the region of the negative electrode, posi-

Fig 3 58 Depolarization of a strip of myocardium with electrodes in direct contact with tissue During the resting stage no difference of potential is recorded When stimulated at arrow depolarization begins and stimulated end becomes negative relative to opposite end Positivity is recorded from positive electrode until activation is completed whereupon no more difference in potential exists and recording drops to zero With positive electrode in middle of strip positivity is recorded until the activation wave arrives under the electrode Since the plane that divides a dipole is at zero potential the recording drops immediately to zero As soon as the dipole passes the electrode maximum negativity is recorded and it gradually lessens until the return to zero when activation is completed

tivity is recorded until the wave of activation passes beneath the positive electrode whereupon the recording drops abruptly to a negative potential which returns to the zero line when the strip becomes completely depolarized In a series of simple but beautifully conceived experiments, Craib (1927) was able to show that this phenomena could best be accounted for in terms of the migration of a dipole across the length of the muscle strip

A dipole may be conceived of as two points of opposite electrical charge separated by a very small distance If these points are connected by a wire it is understood by convention that current will flow along the wire from the positive pole to the negative pole (In point of fact the electrons actually flow from the negative to the positive pole) If the dipole is immersed in a volume conductor such as a pool of weak saline solution, then a three dimensional field will be set up with the lines of current flow distributed in a pattern as illustrated in Figure 3 59 Isopotential lines are arranged at right angles to the lines of current flow Thus, all points which lie on the plane perpendicular to the center of the axis connecting the two points of the dipole are at zero potential The human electrocardiogram may be analyzed in terms of the body surface potentials generated by a series of dipoles within the heart and distributed throughout the body which behaves as a volume conductor

This concept may be clarified by reference to an isolated heart muscle strip immersed in a volume conductor as shown in Figure 3 60 In the resting state the strip is polarized with innumerable dipoles distributed about the surface of the strip, positive charges on the outside and negative charges on the inside Since the positive charges facing the electrode are exactly balanced by the positive charges facing away from the electrode, there is no difference of potential, and no deflection is registered on the galvanometer or on the electrographic tracing

When a stimulus is applied to the end of the strip facing away from the electrode, depolarization begins at that point The dipoles at the point of stimulus are obliterated by a flow of current across the stimulated membrane, the electrical resistance of which drops precipitously The stimulated area is now electrically negative with reference to the remainder of the strip which is still positively charged Thus, the plane that divides the depolarized from the polarized portion may be considered as an interface separating the positive and negative

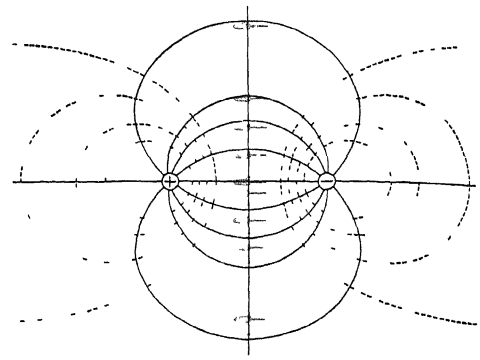


Fig 3 59 Electrical field of a dipole in a volume conductor Solid lines are current flow Dotted lines are isopotential lines

poles of a dipole, and the propagation of the wave of depolarization down the muscle strip may be thought of as the sweep of a dipole across the length of the muscle strip As the dipole approaches the electrode increasingly larger voltages are recorded as the electrode intersects isopotential lines of higher voltage Maximum potential is reached when the dipole arrives at the end of the strip nearest the electrode When the entire strip becomes depolarized, it suddenly becomes electrically inert and the galvanometer and electrogram immediately fall to the zero level

Figure 3 61 illustrates the electrograms which are inscribed when the positive electrode is placed at the stimulated end of the strip or at the midpoint

Repolarization. The process of repolarization is of relatively long duration in contrast to the rapid spike of depolarization, as demonstrated by the monophasic action potential recorded from single fibers with the micropuncture technique Since the resting transmembrane potential is fully restored after each beat, the total electrical charge of repolarization must be equal and opposite to the discharge of depolarization If it were presumed that repolarization followed the same pathway across the muscle strip as the wave of depolarization, then one would expect that the repolarization wave should be inscribed by the recording oscillograph as a slow deflection opposite in direction to the depolarization spike but encompassing the same area While this is indeed the case in the isolated muscle strip electrogram, it is not the case in the normal human electrocardiogram in which the depolarization and repolarization deflections usually have the same direc-

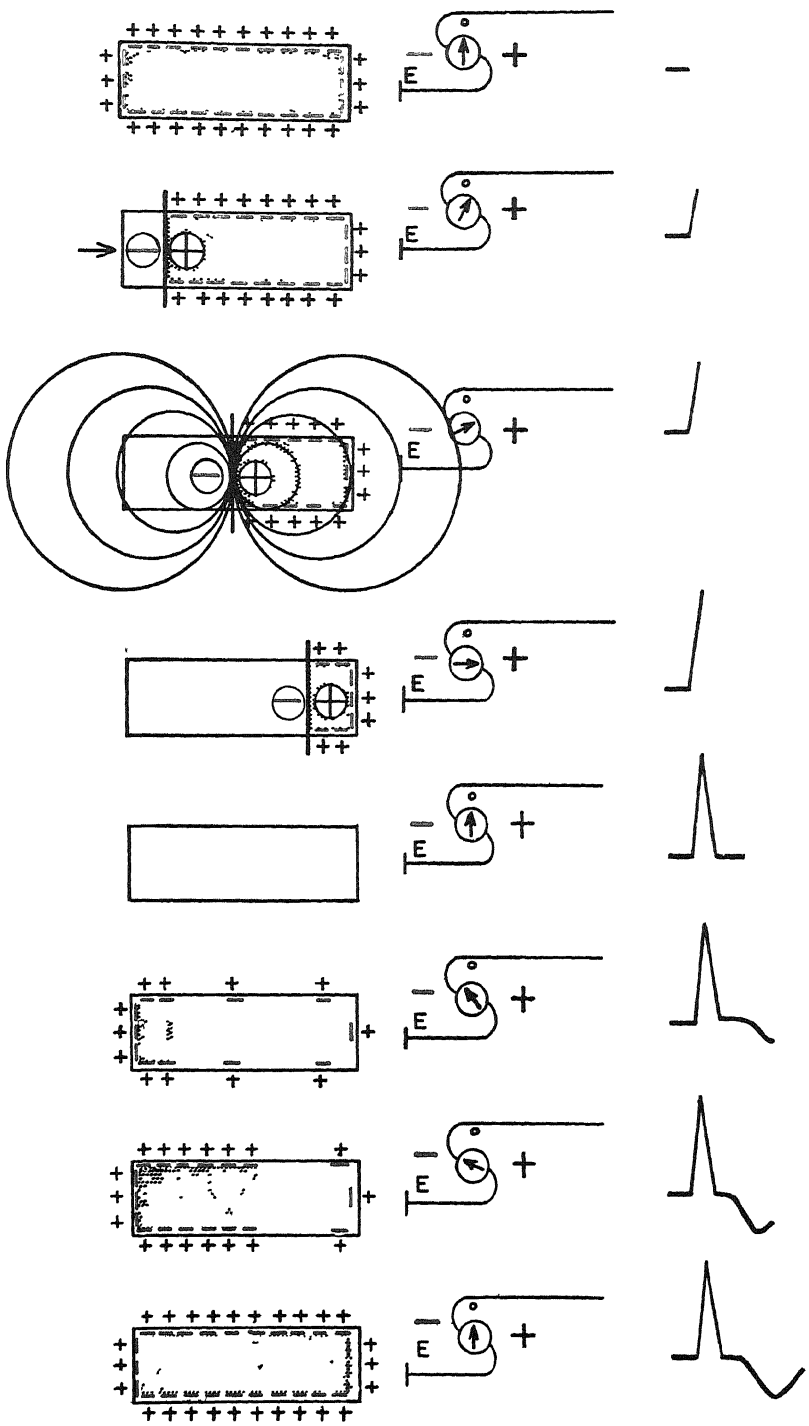

Fig 3 60 Depolarization and repolarization of a strip of myocardium immersed in a volume conductor Electrode E connected to positive pole of recording galvanometer which is paired with a distant electrode at near zero potential The advancing dipole at the border between activated and inactivated muscle produces an electrical field which moves toward the electrode The electrode is intersected by isopotential lines of increasing force until all difference of potential is extinguished by completion of depolarization Recovery occurs in all parts of the muscle nearly simultaneously but is completed at the stimulated end first thus producing relative negativity at the side facing the electrode and giving rise to a negative repolarization wave

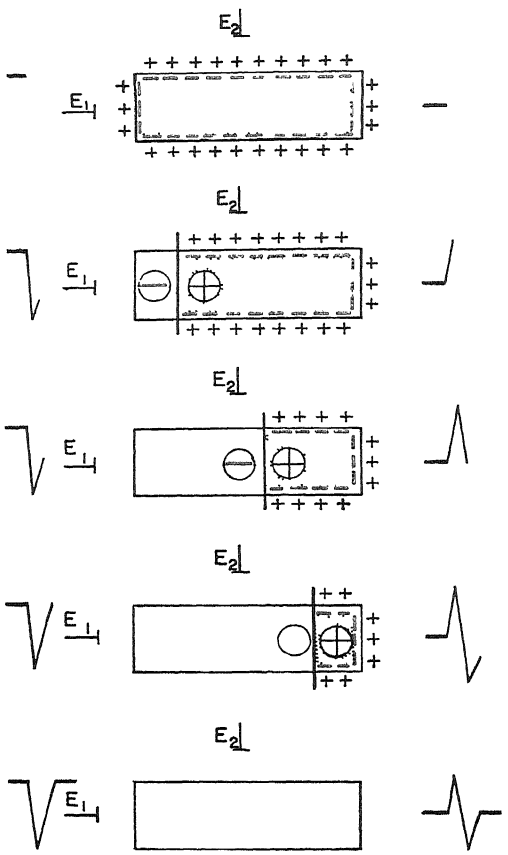

Fig 3 61 Form of complexes inscribed from electrodes placed at positions E_1 and E_2 during depolarization of a strip of myocardium suspended in a volume conductor Each electrode paired with a distant indifferent electrode Tracings on the left side are related to E_1 while tracings on the right relate to E_2 electrode

tion, and the areas of the two are rarely if ever the same The reasons for the paradoxical orientation of repolarization in the human electrocardiogram will be discussed in a subsequent section

Since repolarization is of long duration, different phases of it are proceeding simultaneously in various portions of the muscle strip and indeed throughout the heart (Fig 3 60) Repolarization, therefore, cannot be analyzed as a sequence of propagated electrical events and cannot be viewed as a wave front sweeping across the muscle Changes in temperature, chemical environment, and pharmacological agents may produce marked alterations of the repolarization wave without noticeably affecting the depolarization spike

Current of Injury. When a portion of myocardium becomes injured, whether it be mechanically, chemically, or thermally, the cell membranes in the injured area become more permeable to ions, and this leads to a lessening of the ionic concentration gradients of sodium and potassium across the cell membranes and thus to a reduction of the charge density in the resting polarized state This reduction of positivity in the injured area produces a gradient of charge from the uninjured to the injured zone A current flows from the area of high positivity to the area of low positivity, this current is called the current of injury It flows during the resting polarized state

Figure 3 62 shows how the injury current affects the depolarization and repolarization waves of the electrogram of the isolated muscle strip Prior to injury the polarized muscle strip gives rise to no potential difference and the electrogram tracing is at zero Upon injury of a portion of the strip near the electrode, the base line shifts in a negative direction since the charge density at the injured area is less than that over the remainder of the strip The injured area is thus electrically negative to the noninjured area When the strip is stimulated from the noninjured side the dipole of the depolarization wave sweeps toward the electrode producing a positive deflection The tracing shows an increasing positive spike until the entire strip has become depolarized, whereupon the electrogram deflection falls to the original zero potential, which is well above the negatively displaced base line of the depolarization spike Repolarization then begins at the zero potential line giving the appearance of elevation of the repolarization wave

If the electrode is placed on the opposite side of the strip, then the injury potential displaces the base line upward from the zero line The depolarization spike is negative, and its termination at zero falls below the point of origin This gives the appearance of depression of the repolarization wave Thus, the injury potential produces elevation of the origin of the repolarization wave when the electrode faces the injured zone and depression of the origin of the depolarization wave when the electrode faces the noninjured zone

Another form of injury potential may become apparent when the injured zone fails to completely depolarize As the dipole of the depolarization advances toward the electrode, increasing positivity is inscribed until the activation wave arrives at the border of the injured

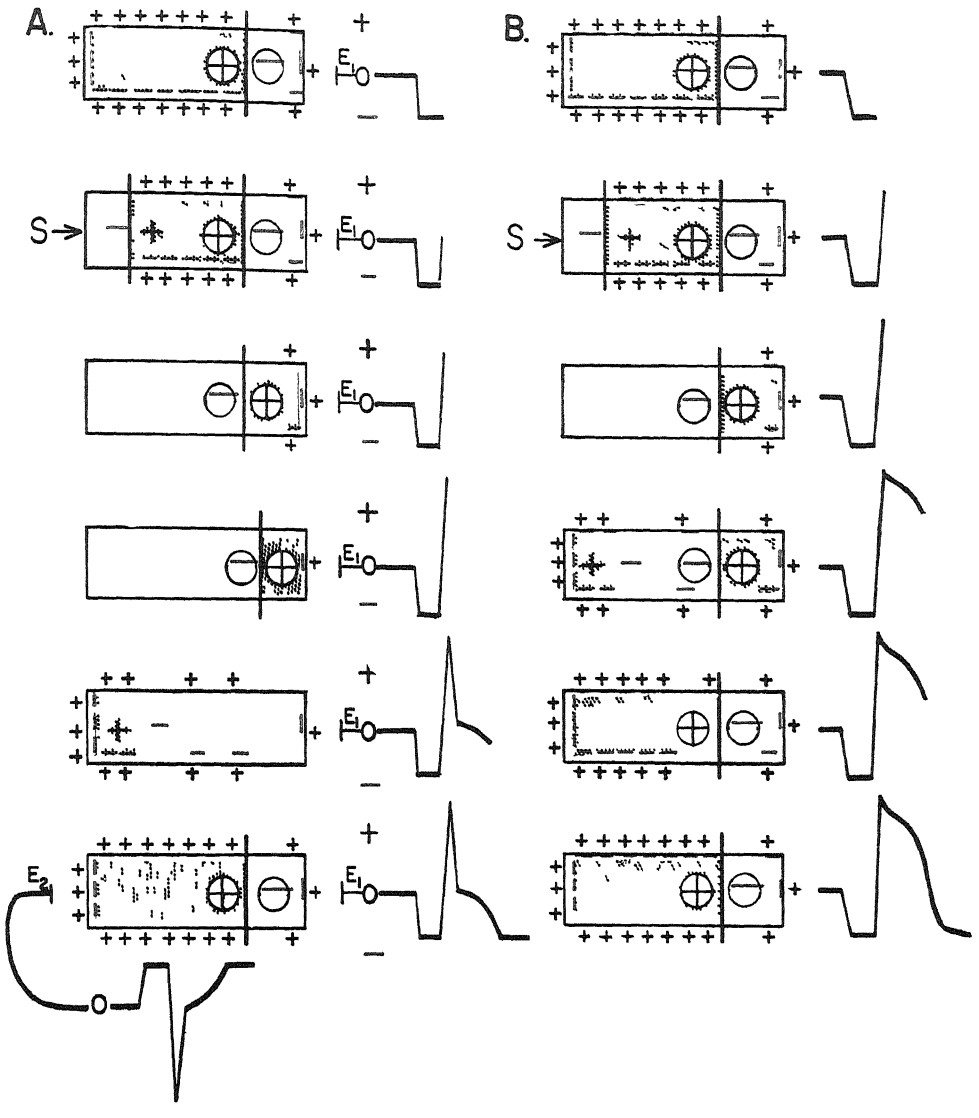

Fig 3 62 Sequence of electrical changes in myocardial strip which has been injured at end near electrode E_1 When portion of strip becomes injured there is leakage of ions and reduction of surface charge density making injured zone less positive than noninjured zone A dipole is thus produced at border of injured zone with negative pole facing the electrode during the resting phase The base line is therefore displaced downward to negative position Following stimulation the dipole of depolarization sweeps toward electrode producing positive force which neutralizes effect of injury dipole In *A*, the injured zone becomes depolarized and injury dipole is abolished Upon completion of depolarization recording falls to original zero position As repolarization is completed from left to right the injury dipole is re-established and tracing returns to negatively displaced base line giving appearance of elevation of onset of repolarization deflection If electrode is on opposite side of strip base line is displaced upward and onset of repolarization appears to be displaced downward *B* shows the sequence when injured zone fails to depolarize The impulse is blocked at the boundary of the injured zone which remains polarized and therefore during systole presents a dipole with its positive pole facing the electrode holding the recording in a positive position until repolarization returns the tracing to the negative base line This phenomenon is called the monophasic injury wave

zone where it is blocked At this point, the injured zone maintains it weakly polarized state, but the noninjured zone has become depolarized making it electrically negative to the injured zone The persistence of the dipole at the completion of activation maintains positivity at the electrode until the repolarization process in the uninjured zone slowly returns the tracing to

the isoelectric line The resulting complex representing a fusion of depolarization and repolarization waves has been called the monophasic injury wave (Fig 3 62*B*)

A third explanation for the injury potential is that the injured tissue repolarizes more rapidly than normal and therefore has a positive charge in relation to the surrounding normal tissue during an early part of the recovery period An electrode near the injured zone faces relative positivity during this part of the recovery period and thus records elevation of the origin of the repolarization wave

Mammalian Electrocardiogram

NOMENCLATURE

The mammalian electrocardiogram contains three major components during each cardiac cycle (Fig 3 63) According to the nomenclature devised by Einthoven, the component produced by atrial activation is called the P wave, the one produced by ventricular activation is the QRS complex, and the component produced by ventricular recovery is the T wave The P wave is separated from the QRS complex by a usually isoelectric interval called the PR segment Atrial repolarization begins after the first portion of the P wave and may produce a visible deflection of the PR segment called the Ta wave In man it is generally not identifiable but may be prominent in certain larger species such as the horse When present, it is usually in an opposite direction from the P wave and may extend beyond the QRS complex, deviating the initial portion of the ST segment (q v) This effect of a large Ta wave can be mistaken for abnormal ST segment deviation Individual deflections in the QRS complex are labeled as follows if the initial deflection is negative (downward from the base line) it is a Q wave, the first positive (upward) deflection is an R wave, and a negative deflection following the R is an S wave Subsequent positive and negative deflections in this complex are labeled R′, R″, etc , and S′, S″, etc , respectively The interval between QRS and T is the ST segment The junction between the end of the QRS complex and the ST segment is called the ST junction or J point A small afterpotential called the U wave is sometimes seen following the T. The duration of the components and intervals vary with species and age

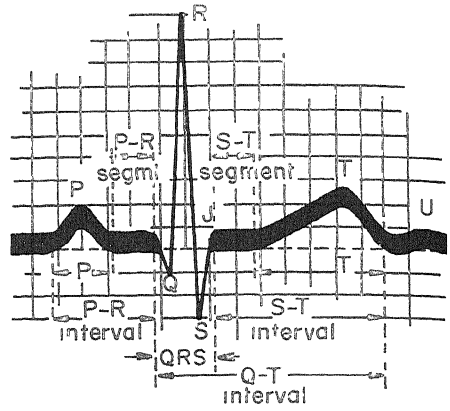

Fig 3 63 A single electrocardiographic complex giving nomenclature of the deflections and the intervals (Burch and Winsor 1966)

The intervals also vary inversely with heart rate In the normal adult human the P wave is 0 07 to 0 12 sec in duration, the PR interval measured from the beginning of the P wave to the beginning of the QRS complex is 0 12 to 0 20 sec , the QRS complex is 0 05 to 0 10 sec , and the QT interval measured from the beginning of the QRS complex to the end of the T wave is 0 26 to 0 45 sec at normal heart rates

DISTRIBUTION OF ELECTRICAL FORCES IN THE BODY

In accordance with dipole theory, the wave front of activation is considered to be a polarized surface with positive charages on its leading side and negative charges on the trailing side The axis joining each pair of positive and negative charges is perpendicular to the polarized surface, and the density of charges is considered to be a constant Atrial and ventricular activation are schematically described by the development of polarized surfaces which spread across the myocardium and are extinguished when they reach a margin of the myocardial syncytium or an area of activated muscle Laws governing the distribution of electricity in a volume conductor define the electrical field produced in the body by such polarized surfaces

When viewed from a sufficiently distant point P, a polarized surface can be represented by a single central resultant dipole with its axis perpendicular to a plane intercepting the boundary of the surface, and its charge proportional to the area of this plane (Fig 3 64*A*)

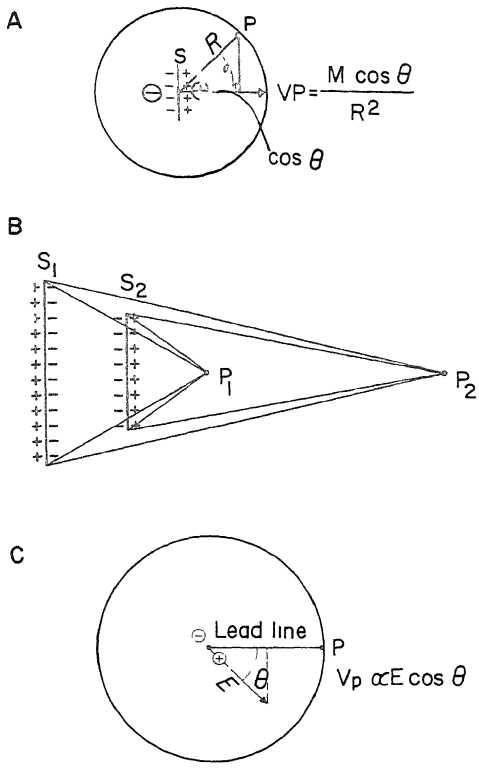

Fig 3 64 ***A*** Calculation of positive potential (V) at point P when polarized surface S is considered as a single dipole Arrow indicates axis of dipole If P is located on a unit sphere then R = 1 As P moves away from the dipole axis its potential diminishes as cos θ diminishes from 1 toward zero The numerical value of cos θ is given by the distance on the axis from the center of the circle to the perpendicular dropped from P M = dipole moment ***B,*** illustration of solid angle principle Two charged surfaces S_1 and S_2 have similar charge density but different areas and opposite orientation of charge At point P_1 the net potential is positive because S_2 subtends a larger solid angle than S_1 At point P_2 the net potential is negative because S_1 subtends the larger solid angle ***C,*** determination of voltage at point P when strength of dipole is represented by vector E Voltage is proportional to E cos θ and is found by drawing perpendicular from the lead line to the terminus of vector Voltage at P is determined by the distance measured along lead line from center of dipole to the perpendicular

The electrical potential (V_p) at a distant point in a large volume conductor containing a dipole with charges close together is proportional to M cos θ/R^2, where M is the electrical force of the dipole (determined by the quantity and distance between charges), R is the distance from P to the center of the dipole, and θ is the angle between the dipole axis and the line from P to the dipole center A positive potential is recorded at P when it faces the positive side of the polarized surface The direct relationship between V_p and cos θ indicates that potential at P is maximal when the dipole axis is parallel to R and zero when it is perpendicular to R V_p is also proportional to the solid angle at P which is subtended by the boundary of the polarized surface (Fig 3 64*B*) This solid angle is equal to the area cut on a unit sphere by lines drawn from its center at P to all points on the boundary of the polarized surface When two or more polarized surfaces subtend solid angles at P, the resultant V_p is proportional to the sum of the solid angles, with due regard for their sign

The electrical potential at any point in the body or on its surface can theoretically be predicted in terms of the solid angles subtended by polarized surfaces developed in the heart during activation, and this has been done in a qualitative fashion However, it is impossible to reverse the procedure and derive information about the size and orientation of the individual polarized surfaces from a knowledge of the resultant solid angle It has been more practical to analyze tracings recorded at a distance from the heart in terms of resultant vectors which indicate the magnitude and mean direction of electrical forces developed during the cardiac cycle without any implications about the polarized surfaces responsible for them When viewed from a distance, the total electrical forces of the heart at any instant can be considered as a single dipole that is described by a vector oriented in the direction of the dipole axis with magnitude proportional to the dipole moment This vector represents the sum of many individual vectors each of which describes a single dipole at a polarized surface

VECTOR ANALYSIS AND ELECTROCARDIOGRAPHIC LEADS

A vector quantity is represented geometrically by an arrow with its direction and length related to the direction and magnitude of the quantity it describes It can be shown that electrical potential (V_p) at a point P in a volume conductor is proportional to the geometric projection of an arrow representing a dipole vector onto a line (the lead axis or lead line) drawn from P to a point of zero potential at the center of the dipole V_p is proportional to E cos θ when E is the magnitude of the dipole vector and θ is the angle between the vector and the

lead line (Fig 3 64*C*) An electrocardiograph will record this potential if one electrode is placed at P and the second electrode is placed at a point of zero potential However, when two electrodes are placed on the body surface, the tracing recorded represents only the difference between potentials of the same order of magnitude at each electrode and does not give any specific information about the potentials at either point

Einthoven described a method for vector analysis of such tracings recorded from pairs of electrodes on the body surface at a distance from the heart He assumed as a first approximation that electrical forces of the heart originate in a relatively small area at the center of a homogeneous volume conductor, and that the regions where each arm and the legs join the trunk are points equidistant from each other The extremities behave as linear conductors connected to the trunk so that an electrode placed anywhere on an extremity is equivalent to one at its junction with the trunk Electrodes placed on each arm and a leg are then considered to be located at the apices of an equilateral triangle with the heart at its center, and differences in potential recorded between these points represent the projection of vector forces originating from a dipole at the center of the triangle onto lead lines drawn between its apices Potential differences between the extremities are customarily recorded in three standard limb leads obtained by connecting two of the limb electrodes at a time to the electrocardiographic instrument in the manner illustrated in Figure 3 65 The polarity of the electrode connections is such that a positive charge facing the left shoulder will produce a positive deflection (upward from the base line) in lead I, and a positive charge facing the foot will produce positive deflections in both leads II and III Einthoven deliberately arranged the polarity of lead II in a manner inconsistent with the other two leads so that ventricular activation would produce positive deflections in all three leads of most normal records Differences in potential are recorded in the three limb leads according to the following relationship I = VL − VR, II = VF − VR, III = VF − VL, where VR, VL, VF represent potentials at the right arm, left arm, and left leg, respectively. Since the three leads form a closed circuit the algebraic sum of their potential differences at any instant is zero Because of the reversed polarity of lead II, this relationship (Einthoven's "law") is actually I − II + III = 0, or I + III = II This is really merely a consequence of Kirchhoff's second law of circuits The validity of this equation does not depend on any assumptions relating to the electrical homogeneity and geometry of the volume conductor or location of the heart

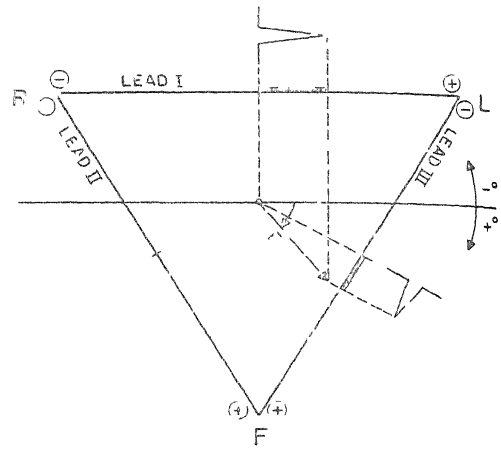

Fig 3 65 Einthoven triangle R right arm L left arm F foot Mean electrical axis is derived from lead I and lead III QRS complexes by drawing perpendiculars from the lead lines at points determined by amplitude of QRS Intersection of perpendiculars determines the mean electrical axis E

It is possible to derive the potentials at each extremity from these bipolar leads if Einthoven's hypotheses are correct That is, if the location of the extremity electrodes is equivalent to the apices of an equilateral triangle on the surface of a homogeneous volume conductor with a point source of electrical potential in the center, then VR + VL + VF = 0, and it can be demonstrated algebraically that VR = −(I + II)/3, VL = (I − III)/3, and VF = (II + III)/3 However, if Einthoven's hypotheses are correct it is also possible to obtain an indifferent electrode of zero potential from a network connecting the three extremities, and then one may determine the potentials at any point in the body with an exploring electrode Wilson (1934) demonstrated that the potential (VT) at a central terminal connecting the three extremities through equal resistances is equal to the mean of the potentials at the extremities, and so VT = (VR + VL + VF)/3 = 0 in this special situation Differences between resistances at the three skin-electrode interfaces which

would affect VT are minimized by a high input resistance in the circuits of modern electrocardiographic instruments Although Einthoven's hypotheses are only a first approximation of actual conditions, several studies suggest that changes in VT are so small during the cardiac cycle that they can usually be disregarded for most clinical purposes, and the central terminal is considered to have a constant or "zero" potential Tracings which record differences in potential between an exploring electrode and the central terminal are called "V" leads and are often described as "unipolar leads" to indicate that they essentially represent changes in potential at the site of the exploring electrode The exploring electrode in V leads is always attached to the positive pole of the electrocardiograph so that when a positive charge faces the exploring electrode a positive (upward) deflection is recorded Since the central terminal is considered to have a zero potential, the lead lines of V leads extend from the exploring electrode to the zero point at the center of the dipole, and projections of vector forces on these lines can be analyzed as described previously

Clinical electrocardiograms usually include six V chest leads recorded with the exploring electrode at the positions indicated in Figure 3 66 The normal precordial lead V_1 displays a small R wave due to the initial activation of the septum from left to right The small R is followed by a deep S wave due to activation of the free wall of the left ventricle which produces electrical forces directed to the left and away from this electrode Leads V_5 and V_6 are more or less the inverse of V_1 They usually show a small Q wave followed by a large R wave In the intermediate leads progressing from V_2 to V_5 there is increasing R wave amplitude and decreasing S amplitude Usually at V_3 there is approximately equal R and S amplitude This is referred to as the transition complex Occasionally the transition complex may be recorded as far to the right as the V_2 position or as far to the left as V_5

Goldberger (1947) suggested that the potential at an extremity could be obtained simply by disconnecting one extremity electrode from the central terminal and recording the difference in potential between it and the remaining two electrodes Such tracings have the same configuration and 1½ times the amplitude of a V lead recorded with an exploring electrode on the same extremity The Goldberger arrangement for recording "augmented unipolar" extremity leads (named aVR, aVL, and aVF) is incorporated into the lead selector switch of modern electrocardiograph instruments

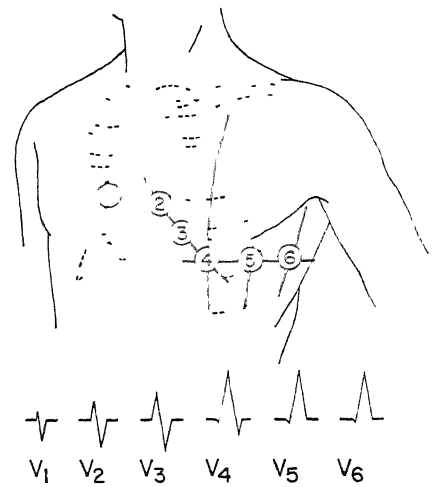

Fig 3 66 Positions of the chest electrodes for 6 standard precordial leads V_1 fourth intercostal space to right of sternum V_2 fourth intercostal space at left of sternum V_4 fifth interspace at midclavicular line V_3 midway between V_2 and V_4 V_5 anterior axillary line same level as V_4 V_6 midaxillary line same level as V_4 and V_5 Below are shown general form of QRS in normal precordial leads V_3 represents transition from predominant negativity on the right to predominant positivity on left (Lipman and Massie 1959)

Knowledge about the pathway of activation of the mammalian heart and the geometry of lead lines as developed from the Einthoven hypotheses can be used schematically to describe the effects of cardiac activation on the extremity leads Ventricular activation can be described by a series of instantaneous vectors, each of which is the resultant of dipoles representing the polarized surfaces present at that instant It is usual to consider only three or four such instantaneous resultant vectors (Fig 3 67) *1*) Initial activation of the septum is represented by a small vector directed to the right and forward *2*) Simultaneous activation of the lower septum, free wall of the right ventricle and anterior left ventricle is represented by a resultant vector directed to the left, forward, and downward *3*) Continuation of the activation process in the posterolateral left ventricular wall after its completion in most regions of the right ventricle is next represented by a large vector directed to the left and backward *4*) Terminal activation of the posterobasal left

ventricle and upper septum is represented by a small vector directed backward and upward

The interval between these instantaneous vectors is 0 01 to 0 015 sec in the dog heart and approximately twice as long in the human heart One can roughly predict the configuration of tracings in various leads by projecting these hypothetical vectors onto the appropriate lead line, or conversely one may derive the instantaneous vectors from the recorded tracings For example, potentials recorded at the same instant in two standard limb leads are measured and plotted in arbitrary units along the appropriate lead lines of an equilateral triangle, starting from the zero point at the center of each bipolar lead line and extending toward the end with the proper polarity Perpendiculars dropped from the ends of these two linear plots will meet at points which define the origin and terminus of the instantaneous mean vector responsible for that particular deflection (Fig 3 65) A single vector depicting the mean direction of the total electrical forces developed during ventricular activation can be derived by plotting the algebraic sum of positive and negative deflections in QRS complexes from each of two leads on the appropriate lead lines and dropping perpendiculars as described above The similarity between this derived vector, called the "mean electrical axis," and the true mean cardiac vector depends on the validity of the Einthoven hypotheses The electrical axis is described according to a system of polar coordinates with 0° at the right hand end of a horizontal line, positive values are below and negative values above this line (Fig 3 65) In normal humans, the electrical axis commonly falls between 0° and +90°, displacement in a clockwise direction beyond +90° is called right axis deviation, and displacement in a counterclockwise direction beyond 0° is called left axis deviation The electrical axis is influenced by the position of the heart, changes in the functioning myocardial mass or the pathway of activation, and changes in the conducting medium surrounding the heart A change in the direction of the long axis of the heart produces a shift in electrical axis in the same direction The electrical axis will shift toward an area of hypertrophied myocardium and away from an area of infarcted myocardium Since the electrical axis is determined from potentials recorded at the body surface, it will also be influenced by changes in the conducting medium, such as the introduction of air or fluid into the pleural space The electrical axis determined from the limb leads represents the projection of spatial vectorial forces onto a frontal plane defined by the Einthoven triangle, an additional lead having a lead line in an anteroposterior direction is required to estimate the spatial orientation of these forces

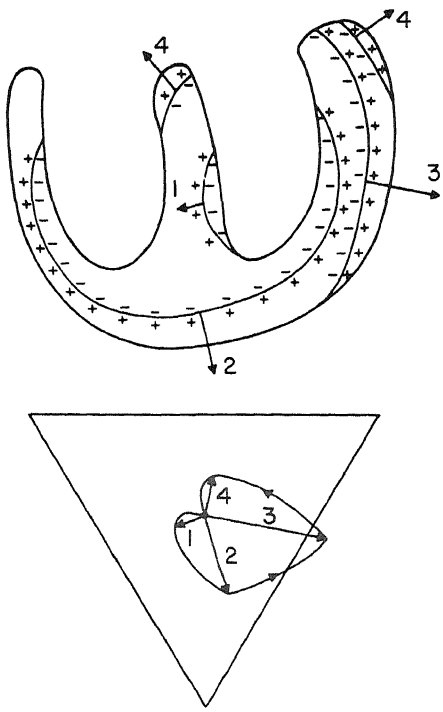

Fig 3 67 The four major dipole vectors generated during ventricular activation giving rise to the deflections of the QRS complex By Einthoven s hypothesis these vectors may all be considered as originating from a single point at the center of an equilateral triangle When the termini of all resultant instantaneous vectors are connected a loop is described The loop is the vectorcardiogram

A line joining the termini of all the instantaneous resultant vectors will form a loop representing the sequential change in amplitude and direction of the resultant electrical forces throughout the cardiac cycle (Fig 3 67) Such a loop can be derived by graphic or electronic integration of potentials from two simultaneously recorded leads When a loop is obtained by electronic integration on an oscilloscope, it is called a vectorcardiogram

RECOVERY PROCESS AND THE VENTRICULAR GRADIENT

The recovery process, which is simply a reversal of changes that occur during activation, is characterized by deflections of much longer duration and lower amplitude than the activation process Atrial recovery produces a prolonged deflection (T_p or T_a wave) which continues through the PR interval and into or beyond the QRS complex, but it is generally of such low amplitude that it is clearly defined only in tracings where P waves are widely separated from the QRS complexes, as in heart block The T_p is opposite in direction to the P wave in tracings obtained from strips of atrial muscle and also from the intact heart, which indicates that the recovery process follows the same sequence of activation since the two processes have opposite electrical signs Ventricular recovery occurs during inscription of the ST segment and T wave The ST segment corresponds to the plateau and the T wave corresponds to the rapid final phase of repolarization recorded from single myocardial fibers In man the tracing generally shows little or no deflection from the base line during inscription of the ST segment when large areas of myocardium are undergoing recovery simultaneously The T wave occurs when recovery is complete in some areas but is continuing in other regions The T wave recorded from muscle strips is opposite in direction to the QRS, as expected when recovery occurs in the same sequence as activation, but this is not true in direct leads on the surface of the intact ventricle where the T wave is in the same direction as the major deflection of the QRS This indicates that the sequence for completion of recovery in the intact ventricle is opposite in direction to the activation process, and therefore occurs later at endocardium than at epicardium

The relationship between the orientation of the electrical forces during activation and recovery has been expressed in vector terms by Wilson (1954) and others These investigators determined the net area enclosed by QRS deflections and that enclosed by ST and T deflections in the limb leads, and used these areas (which represent the product of time and voltage) to plot mean vectors called $\hat{A}$ QRS and $\hat{A}$ T, respectively The resultant of these two vectors is called the ventricular gradient $\hat{G}$ If $\hat{A}$ T was equal in amplitude and opposite in direction to $\hat{A}$ QRS, as expected on a theoretical basis from electrograms of muscle strips, their resultant or ventricular gradient would be zero The degree to which the actual $\hat{A}$ T deviates from the theoretical one is expressed by the vector $\hat{G}$ The gradient is thus a reflection of the difference between the sequence of activation and recovery

Abnormalities of the Electrocardiogram

VENTRICULAR HYPERTROPHY

Left Ventricular Hypertrophy This often causes the following electrocardiographic changes *1*) increased voltage in leads from the precordium, *2*) increased duration of the QRS complex, *3*) rotation of the mean electrical axis toward the left, and *4*) secondary ST and T wave abnormalities in left precordial leads (Fig 3 68) In the frontal plane the mean electrical axis comes to lie in the 0 to $-90°$ quadrant (left axis deviation) *Right ventricular hypertrophy* shifts the mean electrical QRS axis in the frontal plane toward the right (usually greater than $+105°$) The R wave in V_1 usually exceeds S in amplitude and the transitional changes in QRS configuration differ from normal in that there is a progressive decrease in R amplitude and an increase in S amplitude (compare Figs 3 66 and 3 68, top)

RIGHT BUNDLE BRANCH BLOCK

It will be recalled that in the normal sequence of activation the left side of the septum starts to depolarize slightly before the right side, the free wall of the right ventricle is depolarized simultaneously with the left ventricle, and the greater thickness of the left ventricle produces much larger voltages than those from the right ventricle Thus, the only rightward directed voltages seen in the normal electrocardiogram are those generated initially from the left side of the septum and in some instances a small late voltage from a late activation of the pulmonary conus

When the right conducting bundle is blocked either by cutting it experimentally or by some pathological process, the activation of the right ventricular free wall is greatly delayed (Fig 3 69) The first portion of the QRS com-

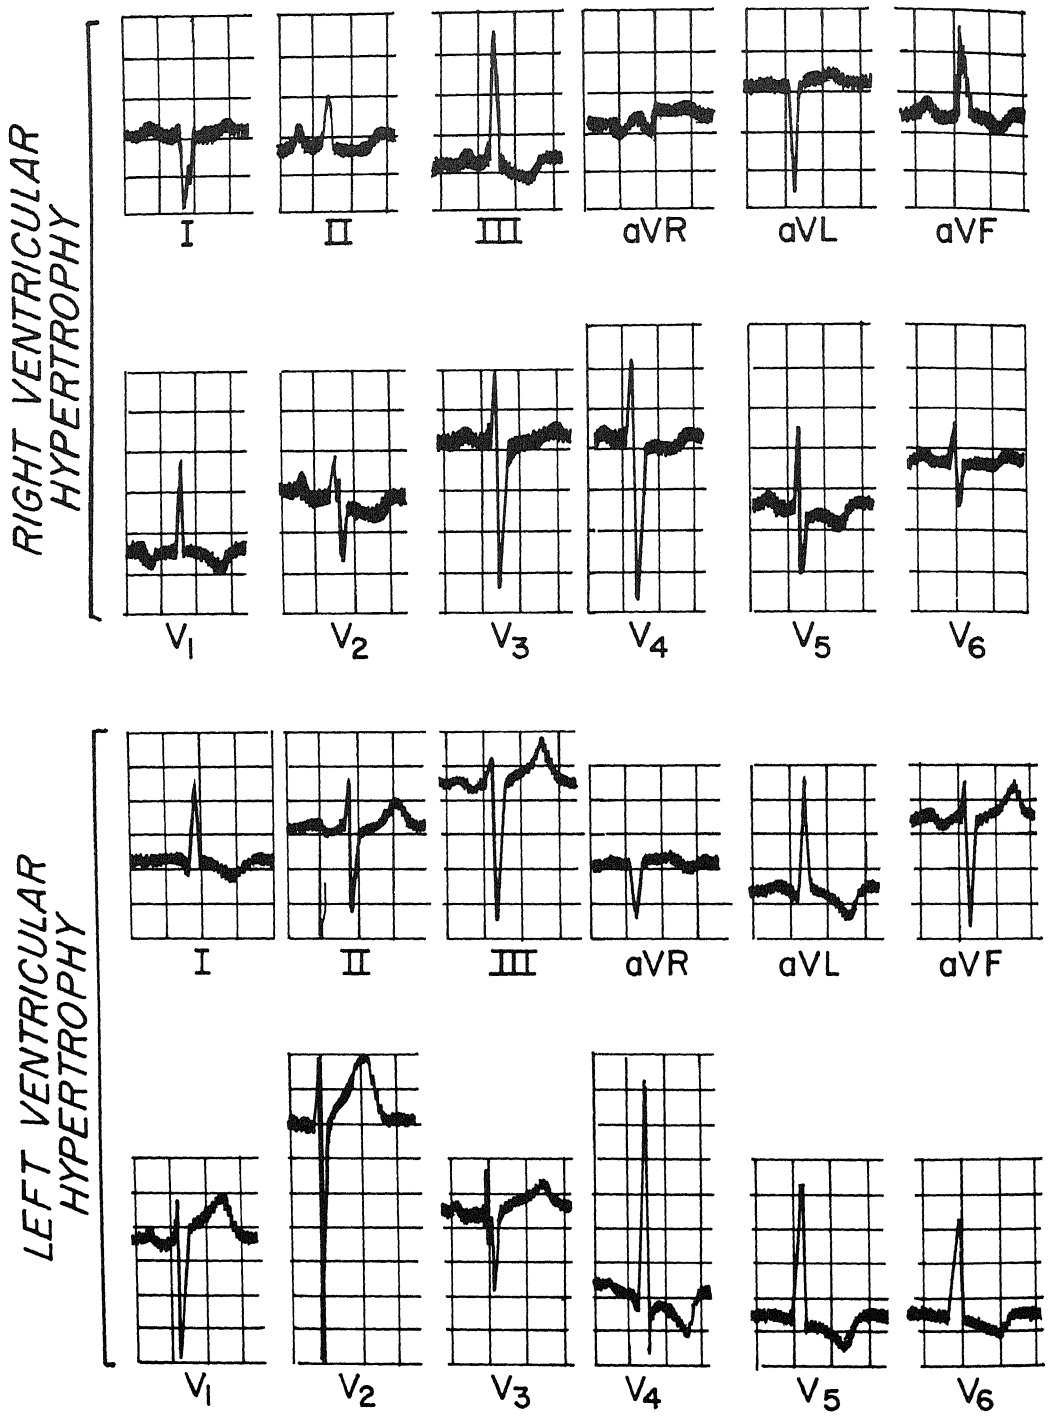

Fig 3 68 Electrocardiogram patterns of right and left ventricular hypertrophy

plex up to about 0 04 sec is inscribed in a normal manner as it records the activation of the septum from left to right and the free wall of the left ventricle When the left ventricle has become completely depolarized, there still remains a considerable portion of the right ventricular free wall which has not been depolarized The impulse may spread slowly in a

tangential direction through the free wall of the right ventricle rather than being transmitted almost instantaneously to all parts of the endocardium by Purkinje fibers and spreading from endocardium to epicardium This slow late right ventricular activation wave, now unopposed by left ventricular forces and not having the high proportion of internal cancella-

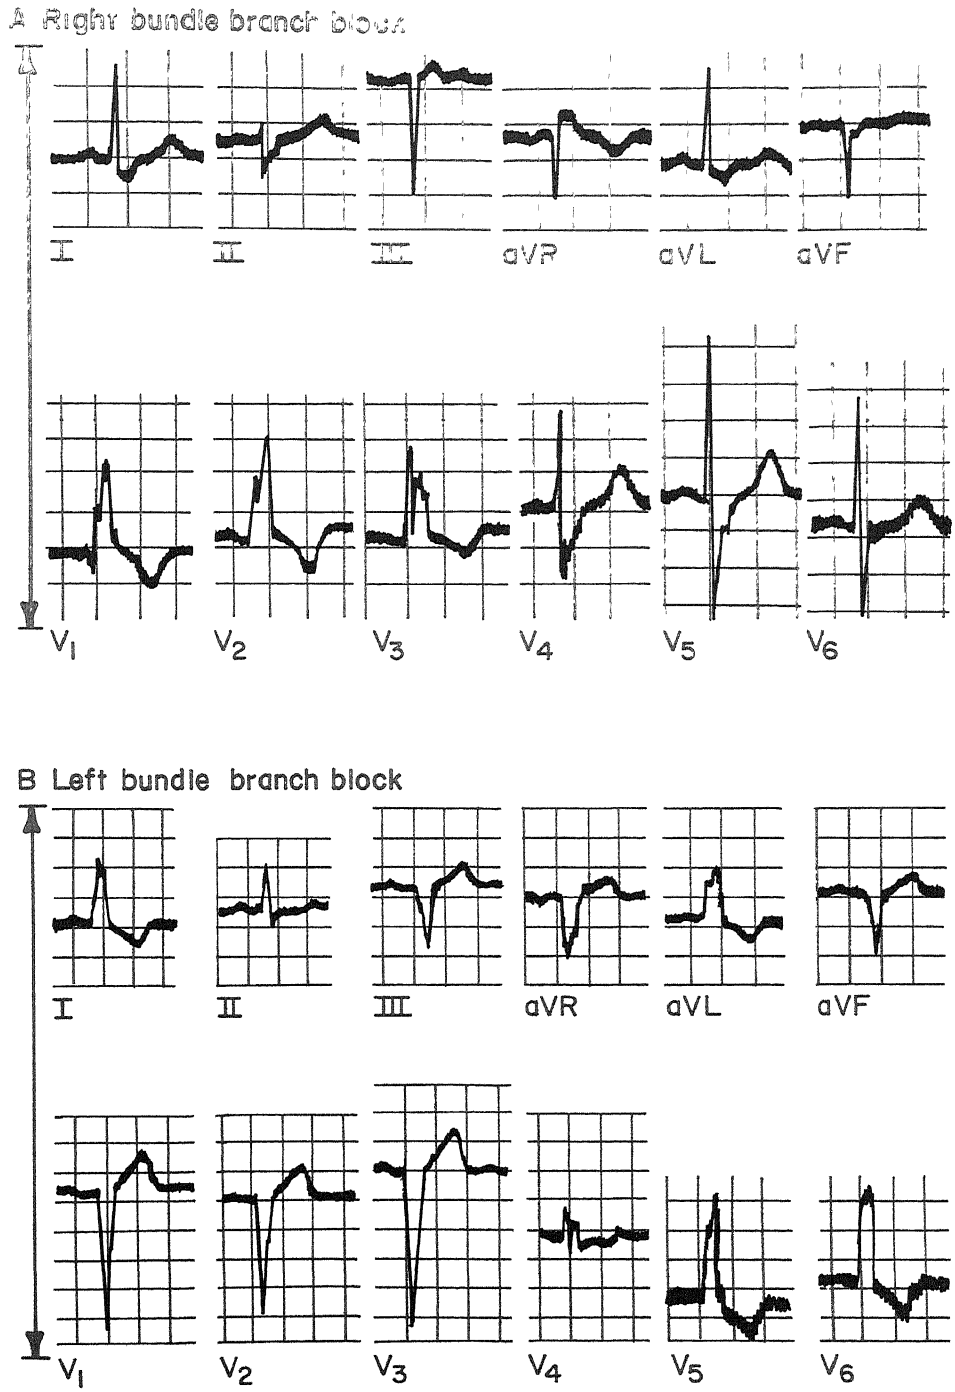

Fig 3 69 Patterns of right and left bundle branch block

tion characteristic of normal transmission, produces a large voltage directed anteriorly and to the right which appears late and prolongs the QRS to a duration of 0 12 sec or more

This late right ventricular voltage is inscribed in the electrocardiogram as a late slurred R wave in V_1 and aVR, and a late slurred S wave in V_5, V_6, and aVL

LEFT BUNDLE BRANCH BLOCK

Interruption of the left conducting bundle causes delay in activation of the left ventricle The first portion of the heart to be activated is now the right side of the septum by way of the right bundle branch The septum is thus activated from right to left, producing a large voltage directed leftward This large leftward voltage is opposed to a small degree by a rightward voltage from the almost simultaneous activation of the free wall of the right ventricle, but because of the greater muscle mass of the septum the net initial voltage is directed toward the left The effect on the electrocardiogram is to produce initial positivity in leads I, V_5, and V_6 The normal septal Q wave is thus abolished in these leads

The wave of activation is transmitted through the septum to the free wall of the left ventricle through which it passes slowly in a tangential direction from apex to base It is probable that there is also some transmission from the anterior and posterior septum circumferentially so as to envelope the free wall in the activation wave The slow activation of the left ventricle continues to produce leftward directed voltages which are inscribed in the electrocardiogram as broad notched or slurred R waves in the left precordial leads V_5 and V_6 Duration of the QRS complex is 0 12 sec or greater In general the ST and T waves are opposite in direction to the QRS complexes

MYOCARDIAL ISCHEMIA, INJURY, AND NECROSIS

When a coronary artery is gradually compressed, the first change seen in tracings from the area of myocardium supplied by that vessel is a deep and symmetrical inversion of the T wave This symmetrical form of T wave inversion is referred to as T wave inversion of the ischemic type (Fig 3 70) It is believed to be due to delay in recovery at the epicardial region so that there is reversal of the normal order of repolarization

The ischemic T wave inversion is rapidly reversible if adequate circulation is restored to the myocardium When the blood supply to the myocardium is more drastically impaired by sudden ligation of a coronary artery, the direct epicardial tracing shows the rapid onset of elevation of the ST segment This elevation may be almost as high as the QRS complex and may yield a wave form closely resembling the transmembrane action potential obtained with micropuncture of a single myocardial fiber The ST elevation is believed to be due to a strong current of injury causing marked depression of the resting isopotential line The ST displacement may be accompanied by ischemic changes in the T waves This injury pattern is also rapidly reversible upon restoration of adequate blood flow

When a coronary artery is permanently ligated, a portion of the myocardium becomes infarcted The presence of electrically inert necrotic myocardium results in alterations of the QRS complexes of the direct epicardial lead If the infarction is completely transmural from epicardium to endocardium this mass of tissue contributes no potential of its own, but simply conducts to the surface the potentials which are to be found in the underlying cavity The depolarization wave in this case is a purely negative QS complex identical to that found in the left ventricular cavity The repolarization phases contain elements of injury and ischemia patterns derived from adjacent viable portions of the myocardium

Exploration of the adjacent areas of myocardium about a zone of necrosis discloses a zone of injury surrounding the necrotic areas (Fig 3 70) Complexes recorded from the injury zone are characterized by marked elevation of the ST segment without significant change in the morphology of the early portion of the QRS The injury zone is surrounded by a zone in which the T waves show inversion of the ischemic type This is called the ischemic zone Beyond it lies normal muscle disclosing normal QRS-T complexes

Electrocardiograms made from the surface of the body include potentials from the entire heart, and therefore, the precise localization of zones of necrosis, injury, and ischemia cannot be derived from the clinical electrocardiogram When infarction is present, all of the phenomena observed in the three zones will be reflected in the appropriate electrocardiographic lead Even a precordial lead adjacent to a large

area of infarction is influenced by electrical events in other parts of the heart and is likely to record elements from all three of the zones of necrosis, injury, and ischemia

Thus, the classical pattern of myocardial infarction consists of a deep wide Q wave, ST segment elevation, and T wave inversion Muscle necrosis cannot be identified with certainty from the electrocardiogram without the appearance of a pathological Q wave which indicates a removal of electrically active myocardium ST and T wave changes of injury and ischemia may occur when myocardium becomes temporarily or even chronically hypoxic but not sufficiently so to produce muscle death On the other hand, there may be myocardial necrosis in areas completely surrounded by viable tissue or in subendocardial zones such that the general pathway of activation might not be markedly altered In such intramural or subendocardial infarctions abnormal Q waves may not appear even though injury and ischemic ST and T changes may be present In such cases the presence of muscle necrosis cannot be proven by the electrocardiogram Evidence of its presence might, however, be obtained by other clinical means

Localization of Myocardial Infarction. The general anatomical localization of areas of cardiac infarction may often be made from the standard 9 or 12 lead electrocardiogram Each lead constitutes, so to speak, an electrical view of the heart from a different point in space (Fig 3 71)

DRUGS AND ELECTROLYTES

Digitalis produces a characteristic alteration of the ST and T complex which might sometimes be mistaken for an injury effect (Fig 3 72) The change consists of a shortening of the QT interval and a sagging of the ST segment The sagging ST has a "scooped-out" or "cuplike" concavity that is easily recognized This electrocardiographic sign of digitalis effect is not related to the adequacy of the dose of the medication nor to drug intoxication

Quinidine and procaine amide have similar effects on the electrocardiogram They cause depression of the ST segment, a decrease in amplitude or diphasic configuration of the T wave, and an increase in amplitude of the U wave The QT interval may be prolonged, or may appear prolonged because the U wave is superimposed on the descending limb of the T wave producing a broad T-U complex which may have a notched or undulating appearance As the dose is increased slowing of conduction

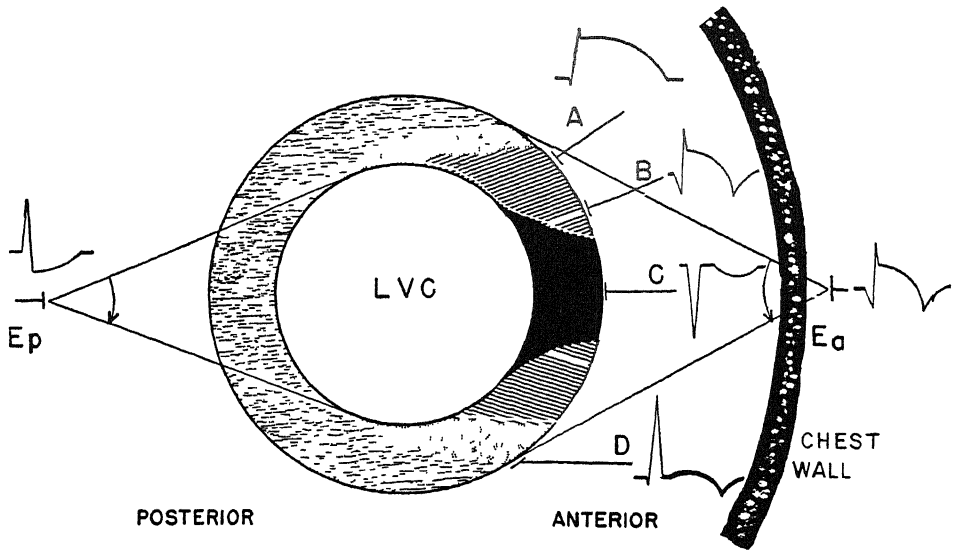

Fig 3 70 Schematic diagram of direct epicardial leads taken over an area of myocardial infarction and over adjacent zones of injury and ischemia Also shown is a chest lead facing the infarct and a lead from the opposite side of the heart At *C* cavity negativity is reflected in the epicardial lead over the necrotic zone At *A* is recorded a monophasic injury wave over the injured zone At *B* the complex reflects a combination of necrosis and injury At *D* there is only T wave inversion of the ischemic type over the ischemic zone At E_a over the chest the complex combines features of all three zones and on the opposite side of the heart there are reciprocal changes of increased positivity of the R wave and depression of ST (From Barker 1952)

through the ventricle is produced with resulting widening of the QRS complexes

Among electrolyte ions, calcium and potassium have the most significant effects on the electrocardiogram (ECG) Hypocalcemia causes prolongation of the QT interval due to prolongation of the ST segment without distortion of the T wave The long flat ST segment is followed by a T wave of normal amplitude and duration Micropuncture studies of transmembrane action potentials have shown that the long ST segment is due to prolongation of the plateau phase of the recovery process The later phases continue at their usual rates

Elevation of the serum calcium has the opposite effect of shortening the ST segment by shortening the plateau phase of the monophasic action potential The T wave itself appears undisturbed

Reduction of serum potassium appears to have two effects, one on the ST-T complex and one on the U wave When the potassium level

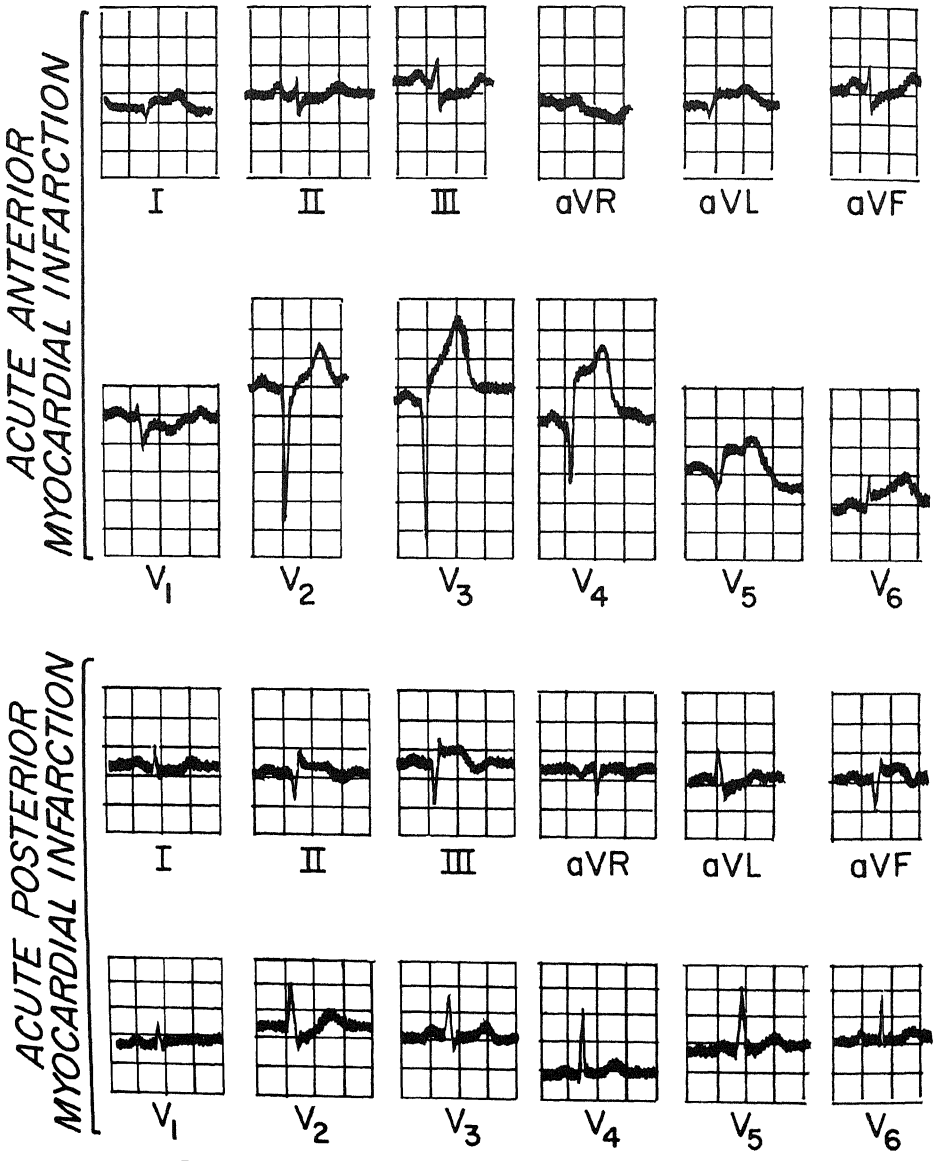

Fig 3 71 Patterns of acute anterior and posterior myocardial infarcts

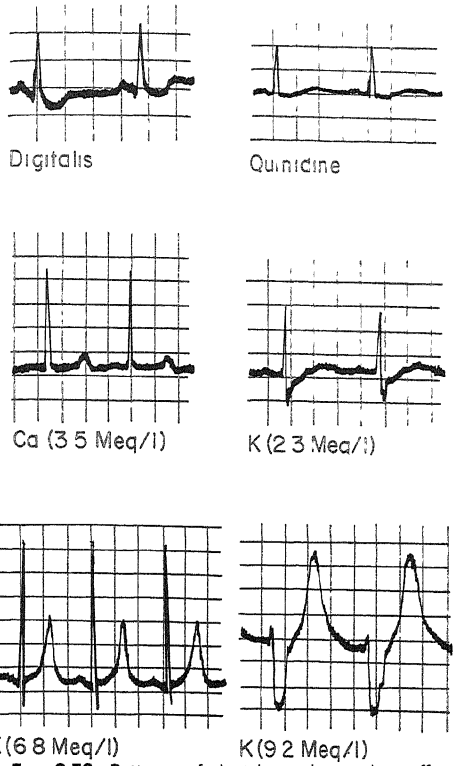

Fig 3 72 Patterns of digitalis and quinidine effect low serum calcium low serum potassium and high serum potassium

in the serum falls to about 3 mEq /liter, the ST begins to sag and the T wave becomes lower while the U wave becomes more prominent The T and U seem to merge into a single wave separated only by a slight indentation or dimple on the crest This gives a false impression of a markedly prolonged QT With very low levels of potassium the ST segment becomes depressed below the base line and the U wave exceeds the T in height This gives the appearance of a stepwise ascent of the ST-T complex This pattern is usually seen with serum potassium of 2 5 mEq /liter or less

Elevation of serum potassium leads first to an increasing amplitude of the T wave in leads where the T is normally upright The tall T waves have a tent-like appearance with similar slopes on the upward and downward limbs With higher levels of serum K (8 mEq /liter approximately), the PR interval becomes prolonged and the QRS begins to widen out as conduction becomes impaired At about 9 mEq /liter, the P wave disappears entirely and the QRS takes on a bizarre shape merging with the tall T wave to produce a distorted sine wave-like pattern which usually heralds terminal ventricular fibrillation or standstill

Cardiac Arrhythmias and Conduction Disturbances

The following is a convenient classification of cardiac irregularities

- A Affections of rhythm due to impaired conduction through the AV node and the bundle of His
  - I Delayed conduction (concealed conduction)
  - II Missed beats, partial heart block
  - III Complete heart block
- B Wolff-Parkinson-White syndrome
- C Affections due to abnormal impulse formation
  - I Extrasystoles
    - (1) Ventricular
    - (2) AV junction
    - (3) Atrial
  - II Paroxysmal tachycardia
    - Atrial, AV junctional, and ventricular
  - III Atrial flutter
  - IV Atrial fibrillation
  - V Ventricular fibrillation
- D Alternation of the heart
- E Affections due to vagal influences
  - I Sinus arrhythmia
  - II Phasic irregularity
  - III Sinus bradycardia
  - IV Sinoatrial block
  - V Atrioventricular block

AFFECTIONS OF RHYTHM RESULTING FROM IMPAIRED CONDUCTION

In the AV Node or Stem of the Bundle Atrioventricular Block. In animals, conduction from atrium to ventricle can be depressed or blocked by crushing, cutting, or the application of cold to the AV bundle This strategic point in the pathway of the excitation wave is also attacked by disease, and conduction through it may be depressed or completely abolished

Concealed conduction is a term used for the situation in which impulses penetrate the AV conduction system but fail to emerge from it (Moore et al , 1971) In the electrocardiogram

such concealed impulses are inferred owing to their known effects on subsequent characteristics of AV conduction such as *1*) delay or blocking of AV conduction of a succeeding impulse, *2*) acceleration of AV conduction of a succeeding impulse, *3*) delay or abolition of the expected discharge of an ectopic pacemaker located in AV junctional tissues Concealment and its subsequent effects are physiological phenomena related to the conduction and recovery characteristics of the AV conduction tissues

Depression of conduction through the node or bundle varies in degree Three stages are recognized

Delayed Conduction (Incomplete Atrioventricular Block) In this stage conduction is merely slowed, every impulse reaches the ventricle The intervals between the atrial and ventricular systoles (A_s-V_s intervals) are lengthened beyond the normal maximum of 0 2 sec and may have a duration of 0 5 sec , though, as a rule, they are considerably shorter than this The condition can be recognized by means of the electrocardiograph or from a venous pulse tracing Lengthening of the PR interval in the former tracing, or of the a-c interval in the latter, beyond 0 2 sec is taken to indicate delayed conduction (Fig 3 73)

Missed Beats—Partial Heart Block (Incomplete Atrioventricular Block with Dropped Beats) When impaired conduction reaches a certain degree, impulses from time to time fail to reach the ventricle, and a beat is missed The atrial beats are perfectly regular, and in this way the condition differs from sinoatrial block A ventricular beat may be missed only occasionally and at irregular intervals The PR interval of the electrocardiogram, or the a-c interval of the venous pulse, may generally, though not invariably, lengthen progressively for several heart cycles preceding a dropped beat The periods of progressively delayed conduction preceding the missed beat are called, after their discoverer, the Wenckebach periods The interval of the cycle succeeding the missed beat is shortened again to near the normal length In a further stage of the condition the beats are dropped more frequently and may be spaced at either regular or irregular intervals in the tracing When the grade of block is still more advanced, impulses fail to penetrate the bundle after every second atrial beat, or three, or even four atrial contractions may occur before an impulse reaches the ventricle, i e , the ventricle responds only to every third or fourth atrial beat So, an atrioventricular rhythm becomes established in which the two chambers beat in the ratio of 2 1, 3 1, or 4 1

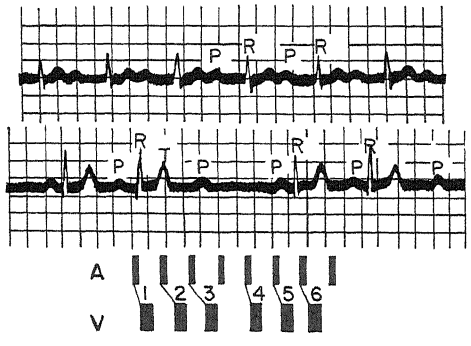

Fig 3 73 Upper tracing delayed conduction lead I Lower tracing incomplete heart block lead I (missed beats) (Kindness of Dr John Hepburn) The diagram below (after Lewis) represents incomplete heartblock The thin rectangles *A*, represent contractions of the atria the thicker ones, *V* contractions of the ventricle The obliquely directed lines represent conduction over the AV bundle the slower the conduction rate the more oblique the line The gaps in the lower rectangles indicate missed beats of the ventricle It will be noted that delay in conduction increases progressively in successive cycles until a beat is missed Heavy vertical lines = ⅓ sec

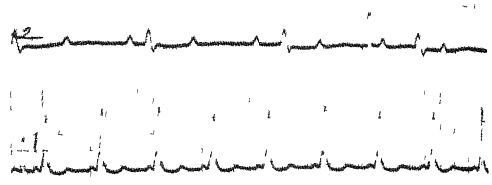

Fig 3 74 Above—complete heart block atrial rate 75 ventricular rate 36 lead 2 Below—Wolff Parkinson-White syndrome lead 1 PR interval 0 09 sec QRS interval 0 11 sec

Complete Heart Block (Complete Atrioventricular Block) When the AV node or bundle offers an absolute barrier to the passage of the impulse, the dissociation of the rhythms of the upper and lower chambers is complete (Fig 3 74) The atria beat at their own rate of about 70/min and the ventricles at their inherent rate of about 35 The impulses that drive the ventricles are believed to arise only in the AV junctional region, bundle of His, right or left bundle branches or in the Purkinje fibers Hoffman has shown through extensive investigation of the transmembrane action potentials of many areas of the heart that only the special-

ized conducting tissues have the property of automaticity that would permit their cells to take over pacemaking function The property of automaticity is characterized by the ability of the cell to undergo gradual spontaneous diastolic depolarization to the threshold level of potential at which an action potential spike is initiated Ventricular myocardial cells do not have this property The speed with which a particular region of the heart can develop and discharge impulses apparently determines its ability to dominate other regions It has been mentioned that when a region of higher rhythmicity is destroyed or isolated the region next in order of rhythmical power assumes the role of pacemaker When, for instance, the SA node is destroyed or isolated the AV junctional region assumes control, and when this or the upper part of the bundle is separated from the tract of tissue below, the lower lying portion takes over the government of the ventricular rate

WOLFF-PARKINSON-WHITE (WPW) SYNDROME (ACCELERATED CONDUCTION, VENTRICULAR PRE-EXCITATION)

In this rare congenital anomaly the PR interval of the electrocardiogram is shortened and the QRS complex prolonged The PR interval is 0 12 sec or less and the QRS complex extended to over 0 10 sec (Fig 3 74) The shortened PR interval may be due, in some cases, to an accessory conducting strand between atrium and ventricle Butterworth and Poindexter (1942) fashioned an extra electrical conduction pathway in the dog's heart, which, when stimulated, produced an electrocardiogram similar to that characteristic of the syndrome Wood et al (1943) in the histological examination of the heart of a patient which had shown this syndrome, also found three accessory pathways from the right atrium to the ventricle

Moreover, Boineau, and Moore (1970) demonstrated a physiologically active atrioventricular muscular bridge (Kent bundle) accounting for ventricular pre-excitation in a dog with spontaneous WPW Further, surgical separation of the right atrium and right ventrical or digital pressure at the site of ventricular pre-excitation in humans with WPW have been shown to normalize atrioventricular conduction Prinzmetal and his colleagues (1952) have produced typical WPW complexes in dogs by applying a noninterrupted direct current of subthreshold strength to the AV node, but such complexes could not be induced after severance of the AV bundle—an indication that the impulses traverse the normal AV connections These investigators carried out a large number of similar experiments in which the movements of the heart were recorded by high speed cinematography, and the records analyzed after slowing down to half speed They conclude from their observations that the accelerated conduction of the WPW syndrome is due to shortening of the delay of the impulse at the AV node to a fraction of the normal which amounts to about 0 12 sec

These experiments indicate the WPW syndrome can have a physiological as well as an anatomical basis

The prolongation of the QRS complex is attributed to early activation of a portion of myocardium followed by normal activation of the remaining muscle The significance of this unusual mechanism lies in the fact that persons who display this electrocardiographic pattern are particularly prone to have frequent bouts of paroxysmal rapid heart action of one type or another

DISTURBANCES OF RHYTHM DUE TO ABNORMAL IMPULSE FORMATION

Extrasystoles or Premature Contractions. An extrasystole can be induced experimentally by stimulating the cardiac muscle at any time except during its phase of absolute refractoriness Extrasystoles occur in the human heart as a result of some abnormal process of impulse formation Though extrasystoles may be associated with organic heart disease they more frequently occur in its absence, they may then be reflexly initiated from the abdominal viscera or be due to some form of intoxication, e g , digitalis, cyclopropane anesthesia, hyperthyroidism, excessive smoking, excessive coffee or alcohol ingestion, stimulant drugs such as amphetamine, nervous tension, anxiety, or exhaustion Electrical stimulation of various parts of the brain (e g , sigmoid gyrus, limbic lobe, hypothalamus, amygdala, etc) in cats can produce atrial and ventricular extrasystoles (Hoff et al , 1963), and their occurrence in man following brain lesions has been reported, which indicates that in some instances they are of central origin The atrium or the ventricle may

be the site of origin of the premature contraction, or the extra impulse may arise in the AV junctional tissues (see diagrams, Fig 3 75)

Ventricular Extrasystoles The premature contraction occurs after the normal ventricular beat has ceased and the muscle has recovered from its absolute refractory state It is not preceded by an atrial contraction, and is not dependent upon an impulse received from the upper chamber (Fig 3 76) Since the impulses arise in one or the other bundle branches or in the Purkinje fibers, the electrocardiographic patterns of ventricular premature beats often resemble those of right or left bundle branch block They are broad and bizarre not resembling the normal complexes The premature contraction is followed by a long pause This is

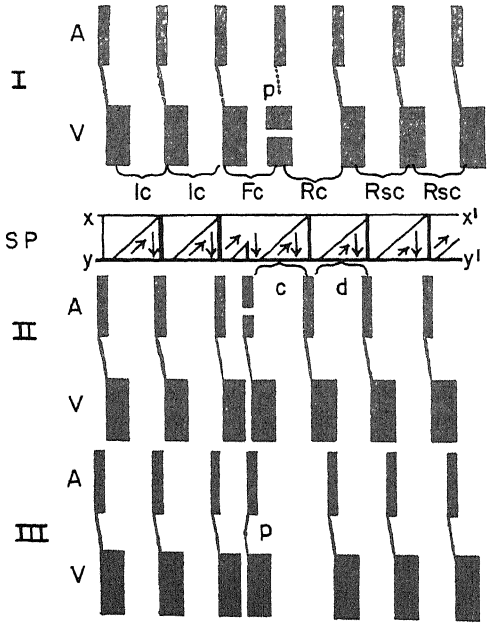

Fig 3 75 (After Lewis) *I* a diagram illustrating disturbance of the heart s mechanism when a systole is caused by exciting the ventricle during diastole Ic initial cycle Fc forced or extrasystolic cycle Rc returning cycle, and Rsc restored cycles p is the premature or forced beat Note that the atrial rhythm remains undisturbed The forced and returning cycles are together equal in length to two initial cycles *II* a diagram illustrating the events when a premature contraction is excited from the pacemaker Stimulus production in the tissue which originates the heart rhythm is indicated by the line S P, the impulse is supposed to discharge when it reaches the line xx' and to fall at each contraction of the heart to the level yy' c and d are equal in length *III*, a diagram illustrating a premature beat arising in the AV junctional tissue

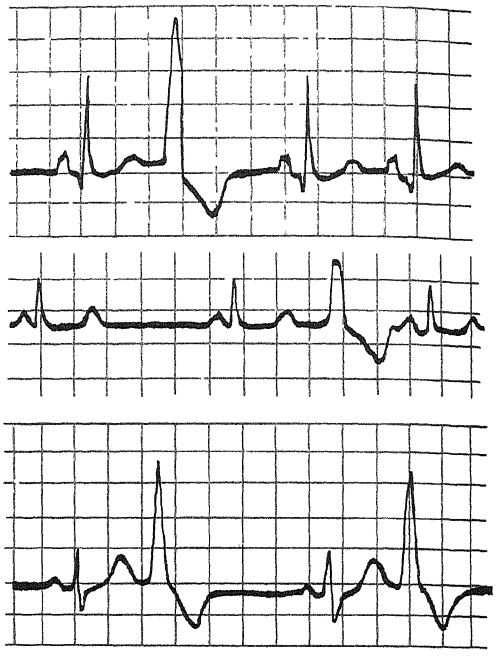

Fig 3 76 *Upper* ventricular extrasystole with compensatory pause *middle* interpolated ventricular extrasystole *lower* coupled ventricular extrasystoles (bigeminal rhythm) Note that the intervals between the ectopic ventricular beat (extrasystole) and the preceding normotopic beat are identical Such 'fixed coupling intervals are characteristic of ventricular ectopic beats arising from the same focus

usually of just sufficient duration to cause the succeeding normal ventricular beat to occur at the instant that it would have occurred had there been no premature contraction The cause of this *compensatory pause* has been explained elsewhere Briefly, it is due to the normal impulse reaching the ventricle when the muscle is still refractory as a result of the premature beat The interval between the normal beat and the one following the premature contraction is therefore equal in length to two normal cardiac cycles (Fig 3 75*I*) Sometimes, however, when the extrasystole occurs early in diastole and the heart rate is slow, there may be no compensatory pause The atrial impulse then reaches the ventricular muscle after it has recovered from the refractory state resulting from the premature beat, the atrial impulse therefore brings about a response at, or (as a result of some lengthening of the As-Vs interval following the premature beat) slightly after the usual time The normal ventricular systoles are then all equally or nearly equally spaced and

the extra contractions are interposed here and there between them That is, the time interval from the normal beat preceding the extra contraction to that following it is of normal length or but slightly lengthened Premature beats of this nature are called *interpolated extrasystoles* (Fig 3 76) It should be noted that except in the case of interpolated beats there is not an extra or additional beat, as the term extrasystole seems to imply The premature beat, in effect, displaces the normal beat

Atrial Extrasystoles The premature contraction arises in the atria at some point outside the SA node The abnormal impulse reaches the ventricle along the usual paths evoking a ventricular contraction and giving rise to an electrocardiographic complex similar to the normal ones If the atrial beat is so premature that sufficient time has not elapsed to permit complete recovery of the ventricular muscle from its refractory state, then the impulse may be conducted aberrantly through the ventricle giving rise to a weak contraction and to an electrocardiographic complex having a different pattern from the normal beats The premature atrial beat prevents the occurrence of the next normal atrial impulse and the pause of the atrium which follows the abnormal atrial contraction is usually precisely equal to a normal interval

AV Junctional Extrasystoles Extrasystoles occur sometimes as a result of impulse formation in automatic cells located in a specific region of the AV junction or supraventricular part (stem) of the bundle The terms AV rhythms or AV junctional rhythms have been adopted because there is uncertainty about their anatomical origin (Marriott, 1966) Spontaneously automatic or pacemaking cells are found in tissues around the AV node and in the His bundle, but not in the node proper (Hoffmann and Cranefield, 1964) On account of its central position between the two chambers, impulses arising in these cells pass upward and downward to cause simultaneous or nearly simultaneous responses from atria and ventricles Sometimes the ventricular contraction may actually occur first, in which case it is suggested that the impulse has arisen in the stem of the bundle and so has its course to the ventricular muscle considerably shortened The extra cycle is usually, though not invariably, followed by a compensatory pause (Fig 3 75*III*)

In rare instances extrasystoles arise as a result of abnormal impulses initiated in the sinoatrial node—*sinus extrasystoles* Except for the interposition of the extra beat the rhythm of atria and ventricles is but little disturbed The interval following the extra beat is normal in length or slightly shortened

Effect on the Arterial Pulse Several long-recognized irregularities of the pulse are the result of extrasystoles For example, in the irregularity known as *intermittent pulse* there appear from time to time relatively long intervals during which no beat is felt in the radial pulse (Fig 3 77*a*) The intervals are most pronounced when a premature contraction of the ventricle is too weak to open the semilunar valves When the extrasystoles are forceful enough to open these valves, and when they occur regularly one after each normal systole, paired pulse beats, each couple being followed by a long pause, are felt in the radial pulse (Fig 3 77*b*) This type of irregularity, sometimes seen following overdosage with digitalis, is called the *bigeminal pulse*

Paroxysmal Tachycardia. This may be defined as a condition in which the rate of the heart is greatly accelerated for a longer or shorter period without obvious cause The rate varies in different cases from 140 to 250/min The onset of the paroxysm is sudden and the increased rate is maintained for a variable length of time with perfect regularity, successive cycles usually not varying in length by more than a hundredth of a second The paroxysm lasts for only a few beats in some instances, in others it persists for a few minutes, hours or even days, though attacks of more than ten days' duration are very rare (Lewis, 1925) The attack ceases as abruptly as it commenced, the heart resuming its normal rate almost instantly

The paroxysm, it is believed, consists of a series of rapidly recurring extrasystoles which completely submerge the physiological rhythm

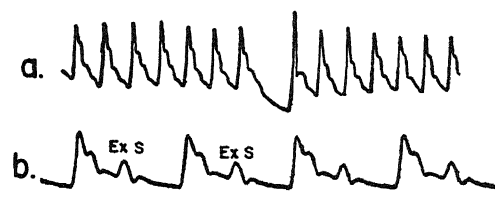

Fig 3 77 *a* Intermission of the pulse *b* pulsus bigeminus due to a single extrasystole with its succeeding compensatory pause occurring regularly after each normal beat *Ex S* extrasystole (After Price)

The site of origin of the extrasystoles, as in the case of single premature beats, may be in the atria, the *AV junctional tissues*, or in the *ventricle* (Fig 3 78) The atrial type is the most common, each atrial impulse spreads to the ventricle and causes a contraction whose features as indicated by the electrocardiogram are normal The P wave is frequently inverted

When the impulses arise in the AV junctional tissues, the PR intervals of the electrocardiogram are shortened Inversion of the P waves is common, or, the contractions of the two chambers may be simultaneous, the P waves being then buried in the ventricular (QRS) complexes Again, the contraction of the ventricle may occur before that of the atrium, it then sometimes happens that a progressive lengthening of the intervals between the R and P waves (RP interval) of the electrocardiogram is seen, ultimately an atrial beat is missed This is termed *reversed heart block* In other instances, as the RP intervals reach a certain length, a contraction of the ventricles occurs prematurely, and is not followed by a contraction of the atria It is thought that the ventricular contraction is caused by the same impulse that caused the preceding atrial beat That is, the impulse arising in the nodal region first excites the atrium, then re-enters the junctional tissue, which has now recovered from its refractory phase, and passes downwards to the ventricle This is spoken of as *reciprocal rhythm*

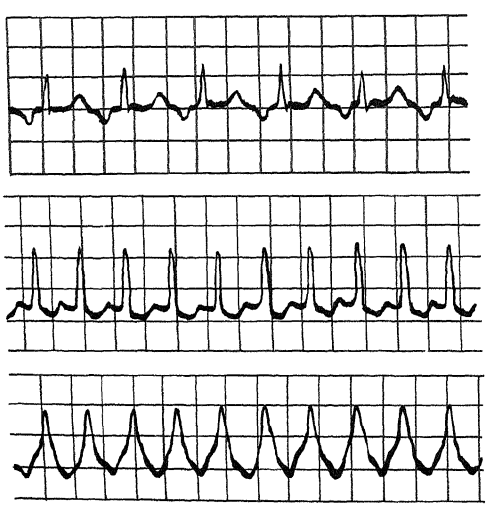

Fig 3 78 *Upper* nodal tachycardia at a rate of 120, lead 2 (note inverted P waves) *middle* atrial tachycardia at a rate of 200 lead 2 *lower* ventricular tachycardia at a rate of 200 lead 2

When the impulses arise in the ventricle the QRS complexes have the characteristics of those caused by ventricular extrasystoles The atrial rhythm is usually undisturbed, but occasionally it is abnormal, for when a series of rapidly recurring contractions arises in the ventricle, the impulses may pass along the bundle in a retrograde fashion and activate the atria to the exclusion of the normal impulse In other words, the ventricle then sets the pace, and the atria follow In such instances the P waves are inverted and succeed the QRS deflections, or are buried in the ventricular complexes as in the AV junctional type mentioned above

Atrial Flutter. There are two forms of this disorder, *pure* and *impure flutter* In both types the atria beat at the phenomenally rapid rate of from 250 to 400 beats per min , but in pure flutter the rhythm is regular, in impure flutter it is irregular Flutter differs from paroxysmal tachycardia in the following particulars *a*) the atrial rate of beating is usually much greater than that seen in paroxysmal tachycardia *b*) the disorder is of much longer duration, persisting unchanged for months or years, though it is sometimes transient *c*) the ventricles fail as a rule to follow the rate of the atria, a state of relative heart block becomes established as a result of the comparatively long refractory phase of the functional tissue

Atrial flutter may become converted to atrial fibrillation

In pure flutter the rhythm is remarkably regular (Fig 3 79) The lengths of the atrial cycles vary no more than a few thousandths of a second over comparatively long periods In impure flutter this constancy of cycle length is not seen and varying degrees of irregularity occur In flutter the atrial walls do not completely relax That is, though the proportion of active to inactive fibers varies during the rapid beating, at no one time are all the fibers in the relaxed state In the electrocardiogram, therefore, the level of the tracing between the P waves is continually changing and the electrical changes of the atria are carried over to alter the form of the ventricular complex

The ventricles rarely keep pace with the racing atria, the refractory phase of the con-

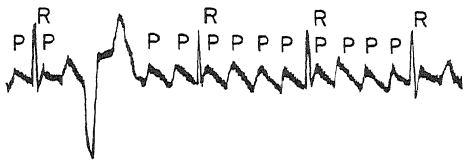

Fig 3 79 Pure flutter with a ventricular extrasystole (Kindness of Dr John Hepburn)

ducting tissue being longer as compared with that of the atrial muscle As a consequence, a state of relative heart block develops and an atrioventricular rhythm of 2 to 1, or less frequently, of 3 to 1 or 4 to 1, becomes established Sometimes there is variable block with 2 to 1, 3 to 1, 4 to 1, and occasionally even greater intervals occurring in the same strip of record Should the ventricle respond to each beat of the auricle, as occasionally happens, serious circulatory disturbances follow, ventricular diastole is so shortened that the ventricle receives a greatly reduced load of blood The output of the heart may be so reduced as a result that loss of consciousness resulting in death may follow

Atrial Fibrillation. In atrial fibrillation sequential coordinated excitation of the atrial musculature is replaced by chaotic, asynchronous contraction of small localized areas The atrial cavity is never emptied of blood and its wall is a quivering sheet of muscle Atrial fibrillation is the most common of all the serious cardiac irregularities It is most frequently seen in mitral stenosis and in thyrotoxicosis, but sometimes occurs in the absence of myocardial disease

Only a proportion of the atrial impulses pass through the AV bundle and activate the ventricle The relatively long refractory period of the conducting tissue shields the ventricle from the high rate of the atrial impulses The arterial pulse, nevertheless, is usually considerably faster than the normal (100 to 150) though it may be normal or even slowed Those impulses which reach the ventricle do so in a somewhat haphazard manner, and indeed one of the most characteristic features of fibrillation of the atria is absolute irregularity in the rate and force of the ventricular beats These features are expressed in the terms "*delirium cordis*," "*complete irregularity of the pulse*," or "*perpetual arrhythmia*," which were applied to the condition before its true nature was recognized A proportion of the heart beats are frequently so weak that they fail to cause pulse in the radial The apex beat is therefore much more rapid than the pulse The former, for example, may be 150 and the latter only 60 or 70 The difference is called the *pulse deficit* With treatment and improvement in the condition of the cardiac muscle, the pulse rate therefore may increase

The venous pulse in atrial fibrillation is of the ventricular form, *a* waves are absent, being represented by a series of rapid vibratory waves (*f* waves) Similarly in the electrocardiogram, small rapid undulations replace the *P* waves (Fig 3 80)

Processes Underlying the Production of Flutter and Fibrillation of the Atria *The Circus Movement Theory vs the Theory of Numerous Separate Points of Excitation* The observation that fibrillation could be induced in animals by electrical stimulation has led to a much clearer understanding of atrial fibrillation and flutter in man Lewis (1925), employing faradization as the method of inducing fibrillation, studied the subject intensively and, applying the results of the fundamental work of Mayer (1908), of Mines (1913), and of Garrey (1924), conceived that the excitation wave followed a circular pathway through the atrial muscle—the so-called *circus movement* That is to say, the wave starting at one place took a devious course through the cardiac musculature, returned to the point from which it started and re-entered the path which it had previously traversed Mayer induced a circus movement in the umbrella of the jellyfish (Medusa) by creating a local block and applying a stimulus to one side of the blocked region (Fig 3 81 top) The contraction wave which resulted was forced as a result of the block to take a unidirectional course, and after completing the circuit of the disk of tissue returned to the region of the block, which by this time had disappeared If the tissue from which the wave had been initiated was again excitable, i e , had passed from the refractory state, the wave circled the ring a second time, then a third time, and so on repeatedly When, on the other hand, the disk was stimulated in the absence of a block, a contraction wave set out in both directions and the two waves meeting, after having completed half the circumference of the strip, were suppressed at *B* (Fig 3 81 *bottom*)

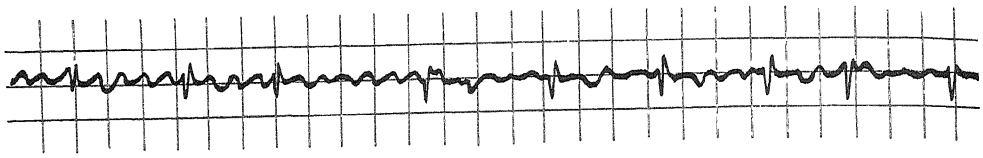

Fig 3 80 Atrial fibrillation lead V_1

That is, further progress of the waves was arrested, for each came to a region of tissue which, being occupied by the other wave, was refractory

Mines and Garrey linked up Mayer's observations upon Medusa with the fibrillation of cardiac muscle Mines showed that a similar circular motion of the contraction wave could be induced in the cold-blooded heart Muscular rings cut from the atria of large rays were employed Garrey thought that he had refuted the prevailing belief at that time, namely, that fibrillation of the atrium was due to the initiation of impulses from multiple foci throughout the auricular muscle—as proposed originally by McWilliam (1887) Garrey (1924) found that if he cut a small piece from the fibrillating atrium, the severed tissue at once ceased to fibrillate, an event which he contended could not occur if numerous points of excitation existed, but such would naturally result if the impulses travelled over a circular pathway from which other parts of the auricle were excited He induced a circulating contraction wave in large annular strips cut from turtles' ventricles

Evidence was obtained by Lewis (1925) which seemed to show that the impulses in the fibrillating atrium travelled in the natural rings of muscle encircling the openings of the venae cavae

The theory of circus movement has been very widely though not universally accepted Brams and Katz (1931) contended that if a circus movement is responsible for flutter and fibrillation more than one circulating wave must exist They base this conclusion upon the observation that if after experimental flutter or fibrillation has been established, the atria (or in the case of ventricular fibrillation, the ventricles) are separated from one another by crushing between them the rapid beating persists with little change in each of the separated parts Scherf (1928), as a result of his failure to abolish atrial fibrillation by clamping or ligaturing the atrial muscle in the path of the supposedly circulating waves, was one of the first to throw doubt upon the existence of a circus movement A little later Andrus et al (1930) concluded, from their experimental results in which fibrillation was induced by a single induction shock applied to the auricular appendix, that the waves did not originate and travel in a ring of muscle

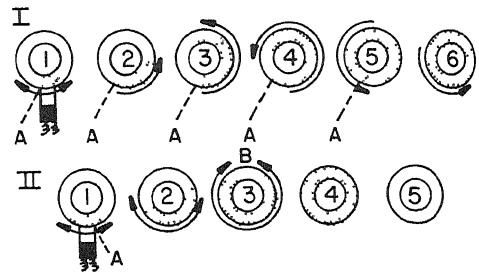

Fig 3 81 (Modified from Lewis 1925) Black = contraction wave Description in text

Evidence against the circus movement theory has been secured by Prinzmetal and his associates (1952) They induced atrial fibrillation by the application of aconitine to the auricles of dogs and observed the auricle by means of high speed cinematography They saw no indication of a circus movement Two types of activity were observed, *a*) contractions and relaxations of microscopic or minute segments of muscle, which they term the "*M*" *activity*, and *b*) stronger contractions and relaxations of macroscopic or larger muscle segments which appear upon the background of the innumerable "M" contractions This type of movement they have designated the "*L*" *activity* Both types of activity are heterorhythmic and utterly chaotic, and apparently arise from numerous discrete ectopic foci

Moe has proposed a variant of the circus movement theory in which he suggests that fibrillation is maintained by the irregular wandering of numerous wavelets generated by the fractionation of a wave front passing through tissue in a state of inhomogeneity with respect to excitability and conduction velocity. He has

devised a most ingenious computer model of atrial fibrillation which supports his theory (Moe et al , 1964)

Direct Current Cardioconversion In the years between 1962 and 1964 the method of direct current cardioconversion devised by Lown (1964) came into wide clinical usage for the conversion of superventricular arrhythmias as well as ventricular tachycardia back to normal rhythm as the apparatus for carrying out this procedure became commercially available The apparatus is designed to deliver a capacitor discharge shock of 100 to 400 watt sec through the chest wall via electrodes 4 in in diameter The shock is timed to fire at the peak of the R wave when conversion of atrial fibrillation, flutter or tachycardia is being carried out, so that the ventricle will be completely refractory when the current hits the heart The atria are depolarized completely, ectopic foci are extinguished, and the opportunity for the sinus node to resume pacemaker function is made available

Lown (1964) has had approximately 95% success in converting superventricular arrhythmias to normal sinus rhythm Maintenance of the sinus rhythm often requires quinidine therapy and even with maximal tolerable doses of this drug, relapse into the arrhythmia may occur, particularly if serious heart disease is present

The cardioconversion apparatus is also effective in abolishing ventricular tachycardia and ventricular fibrillation by administering direct current shock to the heart through the intact chest wall

Ventricular Fibrillation The ventricular muscle may pass into a state of rapid, tremulous and ineffectual contractions closely similar in nature to the condition just described as occurring in the auricle In animals, ventricular fibrillation may be initiated by direct electrical stimulation of the ventricular muscle Mechanical stimulation of the ventricle, especially by pricking the tissue in the AV groove, ligation of a coronary artery or certain chemicals and drugs in excess, e g , digitalis or calcium chloride, may induce fibrillation Chloroform anesthesia renders the hearts of experimental animals (cats) highly susceptible to fibrillation A mere touch of a finger or instrument, the stimulation of a sensory nerve, section of the vagi or their paralysis by atropine, may set the ventricle fibrillating The heart behaves as though sensitized by the anesthetic and ready at the least provocation to fibrillate Adrenaline was found to greatly enhance the effect of chloroform—a fact which indicates the danger of adrenaline administration while a subject is under the effect of this anesthetic Fibrillation may also ensue spontaneously under chloroform, and the condition is more likely to supervene when the animal is passing from deep to light anesthesia Cyclopropane, like chloroform, has the effect of sensitizing the heart to the action of adrenaline in inducing ventricular tachycardia and fibrillation, but these cardiac irregularities are rarely seen under ether anesthesia Quinidine reduces the susceptibility to fibrillation during cyclopropane anesthesia

The effects of ventricular fibrillation upon the circulation are incomparably more serious than those of the corresponding atrial condition This is evident when the importance of the two musculatures in the dynamics of the circulation are compared In fibrillation of the lower chamber the propulsive force of its contraction is practically abolished and the circulation comes to an end, death follows within a few minutes

The basic knowledge of countershock defibrillation acquired through animal experimentation has been applied countless times for the saving of human life The first reports originated from operating room incidents where the exposed heart could be defibrillated by application of the electrodes directly to the epicardium Direct hand pumping massage of the heart was used to sustain circulation until the defibrillating apparatus could be brought to bear Subsequently numerous reports of emergency thoracotomies with open chest massage and defibrillation both in and outside of hospitals appeared Some of these cases were saved, but a distressing number of unsuccessful terminal thoracotomies were carried out

A great advance was made in 1960 when Kouwenhoven, Jude, and Knickerbocker reported the method of closed-chest massage in which circulation is maintained by rhythmic compression of the fibrillating heart through the intact chest wall by strong intermittent manual pressure over the sternum Life can be sustained for periods of time up to an hour or more until external defibrillation can be achieved either by AC or DC countershock through the intact chest

It has been well established that unless circulation can be restored in less than 4 min, irreparable cerebral damage will have occurred, and even though heart action might be restored, a decerebrate patient will be the result

ALTERNATION OF THE HEART

PULSUS ALTERNANS

This is a condition in which every second wave in a pulse tracing is of relatively small amplitude This peculiarity of the arterial pulse is due to alternate variations in the strength of the ventricular systoles, and to a smaller quantity of blood being ejected into the aorta during the weaker beat Figure 3 82 shows a typical sphygmogram of this condition There is as a rule little or no difference in the lengths of the intervals between pulse beats When a slight difference does exist, the interval succeeding the strong beat is then longer than that following the weak beat It will be remembered that in the bigeminal pulse, which might in some instances be confused with alternation, there is inequality in cycle lengths, but the longer interval follows the *weak* (premature) beat Furthermore, in alternation the ventricular rhythm does not share, or does so very rarely, in any irregularity of the pulse intervals which may occur in the arterial tracing The electrocardiogram, for instance, shows no discrepancies in the length of the intervals between the R waves The slight variations in the pulse intervals are attributed by Lewis to a slower rate of transmission of the weaker pulses to the periphery The appearance of alternation in the electrocardiogram (e g , alternate variations in the height of the R wave) is rare When this so-called *electrical alternation* does occur the larger deflections sometimes correspond to the weaker pulse beats But, it will be recalled in this connection that the deflections of the electrocardiogram are determined by the balance of the electrical forces developed during the cardiac contraction rather than upon their total value Electrical alternation bears no relation to the strength of the heart beat

Fig 3 82 Radial tracing showing pulsus alternans (After Mackenzie 1913)

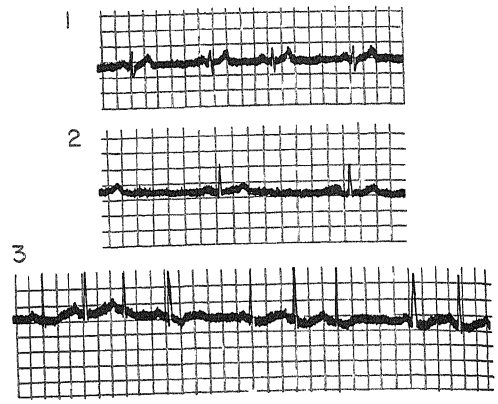

Fig 3 83 / sinus arrhythmia // sinus bradycardia /// sinoatrial block (Kindness of Dr John Hepburn)

Sometimes it is not possible to detect pulsus alternans by palpation of the pulse, the variations in strength of the pulse beat being too slight to be perceptible, but it is clearly revealed in the sphygmogram (Fig 3 82) It may also be detected by means of a blood pressure armlet The pressure in the armlet is raised gradually, when it is found that at a certain level the weaker beats are suppressed, but the stronger beats get through The pulse at the wrist is then precisely half the ordinary rate The pressure during the weaker beats may be as much as 25 mm Hg below that during the stronger, but usually the pressure difference is not more than 5 or 10 mm Persistent alternation of the heart when the pulse is slow or of normal frequency is usually indicative of grave disease of the myocardium Alternation sometimes also occurs at rapid rates of beating, e g , auricular fibrillation, paroxysmal tachycardia etc , but it is then of less serious significance

IRREGULARITIES DUE TO VARIATIONS IN VAGAL TONE

Sinus Arrhythmia (Fig. 3.83I). This is a condition in which rhythmical variations in the rate of the whole heart occur synchronously with respiration It is due to alterations in the strength of the vagal influence upon the pacemaker (SA node) as a result of the respiratory excursions, the heart rate increasing toward the end of inspiration and slowing toward the end of expiration It is an irregularity very com-

mon in children, normal in resting dogs, and may be considered a physiological phenomenon That it is entirely of vagal origin is shown by the fact that it is abolished by atropine It also disappears when the heart rate increases as a result of exercise, fever, etc , but is enhanced by deep breathing

Phasic Irregularity. In this disorder periodic slowing of the heart occurs for a few seconds quite independently of the respirations It also is a vagal effect since it is abolished by atropine The manner of its production is unknown It occurs in convalescence from acute fevers, and sometimes during the administration of digitalis

Sinus Bradycardia (Fig 3.83II). This is a persistent slowing of the whole heart due to increased vagal tone influencing the sinoauricular node The rate may be as slow as 40/min Bradycardia of this nature occurs in apparently healthy persons, many of whom are athletes

Sinoatrial Block (Fig. 3.83III). The entire heart (atria and ventricles) misses a beat at regular or irregular intervals The condition thus differs from AV block in which only the ventricle misses A complete set of waves is therefore dropped from the venous or electrocardiographic tracing, and the arterial pulse intermits Since the condition is temporarily abolished by atropine and may be induced by stimulation of the vagus, it is probable that the missed beats are due to the action of the nerve upon the SA node Sinoatrial block sometimes results from digitalis administration

Atrioventricular Block. Defective conduction between atria and ventricles due to heightened vagal tone is occasionally seen, it is abolished by atropine

4 / MECHANICAL ACTIVITY OF THE HEART

In recent years, the mechanics of cardiac contraction have been examined in accordance with the concepts and methodology developed by A V Hill (1939) and associates for skeletal muscle Isolated strips of myocardium are employed Mechanical activity is analyzed through correlating the interrelations between fiber length, force of contraction, velocity of shortening, tension developed, and load imposed Concepts derived from these in vitro studies are applicable to the analysis of the functional behavior of the intact heart

Muscle Mechanics

The heart is primarily a muscle, which functions in the intact animal as a hydraulic pump Thus, it is appropriate to analyze first the mechanics of cardiac muscle contraction and then apply these results to the functional characteristics of the heart as a hemodynamic pump

THREE COMPONENT MODEL OF MUSCLE

The three-component model of skeletal muscle proposed by Hill (1939) to explain the mechanical properties of skeletal muscle can serve to describe the physiology of contraction of isolated strips of cardiac muscle The three components are (Fig 3 84) *1*) a contractile element (CE) which develops force and shortens when activated, but which is extensible at rest, *2*) a series elastic (SE) element which is in series with the CE and is passively stretched by shortening of CE or stretching of the muscle *3*) A parallel elastic (PE) element which, in the version of the model in Figure 3 84, is depicted as being parallel to both CE and SE It maintains the resting length of the freely extensible CE and supports SE during resting tension, but plays little role during contraction. The anatomical sites of SE and PE are uncertain but may be in the contractile filaments, in the cell membranes, or in both.

In Figure 3 85, the arrangement employed by Sonnenblick et al (1970), for studying muscle mechanics in the isolated papillary muscle from the right ventricle of the cat is diagrammed One end of the muscle is attached to a tension (force) transducer and the other end to an isotonic lever, so that shortening and tension may be recorded simultaneously

Preload is the term applied to the amount of weight attached to the lever which establishes the resting length and tension in the inactive muscles before a contraction is induced *Preload* is analogous to factors which determine muscle fiber length in the intact ventricle at the end of diastole, i e , end-diastolic pressure The lever system is then fixed by means of a stop so as to prevent any further stretching of the muscle *Afterload* is the term applied to any additional weight added after the stop has been fixed, preventing further stretching of the resting muscle This is the additional load which the muscle engages when it begins to contract *Preload* and *afterload* make up the *total weight* against which the muscle is contracting when stimulated The *afterload* component is approximated by aortic pressure in the intact heart

The sequence of events during contraction is diagrammed in Figure 3 86 In the schema the parallel element (PE) is omitted When the muscle is stimulated and excitation-contraction coupling occurs, the contractile element (CE) shortens and develops force This is called the *active state* of the CE (see also p 3-39) The active state represents the time course of the onset and termination of the biochemical processes occurring at active sites along the actin and myosin myofilaments which produce force and shortening Because of the spring-like properties of SE, the active state of CE is translated into mechanical force development or shortening only after some delay The course of mechanical contraction which can be recorded is thus governed by the contractile prop-

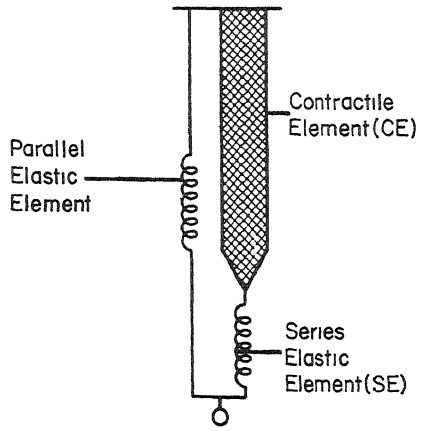

Fig 3 84 Three-component model for muscle proposed by A V Hill (1939) (Redrawn from Sonnenblick 1966)

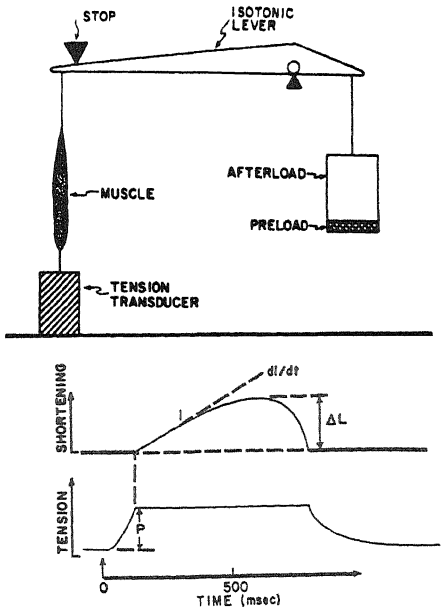

Fig 3 85 *Upper* Arrangement for study of mechanics in isolated papillary muscle *Lower* Records of shortening and tension of afterloaded isotonic contraction P afterload dl/dt initial shortening velocity (Redrawn from Sonnenblick et al 1970)

erties of CE, the duration of CE active state and the elastic properties of SE As seen in Figure 3 86 (*upper*), during an isometric contraction when the muscle cannot shorten, force develops along a delayed time course relative to CE contraction, owing to the time required for stretching SE In Figure 3 86 (*lower*), the model illustrates an afterloaded isotonic con-

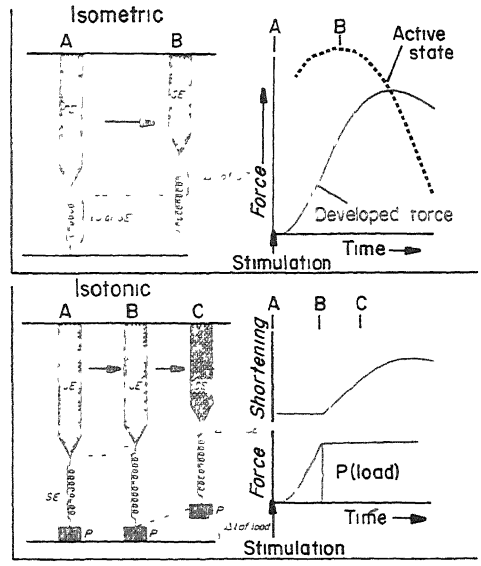

Fig 3 86 Sequence of events during contraction *Upper* isometric contraction showing events in the Hill model (*left*) and curves of force development (solid line) and active state (dashed line) *A* initial resting state *B* an instant during active contraction The difference between the active state curve and developed force curve is owing to the time needed for CE shortening to stretch SE *Lower* afterloaded isotonic contraction (*left*) and curves of force and shortening (*right*) as functions of time (Redrawn from Sonnenblick 1966)

traction The load (*P*) rests on a surface and is not exerting tension (afterload) With stimulation, CE starts to contract and shortens, thus stretching SE When contractile force stretches SE so that its elastic tension equals load (*P*), the muscle begins to shorten and lifts the load (Fig 3 86, *lower*, *B*, *C*)

FORCE-VELOCITY CURVE

During contraction, the force stretching SE remains constant and the course of shortening now represents the shortening of CE In an isolated muscle allowed to contract isotonically against various total loads (preload and afterload), the relation between force and velocity may be determined (Fig 3 87) When preload, which determines initial muscle length, is kept constant, an inverse relation between force and velocity is found The beginning or initial velocity of shortening is plotted as a function of load (*P*) The symbol P_0 is used for the load which just prevents external muscle shortening and thus represents maximum isometric force By extrapolating the force-velocity (or load-velocity) curve to zero load, the theoretical max-

imum velocity of shortening (V_{max}) is obtained The force-velocity relationship of cardiac muscle is changed characteristically by alterations in initial muscle length (preload) and by changes in the fundamental activity level of the shortening processes (contractility, contractile state, inotropic state) When initial muscle length is increased, there is a change in force developed (P, P_0) without a change in extrapolated maximal velocity of shortening (V_{max})[1] (Fig 3 88) In the intact heart this has its counterpart in the Frank-Starling relationship in which the stroke volume and force of contraction can be shown to increase with increasing ventricular volume

Inotropic agents (e g , norepinephrine, calcium, digitalis, glycosides) and procedures increasing frequency of contraction (e g , postextrasystolic potentiation by paired electric stimulation) produce an increase in the V_{max} and P_0 Thus, the muscle shortening is faster for a given load and stronger at isometric loads (see Fig 3 89) Since V_{max} is unchanged by alterations in initial muscle length, but is varied by changes in the contractile state, it can be used as an indicator of the fundamental condition of contractility

The effect of initial muscle length on force of contraction is related to the length of the sarcomeres (Fig 3 90) Alterations of muscle length change the degree of overlapping of the contractile filaments This seems to alter the number of active contractile sites which generate force but not the maximal rate of reaction at these sites This would account for the changes in P_0 with increased muscle length occurring without changes in the V_{max} On the other hand, a change in contractile state appears to result from an influence on the rate of reaction at contractile sites, but not necessarily an effect on the number of sites which are active

[1] There is not general agreement that this relationship holds Although it has been shown that whole cardiac muscle V_{max} is independent of fiber length under specific experimental conditions (i e , afterloaded isotonic contraction at 23° C), there is evidence that this independence is absent under other experimental circumstances Thus, this may not be a general property of cardiac muscle If so, this would limit the value of V_{max} as an index of contractility in cardiac muscle (Pollack, 1970, 1971) However, the concept as described here has been and is widely used as an index of the inotropic state of cardiac muscle and has been vigorously defended (Sonnenblick, 1970) although the controversy remains unresolved

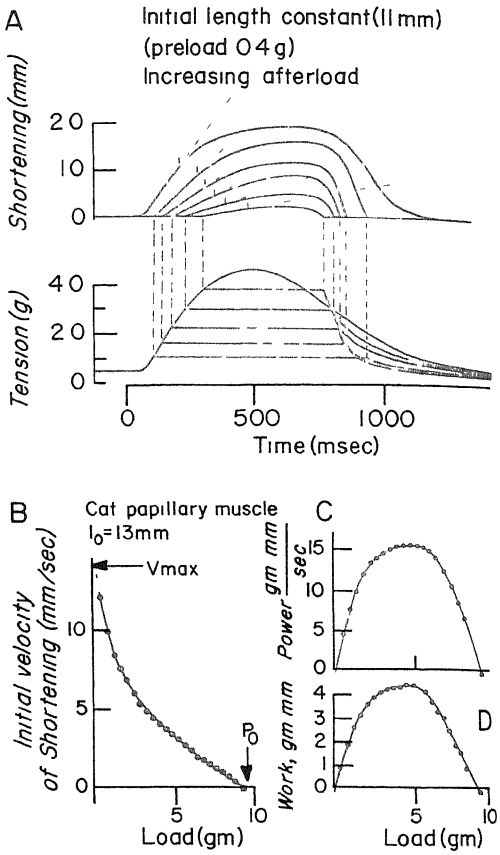

Fig 3 87 *A* curves of the time course of shortening and tension with increasing afterload The initial velocity of shortening (represented by the slope of the dashed lines in the top curves) decreases with increasing afterloads *B* force velocity curve (cat papillary muscle) showing this inverse relation between afterload and initial velocity of shortening *C*, the relation between power $\left(\text{load} \times \text{velocity} = p \frac{dl}{dt}\right)$ and load (p) *D* the relation between work (load $\times$ distance $= \int_{t_0}^{t^1} p \, dl = p \, \Delta L$) and load (Redrawn from Sonnenblick 1966)

LENGTH-TENSION DIAGRAM

As can be seen in Figure 3 91, the force of contraction depends on initial muscle length in both cardiac and skeletal muscle Since muscle length and sarcomere length are directly proportional, the changes in force of contraction with degree of stretch can be related to sarcomere dimensions The extent of thick and thin filament overlap in skeletal muscle determines tension development (Fig 3 92) The evidence supporting these relationships is best for skeletal muscle

The length-tension diagrams are similar in

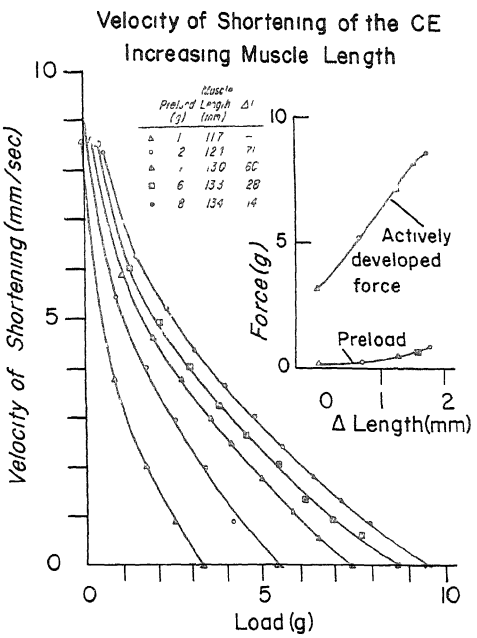

Fig 3 88 Force-velocity curves of cat papillary muscle with increasing preload which increases initial fiber length (insert represents length-tension curve at these preloads) Increasing preload (fiber length) does not alter V_{max} but increases actively developed force (Redrawn from Sonnenblick et al 1970)

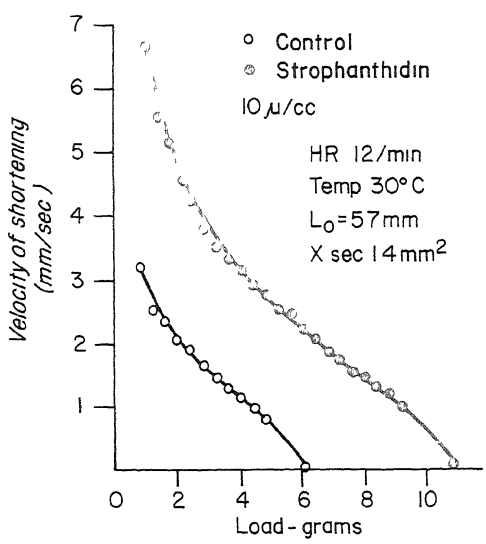

Fig 3 89 Strophanthidin effect on force-velocity relation Both V_{max} and maximal force of contraction are increased (Redrawn from Sonnenblick et al 1970)

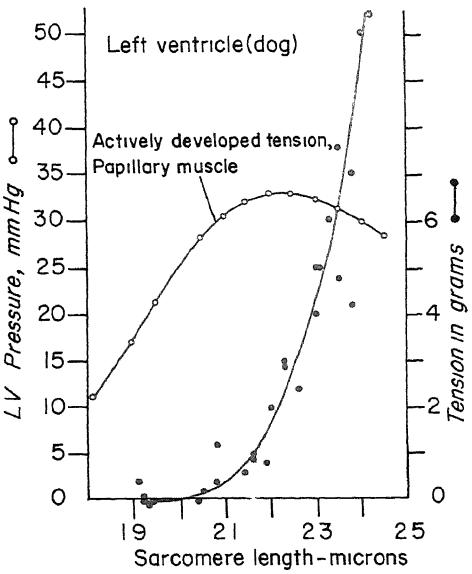

Fig 3 90 Sarcomere length plotted against left ventricular filling pressure (data from dog heart) and sarcomere length-tension diagram from cat papillary muscle Curves are displayed on the same coordinates to indicate the probable relation between sarcomere length and actively developed tension (Redrawn from Spotnitz et al 1966)

form for both cardiac and skeletal muscle However, the maximum force of contraction per unit mass of heart muscle is less than that of skeletal muscle Also, the resting tension of cardiac muscle is considerably higher than that of skeletal muscle at lengths which produce maximum contraction The lesser contractile strength of heart muscle is explained in part because there is a relatively larger amount of noncontractile mass (mitochondria, etc) per cross-sectional area in cardiac than in skeletal muscle When this factor is corrected for and heart muscle is induced to contract at a maximum, the force generating capacity of the two types of striated muscle is similar

The tension curves rise to a maximum and then decline as muscle length is increased (Fig 3 91) The point at which maximum tension develops is termed L_{max} The ascending limb of the length-tension curve represents increasing tension response to increasing length up to L_{max} The descending limb is the part of the curve showing decrease in tension as the initial muscle length is increased beyond L_{max}

There is considerable difference in the resting tension curves between the two muscles

In skeletal muscle, resting tension is very small at L_{max} and only increases significantly during the descending limb of the tension curve In contrast, resting tension in heart muscle is high at L_{max} The structures responsible for this dif-

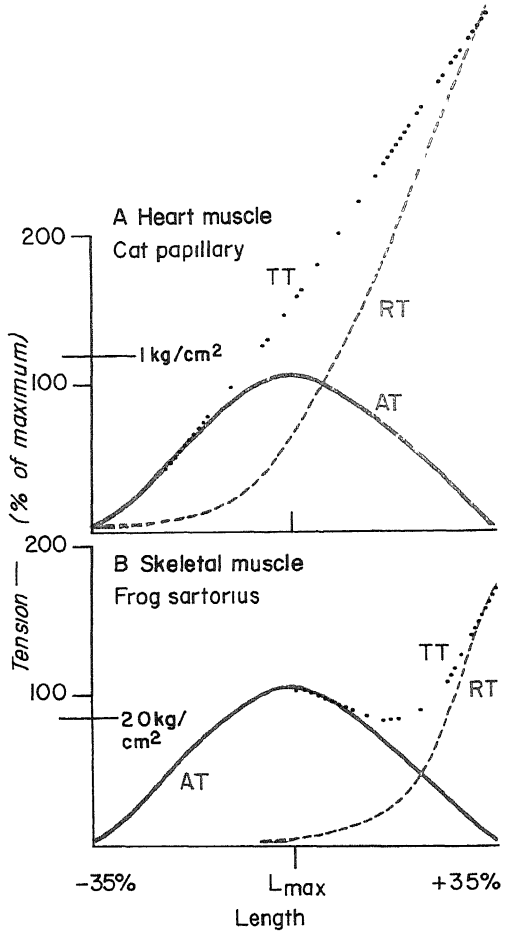

Fig 3 91 Length-tension diagrams for heart (*A*) and skeletal (*B*) muscle compared RT resting tension AT actively developed tension TT total tension (AT + RT) (Redrawn from Spiro and Sonnenblick 1964)

ference in resting tension at L_{max} are not known The connective tissue, sarcolemma, or some other structure may be responsible For cardiac muscle, however, this is a useful feature since the ventricle must function along the ascending limb of the length-tension curve for increasing strength of contraction to be directly related to increases in ventricular volume at the time systole is initiated The cause of this greater stiffness of cardiac muscle may be related to the relatively greater amount of connective tissue present Since cardiac muscle cells are smaller in diameter (5 to 10 μ) than skeletal muscle cells (50 to 100 μ), the relative amount of sarcolemma is greater in the former The sarcomere length-tension curve for papillary muscle is shown in Figure 3 93 The tension curve reaches its apex at sarcomere length between 2 10 and 2 25 μ and tension is close to zero at 1 5 μ As muscle length increases beyond L_{max}, tension decreases but in the descending limb of the curve for cardiac muscle, the relationship between sarcomere length and length of muscle no longer holds strictly and the resting tension increases markedly Thus, sarcomeres longer than 2 60 μ are seldom produced Further, lengthening in response to stretch cannot be due to sarcomere lengthening and must be the result of fiber slippage as explained in the foregoing (see Chap 2, "Dilatation") The effect of sarcomere length on tension development is explained by the "sliding

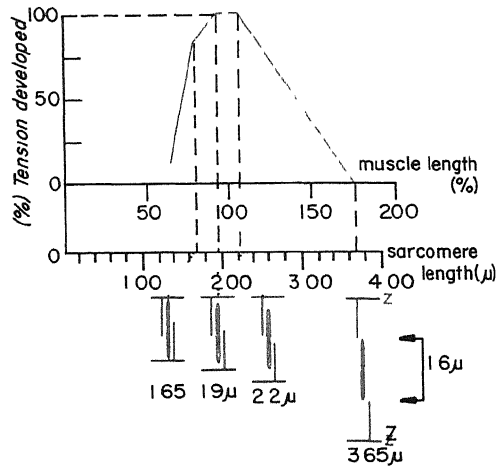

Fig 3 92 Sarcomere length in relation to tension development for skeletal muscle (Redrawn from Hanson and Lowy 1965)

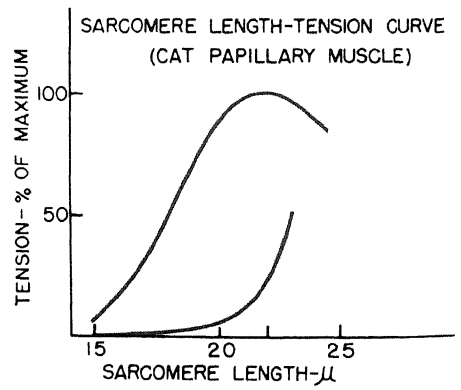

Fig 3 93 Sarcomere length-tension diagram for cat papillary muscle (Redrawn from Sonnenblick, 1968)

filament" theory of muscle contraction (Fig 3 92) Maximal tension depends on optimal overlap of actin and myosin filaments such that all reactive sites between the two contractile protein filaments may be engaged When the sarcomere is stretched, overlapping is decreased and reduction in force development follows If stretched sufficiently, so that no overlap occurs, the muscle becomes incapable of contraction As muscle length is decreased below the apex of the length-tension curve, the actin filaments slide into the center of the sarcomere, this is accompanied by a reduction in force development The latter may be the result of disruption of bond formation in the opposite half of the sarcomere by actin filaments or actual repelling forces developing between them

In the intact ventricle, the volume of ventricular filling determines the initial length of the muscle fibers (preload) At the time of systole the fibers contract isometrically (do not shorten) until the pressure in the ventricle exceeds that in the arteries and ejection begins At this time, shortening of the fibers occurs as contraction proceeds against the pressure in the aorta and pulmonary arteries (afterload) In Figures 3 94 and 3 95, sarcomere lengths, as determined from studies on isolated cat papillary muscles, are plotted to show the relationship

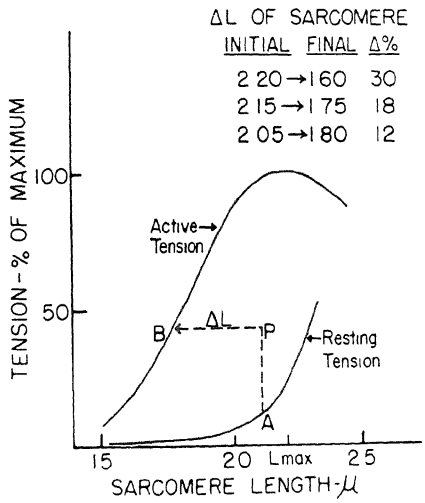

Fig 3 94 The relationship between sarcomere length and active tension during isometric contraction and contraction as the muscle shortens from studies on isolated cat papillary muscle *A* onset of contraction *P* afterload ΔL change in sarcomere length (Redrawn from Sonnenblick, 1968)

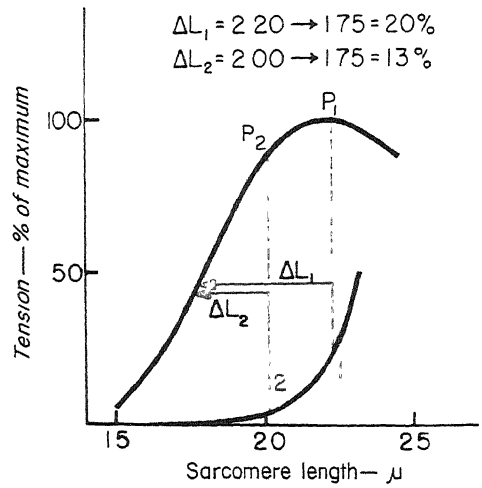

Fig 3 95 The effects of changing initial sarcomere length from 2 to 1 on force of isometric contraction (P_2 to P_1) and extent of shortening (ΔL_2 to ΔL_1) There is little change in contractile force but a substantial change in extent of shortening from 13% to 20% (Redrawn from Sonnenblick 1968)

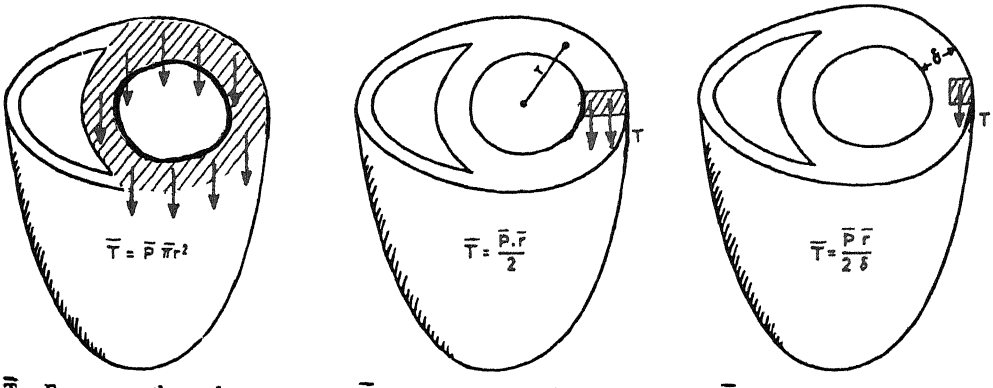
between sarcomere length and the active tension curve during isometric contraction and contraction as the muscle shortens The latter, auxotonic contraction, is not termed isotonic because the pressure against which the sarcomeres are shortening is changing during ejection (see p 3-96) Force is developed without shortening (Fig 3 94, *A* to *P*) until tension equals blood pressure and the sarcomere shortens (ΔL) The sarcomere then shortens until it reaches the active tension curve (*B*) at which time it can shorten no further In isolated preparations sarcomere shortening of about 30% (from 2 20 to 1 60 μ) may occur (see Fig 3 94). However, under the loading conditions of the intact heart, the sarcomere can only shorten about 12 to 18% In Figure 3 95, the effects of changing initial sarcomere length from 2 00 to 2 20 μ is depicted This is the sole change which would occur in the intact heart with increased filling pressure of the ventricle Because the ventricle operates normally, on the ascending limb of the length-tension curve near its apex (i e , at optimal sarcomere length for developed tension) the resulting increase in force of contraction is only moderate (from P_2 to P_1). However, note that a substantial increase in shortening (ΔL_2 to ΔL_1, 13 to 20%) occurs These fundamental characteristics of cardiac muscle mechanics form the basis of



the Frank-Starling relation (Starling's "law" of the heart), according to which, force of ventricular contraction and volume of ejected blood increase directly with an increase in initial volume of the ventricle at the time of systole (end diastolic volume)

VENTRICULAR WALL TENSION AND THE LAPLACE RELATIONSHIP

Ventricular myocardial tension is related to intraventricular pressure per square centimeter of surface upon which the pressure is exerted The larger the surface the greater will be the total pressure This relationship may be calculated by employing the law of Laplace It applies to distensible membranes with a spherical or cylindrical shape Assuming that the ventricle has a spherical cavity, three definitions of contractile tension have been employed for the ventricular myocardium (Fig 3 96) Badeer (1963) recommended expressing myocardial tension in terms of force per unit of cross-section area as follows

$$\bar{T} = (\bar{P}\ \bar{r})/2\delta$$

$\bar{T}$ (stress = mean force per unit cross sectional area of wall during systole, $\bar{P}$ = mean transmural pressure during systole, $\bar{r}$ = mean radius during systole, and δ = thickness of wall during systole Accordingly, a greater pressure or radius (dilatation) increases the contractile tension in the wall of the ventricle (this, of course, applies to the atria as well) The Laplace relationship results in a disadvantage when the ventricle is excessively dilated In the normal ventricle the radius of the chamber during systole decreases as the blood is ejected Thus, the wall tension begins to decrease after the beginning of ejection and at the time of peak systolic pressure may actually be less than at the onset of systole When the ventricle is markedly dilated, the wall tension is greater than normal and the magnitude of fiber shortening may be so compromised that reduction in chamber radius is minimal In such instances, the tension on myocardial fibers may continue to increase from the beginning of ejection to the peak of systolic pressure A further disadvantage of dilatation is that the sarcomeres may be stretched somewhat although there is little anatomical evidence for this Insofar as sarcomeres are stretched, however, the ventricle will be functioning on the descending limb of the length-tension curve Further, the Laplace relation means that, at the same pressure, a dilated heart must generate greater force than normal and, in accordance with the force-velocity relationship, the rate of myocardial fiber shortening will be decreased These factors diminish the ability of the ventricles to eject blood The increased tension in dilated hearts is believed to be adequate stimulus for my ocardial hypertrophy This accounts for hyper trophy in those abnormal states in which the heart is subject to a volume overload at normal

$\bar{T}$ = Force across the total cross-sectional area of muscle

$\bar{T}$ = Force per unit length of circumference and the entire thickness of wall

$\bar{T}$ = Force per unit cross-sectional area of muscle

Fig 3 96 Three ways of representing the relations between ventricular wall tension, intraventricular pressure and ventricular dimensions according to the law of Laplace The ventricle is assumed to be a sphere $\bar{T}$, mean contractile tension (force) $\bar{P}$, mean transmural pressure during systole $\bar{r}$ mean ventricular radius during systole $\bar{\delta}$, ventricular wall thickness (Redrawn from Badeer 1963)

pressure (e g , right ventricular hypertrophy in atrial septal defects)

THE ACTIVE STATE IN THE FORCE-VELOCITY RELATIONSHIP

The concept of the active state has been defined previously (see pages 3-39 and 3-86) The term designates the degree of activity of the contractile element The time course of the active state has been determined on isolated papillary muscles of the rabbit, employing the "quick release" method of Jewell and Wilkie (1960, Edman, 1968) In this method, the muscle is attached to an isotonic lever which, at first, is fixed by a releasable catch so that the muscle begins to contract isometrically At varying intervals during an isometric contraction, the lever is released abruptly and the muscle shortens against a small load The initial rapid phase of shortening involves movements of both the series elastic element and the contractile element A second slower phase is caused by shortening of the contractile element alone The velocity of shortening during the second phase, at a given length change, is an index of the intensity of the active state at that instant of the isometric contraction By releasing the muscle at various times after the stimulus, the time course of the active state may be determined An active state curve of rabbit papillary muscle is shown in Figure 3 97 and the relation of active state to isometric contraction on the right top in Figure 3 86 The active state attains a maximum slowly and starts to decay without reaching a plateau The latter suggests that the contractile element of the myocardium does not reach mechanical "saturation" during contraction It has been shown (Edman, 1968) that the course of the active state depends on how much the contractile element is allowed to shorten during the contraction period As the contractile element is allowed to shorten, there is a progressive decrease of the maximal intensity of the active state and a reduction in its duration Thus, shortening of the muscle during contraction reduces the duration of mechanical activity (see Figs 3 98 and 3 99)

THREE DIMENSIONAL DIAGRAM OF VENTRICULAR CONTRACTION

The force-velocity curve and length-tension curve for the papillary muscle can be arranged

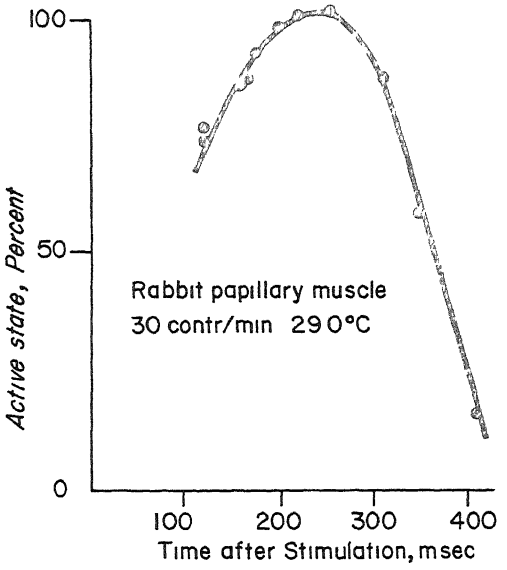


Fig 3 97 Active state curve of rabbit papillary muscle (Redrawn from Edman 1968)

in a three dimensional diagram to illustrate their interrelations, in particular the effect of change in muscle length on the force-velocity curve Such a diagram is seen in Figure 3 100 The vertical plane on the right represents the force-velocity relation, the vertical plane on the left the velocity-length relation, and the triangle at the base the length-tension relation A series of force-velocity curves with decreasing fiber length is displayed The course of the contraction is depicted by the heavy dashed line The muscle is stimulated at point A and, after an appropriate interval for the development of the active state, the CE reaches point B on a given force-velocity curve Note that the force-velocity curve followed depends on the muscle length at which the CE begins to develop force As force (load) increases, the velocity of shortening of the CE travels down the force-velocity curve to some point C At this point C, force of contraction equals load (afterload) and mechanical shortening starts at that load (isotonic contraction) The velocity of shortening now decreases as the length of CE decreases, traveling down the family of instantaneous force velocity curves The active state, and thus, the velocity of shortening of the CE at any instant, depends on the muscle length at that moment in time Thus, during contraction, as the muscle shortens, it operates on a series of instantaneous force-velocity planes of decreasing magnitude

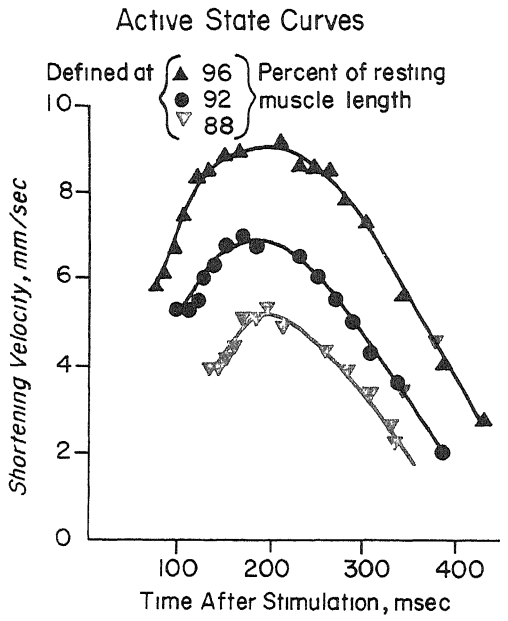

Fig 3 98 Changes in active state curves of papillary muscle in relation to the degree of muscle shortening permitted Shortening of the contractile unit decreases the intensity and duration of the active state (Redrawn from Edman 1968)

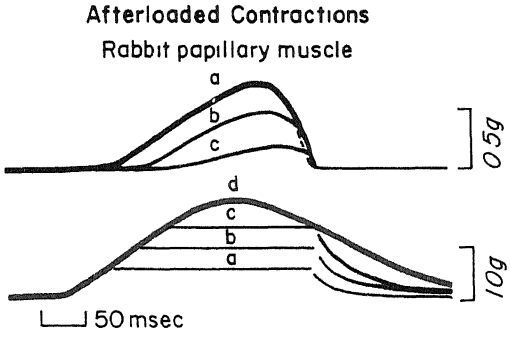

Fig 3 99 Relationship between papillary muscle shortening and duration of mechanical activity Isotonic contraction curves a b c (*upper*) superimposed on the same time base with isometric myogram c b a (*lower*) Curve d is the ordinary isometric contraction myogram The more the muscle is allowed to shorten during the isotonic phase the briefer is the isometric portion of the myogram (Redrawn from Edman 1968)

PRESSURE-VELOCITY-VOLUME (PRESSURE-VELOCITY-LENGTH) DIAGRAM FOR THE INTACT VENTRICLE

In the intact ventricle, pressure, velocity, and volume are analogous to force, velocity, and length of the isolated cardiac muscle (Fig 3 101) Here, force is analogous to developed

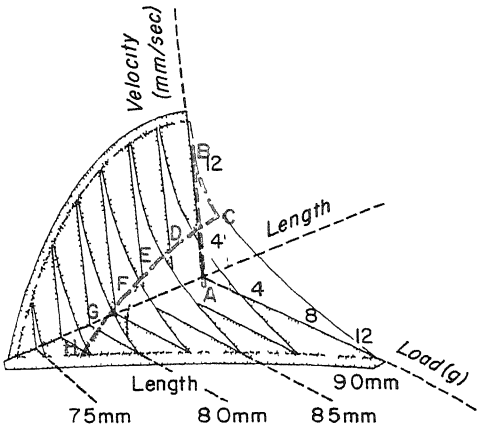

Fig 3 100 Three-dimensional diagram representing the interrelations between force-velocity and length tension curves of papillary muscle Base length-tension curve Vertical plane on right force-velocity curve Vertical plane on left velocity-length curve Dashed line (ABCDEFGH) the course of a single afterloaded contraction (Redrawn from Sonnenblick 1966)

pressure, length analogous to volume, and muscle shortening analogous to the amount of blood ejected (stroke volume) In Figure 3 101, work is illustrated on the horizontal plane as the product of force (or load, obtained from pressure) times distance (muscle shortening or stroke volume change) On the vertical plane, power is represented as the product of force (load) times velocity As in Figure 3 100, the dark line represents the course of a single contraction At A, contraction is initiated and CE velocity rises toward V_{max} as CE begins to shorten It travels down the force velocity curve to point C This represents isometric or isovolumetric contraction of the ventricle At C, force equals load and mechanical shortening begins traveling from C to E (ventricular ejection, stroke volume) The area ADEF represents stroke work (pressure $\times$ volume) The area ABCD represents power (pressure $\times$ velocity) The effect on these relationships of increasing ventricular volume at the onset of contraction is shown on the curve HJICE The maximum isometric force is increased from P_0 to P_0' Little change in V_{max} is seen but both stroke work and stroke power are increased This is the change which occurs with increasing end diastolic volume of the ventricle There is little change in the contractile state of the myocardium since V_{max} is not changed The insert in the lower right shows predicted relations of stroke volume, stroke work, and

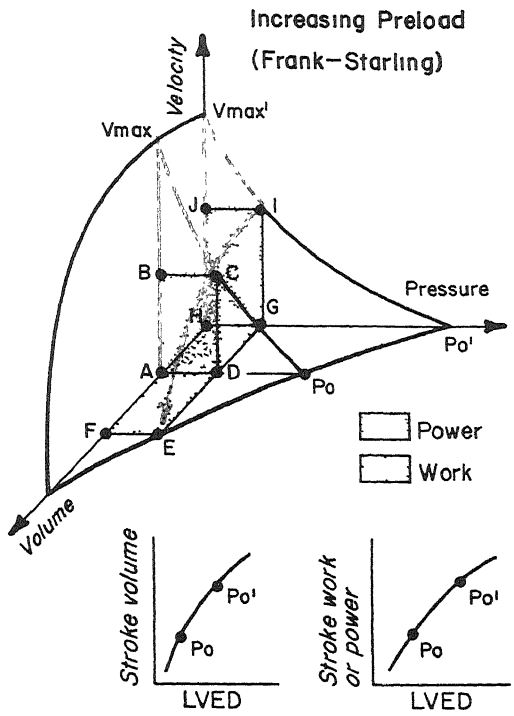

Fig 3 101 The effects of increasing preload on the work and power in analogy to pressure volume relations in the intact ventricle Load is represented as pressure and volume as length on the three-dimensional force-velocity-length construct for papillary muscle When preload (analogous to left ventricular end diastolic pressure LVED) is increased and pressure remains the same work increases (ADEF to HGEF) and power increases (ABCD to HJIG) V_{max} representing contractile state is unchanged *Insert* Relations between stroke volume and stroke work or stroke power predicted from the changes in work and power areas of the three dimensional diagram (Redrawn from Sonnenblick 1966)

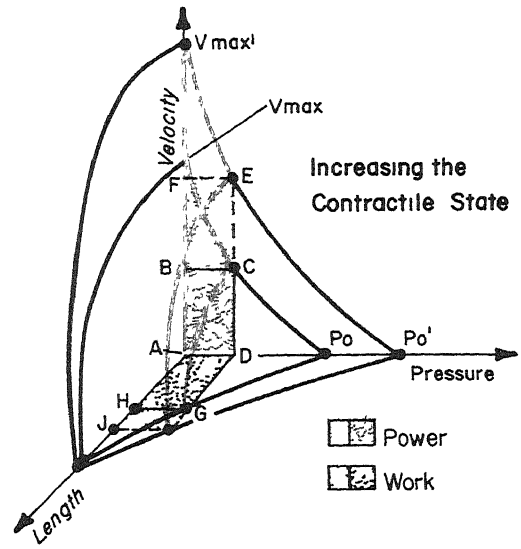

Fig 3 102 The effects of increasing contractile state with inotropic agents (sympathetic nerve stimulation norepinephrine) on force-velocity-volume (length) relations V_{max} and P_0 are increased Load (pressure) is kept constant Work and power are increased (Redrawn from Sonnenblick 1966)

stroke power to left ventricular end diastolic pressure The effect of increasing contractile state (e g , as with increase of sympathetic tone, norepinephrine) is shown in Figure 3 102 Note that an increase in both V_{max} and P_0 occurs and velocity of ejection of the ventricle is increased at any given intraventricular pressure and volume Work and power increase as shown Observe that the pressure (distance from A to D) has not been increased

In Figure 3 103, the effects of increasing heart rate are portrayed An increase in V_{max} without a change in P_0 occurs Power is augmented from ABCD to AFED, while work remains the same, ADGH Ventricular performance curves in Figure 3 103 relate left ventricular end-diastolic pressure to stroke volume, work, and power These show that there is no increase in the first two but the stroke power curve is shifted to the left

Figure 3 104 illustrates the effect of alterations in blood pressure (afterload) alone Both power and work may be increased with increasing aortic pressure from P to P' in the absence of a change in contractile strength The effects of afterload increases on ventricular performance are shown in the insert. With increased afterload the initial velocity of shortening is decreased (V to V') and the extent of shortening is decreased Thus, the ventricular function curve relating stroke volume to left end diastolic pressure (Fig 3 104) is shifted to the right as stroke volume and peak ejection velocity decrease Both stroke work or stroke power may be increased at any given left ventricular end diastolic pressure, thus shifting this function curve to the left (bottom, Fig 3 104) Therefore, the effect of increasing afterload or blood pressure may be limited to mechanical changes alone with no influence on contractile state (however, see Anrep effect, p 3–110)

The three dimensional diagram in Figure 3 105 represents more realistically the relations in the intact ventricle, since part of ventricular systole is *auxotonic*, i e , contraction against an

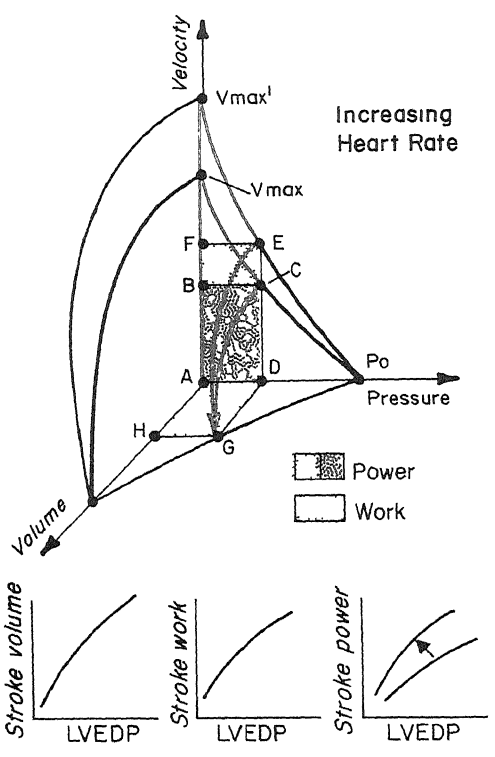

Fig 3 103 The effects of increasing heart rate on force-velocity-length relations V_{max} is increased without a change in P_0 Power is increased with no change in work *Insert* Relations between stroke volume stroke work and left ventricular end diastolic pressure (LVEDP) show no change but the stroke power curve is shifted to the left (Redrawn from Sonnenblick 1966)

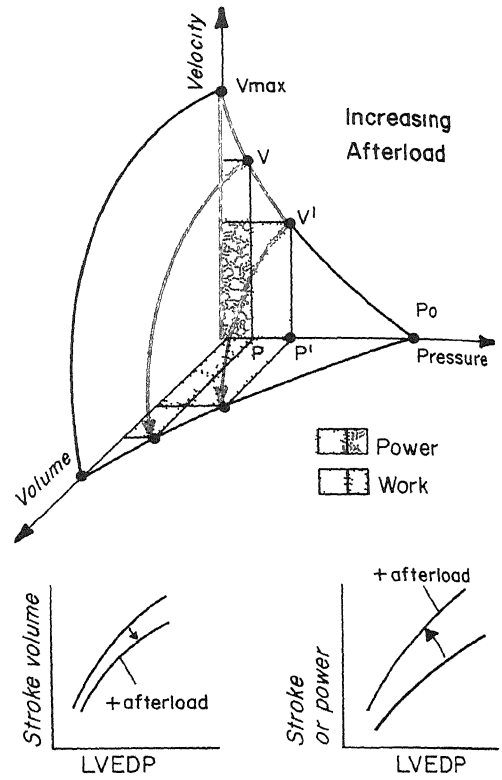

Fig 3 104 The effects of increasing afterload (analogous to blood pressure) on power and work Work and power are both increased with no change in V_{max} (i.e., contractile state remains constant) *Insert* In the intact ventricle with no increase in contractile state elevation of blood pressure would tend to diminish stroke volume relative to left ventricular end diastolic pressure (LVEDP) but stroke work and power would be augmented However in the intact heart contractile state may be augmented with a pressure increase (See Anrep effect p 3-110) (Redrawn from Sonnenblick 1966)

increasing pressure [2] Velocity of CE shortening follows the usual course until the onset of ejection (point B) Fiber shortening is then determined by the varying afterload (blood pressure) and the instantaneous relation between fiber length and velocity Point C marks the end of ejection, the question mark indicates that its exact location relative to the length-tension curve is not certain The length-tension curve depicted is determined from isovolumetric beats in which the ventricle is caused to contract with the aorta clamped or obstructed by a balloon so that ejection cannot occur Following isovolumetric relaxation (C to D), ventricular filling occurs and fiber length increases along the line D to A Point A is end diastole and beginning systole

[2] Actually, these relations are more complex, since during ventricular ejection the pressure first increases and then begins to decline before contraction (systole) is complete and ventricular wall tension relative to pressure (Laplace relation) decreases as ventricular radii decrease during systole The term "negative" auxotonic contraction is sometimes used for contraction against a decreasing pressure Thus, the ejection phase of ventricular contraction can be described as "positive" auxotonic initially and "negative" auxotonic terminally See also p 3-91

WORK, POWER, AND EFFICIENCY

In simplest terms work (W) equals force (P) times distance or displacement (ΔL)

$$W = P \Delta L$$

and power ($\dot{W}$), the rate of work or the work performed per unit time (t)

$$\dot{W} = W/t = P \Delta L/t$$

or force times velocity (dl/dt or v) $\dot{W} = P\ dl/dt = P\ v$

Thus, work performed is the power integrated as a function of time

$$W = \int (P\ dl/dt)\ dt = \int_{t_0}^{t_1} Pdl = P\ \Delta L$$

In Figure 3 87 *C* and *D* are depicted the relations between load and power and work development by the contracting papillary muscle The kinetic component of work equals ½ mv^2, comprises less than 5% of work, and has been omitted

From Figure 3 87 *B*, *C*, *D*, it can be seen that for any given muscle length, work and power vary with load (*P*) reaching a maximum at 50% of the maximum force (P_0) the muscle can develop at that length When shortening does not occur (at P_0 and at the end of contraction, V_{max}) the load is not moved through any distance Distance becomes zero and both work and power reach zero Thus, when mechanical shortening of the muscle does not occur, no work, in a physical sense, is done In another sense, however, work is performed in isometric contraction as represented by shortening of the contractile elements (CE) in the total muscle

In Figure 3 106, various expressions of cardiac work are represented *Contractile element work* (shortening of CE against SE) has been explained in the foregoing *Total cardiac work* includes that produced during the entire contraction period (systole) This would also incorporate work expended in propelling blood in

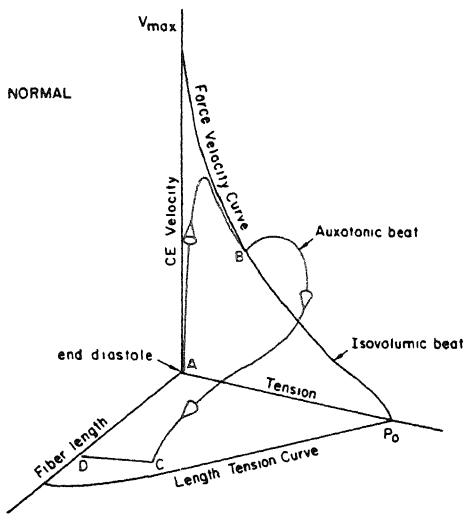

Fig 3 105 Three dimensional construct for the intact ventricle (Redrawn from Braunwald et al 1967)

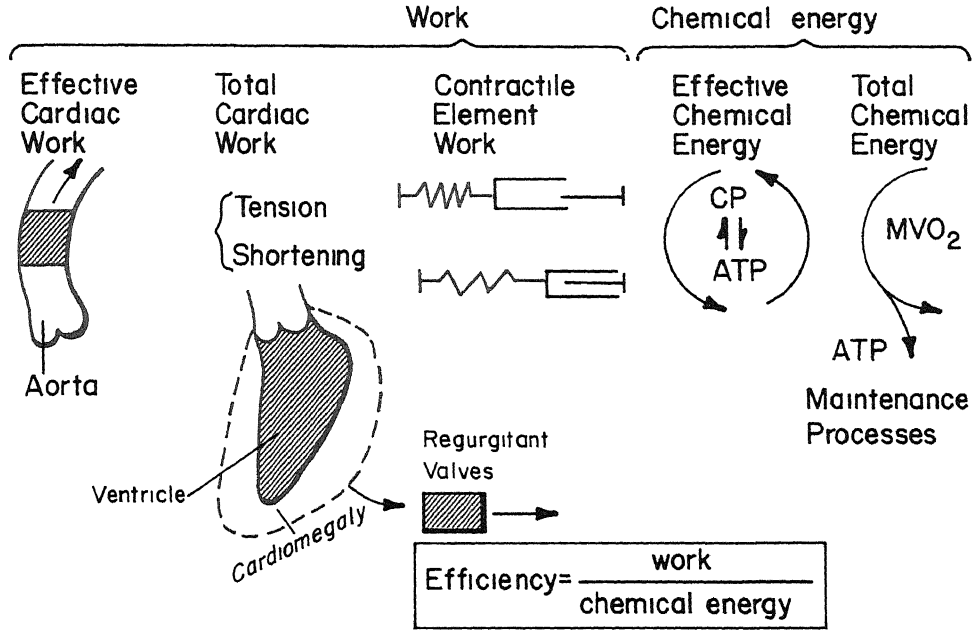

Fig 3 106 Various factors employed to calculate cardiac efficiency Chemical energy can be taken as total myocardial oxygen consumption (MVO_2) or by effective energy used in the contractile process (ATP utilization) Work can be considered as merely contractile element (CE) shortening against load or by the total cardiac work (which is a product of volume of blood ejected against pressure) The latter is affected by ventricular geometry dimensions and regurgitation of cardiac valves (pp 3-92 and 3-44) Effective cardiac work considers only that calculated from the stroke volume delivered forward into the great vessels (e g aorta) against a given pressure (Redrawn from Braunwald et al 1967)

the wrong direction (regurgitation) should cardiac valves be insufficient *Effective cardiac work* is that which produces forward movement of blood against arterial pressure This includes only that work accomplished during systolic ejection when a volume (stroke volume) of blood is delivered into the aorta (or pulmonary artery) against the existing arterial pressure

Efficiency (Eff), most simply defined, is the ratio of useful energy output (work) to total energy expenditure (work + heat)

$$\text{Eff} = \text{work}/(\text{work} + \text{heat}) = w/w + h)$$

Work plus heat is the equivalent of total chemical energy expended (e) Thus, efficiency can be represented as

$$\text{Eff} = W/e$$

as in Figure 3 106

Since practically all energy consumed in the myocardium is linked to oxidative metabolism, myocardial oxygen consumption (MVO_2) can be considered an equivalent of total chemical energy Then the efficiency ratio becomes

$$\text{Eff} = \frac{W(\text{pressure} + \text{kinetic})}{\text{Total } MVO_2 - \text{resting } MVO_2}$$

Values for cardiac efficiency calculated in this way have varied between 10 and 20% in experimental animals This expression of efficiency relates only oxygen consumption to effective cardiac work (Fig 3 106) and neglects a number of factors linking the chemical and mechanical processes Effective ventricular work excludes part of total cardiac work and part of oxygen consumption represents noncontractile processes

A closer approximation to true cardiac efficiency is the ratio of contractile element work (CEW) to chemical energy of activation (AE) and chemical energy of work (WE) less resting energy (RE)

$$\text{Eff} = \text{CEW}/[(\text{AE} + \text{WE}) - \text{RE}]$$

An efficiency of 33% was obtained for the anaerobic iodoacetate-treated papillary muscle using this approach (Pool and Sonnenblick, 1967) When RE was not subtracted the efficiency obtained was 23%

The Heart as a Pump

ATRIAL AND VENTRICULAR BLOOD VOLUME

In man, the atrial capacities are slightly greater than those of the corresponding ventricles, thus providing a reservoir of blood sufficient to fill the ventricular cavities completely For example, in the dead human heart such values as the following have been found the right atrium 163 ml , the right ventricle 137 ml , the left atrium 140 ml , the left ventricle 120 ml

It is now well established that the heart is not completely emptied of blood during ventricular contraction, i e , a residual ventricular volume of blood remains at the end of ejection Observations in dogs indicate that the right ventricle and left ventricle both empty in a fractionate manner

Under control conditions in anesthetized dogs, ejection fraction averaged 47% of left ventricular end diastolic volume With reduction of outflow resistance (afterload), ejection fraction increased to 73%, with little change in stroke volume (Tsakiris et al , 1968) Caution is necessary, however, regarding the methodology of in vivo ventricular volume measurements Two such methods are currently available one is based on the indicator dilution technique, measuring during successive heart beats the decline in concentration of the indicator introduced into the ventricle, the other utilizes cineradiographic measurements following the injection of a radiopaque substance outlining the ventricular cavity Theoretical objections to the former method include the demonstrated incomplete mixing of the indicator within the ventricular chamber, while angiographic methods must necessarily involve certain geometric assumptions, in addition to the unknown effect on the heart of the rapid injection of a relatively large volume of contrast material

In man, a roentgenographic method gave left ventricular diastolic volumes of 70 to 80 ml ± 10 to 20 ml /sq meter of body surface, with 60 to 75% ejected during systole (Dodge et al , 1966) With a thermodilution method diastolic volumes of about 100 ml /M^2 and about 50% of the diastolic volumic ejected during systole were reported (Rapaport, 1966) Stroke volume (SV) is the difference between end-diastolic volume (EDV) and end-systolic volume (ESV) The ratio SV/EDV has been shown to be quite constant in mammals varying in size from rat to horse and to vary linearly with body weight (Holt et al , 1968) In man and dog it varies between about 50 and 65%. Sonnenblick (1968) explains this proportion constancy in hearts of vastly different size on the basis of sarcomere

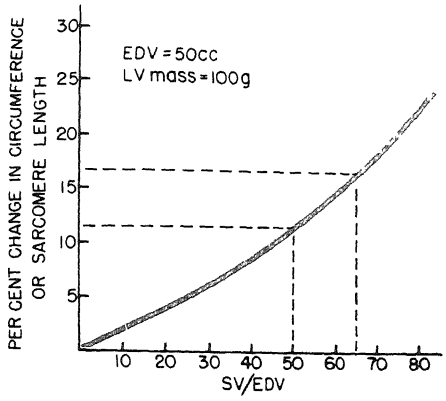

Fig 3 107 The percentage change in midwall circumference or sarcomere length to ventricular ejection fraction (SV/EDV stroke volume/end diastolic volume) (Redrawn from Sonnenblick 1968)

characteristics, which, in all species, have similar dimensions In Figure 3 107, percentage change in ventricular midwall circumference and sarcomere length is plotted against ejection fraction (SV/EDV) The dashed lines represent ejection fractions within the reported range of 50 to 65% This would require sarcomere shortening of 12 to 17%, which corresponds well with that predicted from afterloaded sarcomere shortening Thus, the characteristics of sarcomeres, which are uniform in different-size hearts, would explain ventricular ejection and apply to hearts of any size

PATTERNS OF VENTRICULAR EMPTYING

Traditional concept has it that the ventricles eject blood primarily by shortening of the longitudinal axis accompanied by a rotational action comparable to a wringing out of a wet rag Direct measurements, however, of changing ventricle dimensions in unanesthetized dogs by cinefluorographic techniques with contrast media, by intraventricular gauges and by external resistance gauges, indicate that the left ventricle resembles a cylinder with a conoid apical segment The cylindrical portion is made of a strong cuff of deep fibers between thin layers of spiral muscle The conoid section is made primarily of closely woven spiral muscle entering and leaving "the vortex." Left ventricular contraction involves primarily a reduction in transverse diameter This action accounts for most of the power and volume of the ejection since the contained volume decreases with the square of the radius in a cylinder There is relatively little rotation or shortening of the longitudinal axis All this would be expected since the bulk of the fibers is circularly arranged

By contrast, right ventricular ejection of blood can be effected by three means *1)* Longitudinal shortening of the chamber, i e , base moving toward apex is the most obvious movement This might be expected since the inner and outer layers of spiral muscle making up most of the right ventricle are oriented at about 90° from each other Hence, simultaneous contraction of the two layers of spiral muscle produces shortening along the longitudinal axis of the right ventricle chamber *2)* The right ventricular chamber is roughly triangular in shape, being bounded by a convex septal well and a concave free or lateral wall which enclose a crescent shaped area between them The free wall of the right ventricle moves toward the convex surface of the septum This movement although slight could be extremely effective in moving blood, and it would operate like a bellows used to kindle a fire, i e , since the sides of the ventricle or bellows are large compared to their enclosed space, slight movement toward each other should cause displacement of a large volume of blood *3)* Contraction of the left ventricle must produce a greater curvature of the septum, and thus, since this is attached to the right ventricular lateral wall, traction on it will add to the bellows action The action of this or the other factors has not been quantitated That it can be a potent mechanism, however, is borne out by the observation that right ventricular ejection can be maintained when the free wall of the right ventricle has been almost completely destroyed by cautery in the dog or by coronary occlusion in man

The reduction in diameter and circumference necessary to eject the stroke volume is different in the two ventricles because of their shape and manner of contraction but they are small in both cases Under normal circumstances the ventricles function at relatively large diastolic and systolic dimensions since possibly half their contained volume is not ejected with each contraction If the left ventricle is regarded roughly as a cylinder which ejects approximately half its contained volume of 130 ml , then the diameter can decrease from 5 2 cm to 3 9 cm , and the circumference from 16 5 cm to 12 1 cm

The right ventricle has some semblance to a segment of a sphere, and a small shortening of its fibers will eject a large blood volume If its volume is also 130 ml , and half is ejected, the diameter will decrease from 6 3 cm to 5 1 cm ,

and the circumference from 19 8 cm to 16 0 cm The average shortening of the right and left ventricle walls might be estimated as 20% and 25% of the diastolic size The extent of myocardial shortening also varies greatly for the same volume of ejection depending on the size of the cavity or the fiber length before ejection takes place It takes a much smaller reduction in fiber length of a larger sphere or cylinder to eject the same volume For example, if in a heart enlarged by congestive failure of the circulation the right ventricle contains 500 ml blood, then ejection of 60 ml will decrease the diameter from 9 8 cm to 9 4 cm , or by 0 4 cm , and the circumference from 30 8 cm to 29 5 cm

It would be expected that the shortening of muscle fibers of the lateral wall of the right ventricle at different depths would be similar since the wall is so thin In the left ventricle, however, the circumferentially arranged deep constrictor fibers form a cuff of muscle making up most of the muscle wall which is so thick that the inner layers near the endocardium have a much smaller radius and circumference than the outer layers near the epicardium With the onset of contraction, the inner layers must shorten more than the outer layers in ejecting a particular volume Thus, presumably, no two layers of the myocardial fibers shorten to the same extent during ejection

The following ventricular volumes, somewhat analogous to lung ventilatory volumes, are identified (Fig 3 108) *stroke volume*, the quantity of blood ejected during systole, *residual volume*, the quantity of blood remaining in the heart after a maximal systolic ejection, *systolic reserve volume*, the quantity of blood remaining in the heart at the end of systole, minus the residual volume, *diastolic reserve volume*, is the maximal amount of blood which the heart can, under physiological conditions, receive and then eject, in addition to the normal diastolic inflow Thus, it is the potential volume increase which the heart can accommodate under physiological conditions

Rushmer et al , (1958, 1970) have shown in studies of ventricular dimensions (diameter) and stroke volume in dogs, that the left ventricle functions close to its maximal diameter while the animal is reclining at rest (Fig 3 109), i.e , little diastolic reserve volume is maintained Upon standing, ventricular dimensions and stroke volume diminish Now, with exercise, stroke volume can be increased by increasing diastolic distention (decreasing diastolic reserve) or increasing systolic ejection (decreasing systolic reserve) or both (Fig 3,109) See pages 3-44 and 3-91 for a discussion of the effects of dilatation (increasing diastolic distention) on ventricular contraction Large diasolic size favors ventricular contraction by

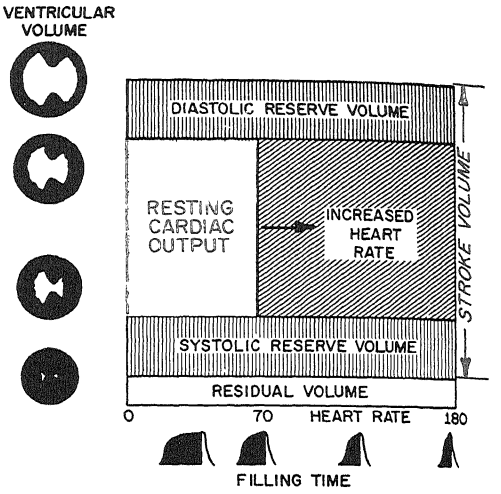

Fig 3 108 Ventricular volumes Resting cardiac output (about 5 liters/min) equals stroke volume (about 70 ml) times heart rate (about 72/min) Maximal cardiac output increase of about sixfold (total shaded area) can occur through elevation of heart rate and stroke volume Stroke volume increases by encroachment on systolic and diastolic reserve volumes (Redrawn from Rushmer 1970)

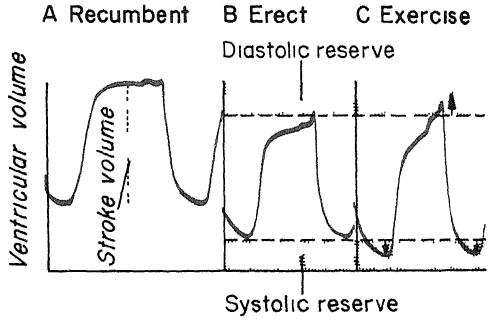

Fig 3 109 Alterations in ventricular volume with postural changes and exertion *A* in supine recumbency diastolic volume is near maximal and stroke volume large *B* upon assuming erect posture diastolic and stroke volumes decrease and the heart has diastolic and systolic reserve volumes *C* with bodily exercise stroke volume increases at the expense of these reserve volumes (Redrawn from Rushmer 1970)

) the Frank-Starling mechanism (pp 3-44, 3-19, and 3-91, 2) the larger volume ejected for i given amount of fiber shortening (see p 3-100), and 3) reduction of internal friction within the myocardium Opposing these favorable factors is the increase in wall tension required to eject blood at a given pressure (Laplace relation, see p 3-92) See page 3-129 for a discussion of cardiac reserve

PRESSURE AND VOLUME EVENTS OF A CARDIAC CYCLE

For describing the events of the cardiac cycle, terminology and symbols according to Wiggers (see Table 3 12) and the schema and time intervals (Fig 3 110) by Selkurt and Bullard (1966) are used

Sequence of Events The upper set of pressure pulse curves in Figure 3 110 are for the left heart and aorta and the lower set for the right heart and pulmonary artery These events are correlated with periods when semilunar and atrioventricular valves are opened and closed, with heart sounds, and with the electrocardiogram (*lower*, Fig 3 110) The phases of the cardiac cycle according to Wiggers are identified by Roman numerals

I Isovolumetric Contraction At the time of the peak of the R wave in the electrocardiogram, ventricular contraction begins The pressure curve starts to ascend and at the moment it exceeds the atrial pressure curve, the atrioventricular valves close The "C" wave in the atrial curves begins at this time, caused by bulging of the closed AV valves into the atria as ventricular pressure increases The "C" waves are variable and may be absent (dotted lines, Fig 3 110) Both atrioventricular and semilunar valves are now closed and the ventricles are contracting on the contained blood which is incompressible Therefore, the volume of the ventricles does not change and pressure increases rapidly This period terminates and the next period begins at the moment ventricular pressures exceed aortic or pulmonic pressures The semilunar valves open and the blood is accelerated into the great arteries

II Maximum Ejection This period begins with the opening of the semilunar valves Most of the blood ejected during systole flows during this period, as can be seen by the rapid descent of the left ventricular volume curve It lasts until the peak of the arterial pressure curve For about one-third of the period of

Table 3 12
Events of the cardiac cycle (Wiggers)

Phase	Interval	Events at Onset of Phase	Main Events during Phase	Events at Close of Phase
Isovolumetric contraction	I	Onset of ventricular contraction	Closure of atrioventricular valves, rapid rise of intraventricular pressure	Opening of semilunar valves
Maximum ejection	II	Opening of semilunar valves	Rapid outflow of blood from ventricles	Peak of intraventricular pressure
Reduced ejection	III	Peak of intraventricular pressure	Declining outflow of blood from ventricles	Onset of ventricular relaxation
Protodiastole	IV	Onset of ventricular relaxation	Rapid drop in intraventricular pressure	Closure of semilunar valves
Isovolumetric relaxation	V	Closure of semilunar valves	Continued ventricular relaxation with no volume change	Opening of atrioventricular valves
Rapid inflow	VI	Opening of atrioventricular valves	Rapid flow of blood from atria to ventricles	Slowing of inflow rate
Diastasis	VII	Slowing of inflow from atria to ventricles	Continued slower flow from atria to ventricles	Onset of atrial contraction
Atrial systole	VIII	Onset of atrial contraction	Increased flow from atria to ventricles	Termination of atrial, and onset of ventricular, contraction

From Dittmer and Grebe, 1963

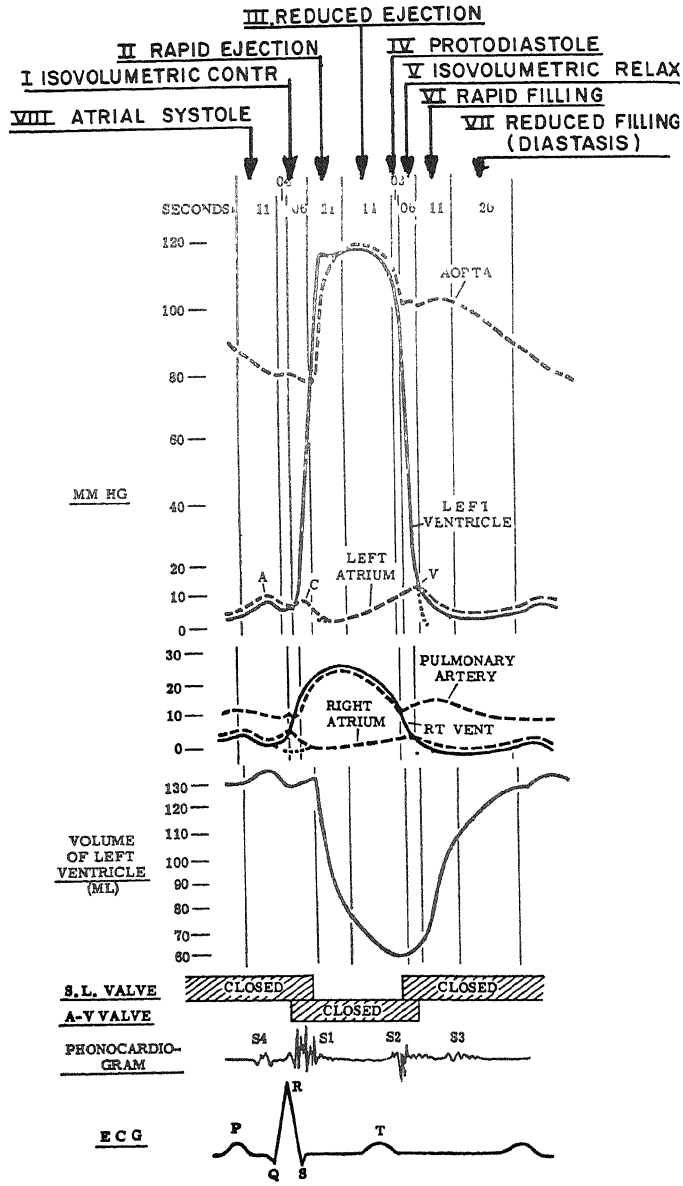

Fig 3 110 Events of the cardiac cycle *Upper* left heart *lower* right heart (Redrawn from Selkurt and Bullard 1966)

systole, aortic pressure is exceeded by left ventricular pressure at the time of greatest acceleration of aortic flow

III Reduced Ejection During rapid ejection, blood flow into the aorta (and pulmonary artery) has exceeded runoff into the peripheral arteries and pressure continues to rise As runoff reaches equilibrium with flow into the great arteries, the pressure curve reaches a maximum This is the beginning of the reduced ejection period Runoff now exceeds cardiac output and the pressures begin to fall The pressure in the left ventricle falls slightly below that in the root of the aorta, although forward flow continues as indicated by progressive decrease in ventricular volume

IV Protodiastole This marks the beginning of ventricular relaxation and is a point on the

ventricular pressure curves which is often difficult to identify The pressures in the ventricles continue to fall below those in the aorta and pulmonary artery A brief retrograde flow occurs, closing the semilunar valves This marks the end of protodiastole and the beginning of the next phase

V Isovolumetric Relaxation With closure of the semilunar valves, the incisura in the arterial pressure curves is seen, marking the beginning of this phase Once again, the ventricles are closed chambers and myocardial relaxation continues, causing a steep fall in intraventricular pressures but little alteration in ventricular volume When the intraventricular pressures fall below those in the atria, the atrioventricular valves open, marking the end of this period During this phase, the ventricles have just completed ejection of perhaps 50 to 65% of their diastolic volumes, and thus remain partially filled with blood

VI Rapid Filling Beginning with the opening of the atrioventricular valves, ventricular volumes increase rapidly as blood which has accumulated in the atria under increasing pressure flows quickly into the relaxed ventricles During this phase the ventricular volume curve ascends steeply at first and then begins to level off The end of this phase is not clearcut as it merges with the next phase At the transition between this and the following phase the usually inaudible third heart sound may be recorded in the phonocardiogram

VII Reduced Filling (Diastasis) This is a period of slower filling during which blood continues to flow into both atria and ventricles as into a common chamber. It is terminated by onset of atrial systole

VIII Atrial Systole This period is marked by the onset of the atrial contraction ("A") wave which is reflected in the ventricle since the two chambers are now continuous This atrial systolic pressure wave peaks and begins to decline, finally being interrupted by the onset of ventricular isovolumetric contraction, completing the cardiac cycle

During the preceding ventricular contraction, the atrial pressure undergoes a temporary abrupt decline as a result of an artefact imposed by cardiac movement However, as blood pours into the cavity of the left atrium from the veins, the atrial pressure rises continuously to the end of the isometric relaxation period forming the "V" wave This atrial blood which has accumulated during the previous ventricular contraction is now transferred to the ventricle Ventricular filling begins at the time the intraventricular pressure drops below the intra-atrial pressure and the AV valves reopen

The period of rapid ventricular filling, i e , the early diastolic inflow period is marked by a continuous decline in ventricular pressure and in the "V" wave of the atrial pressure curve (the so-called "Y" descent) Inflow into a ventricular cavity is regulated by mechanisms operating in both its systole and diastole Since no blood enters the ventricles until it has passed through the atria, it is important to know their means of filling It is not possible to measure flow into the atria, but since the right atrium is continuous with the venae cavae without intervening valves, vena caval flow should indicate right atrial flow Caval flow into the right atrium shows three phases It is reduced nearly to zero during atrial contraction During ventricular diastole inflow is considerable, but the volume of atrial inflow is greater during ventricular systole when the AV valves are closed and no blood can enter the ventricle, than during ventricular diastole when AV valves are open and atria and ventricles form a common cavity Atrial inflow during ventricular contraction is particularly effective in the presence of tachycardia in which the time available for diastolic inflow is shortened The piston-like downward movement of the atrioventricular junction during ventricular systole enlarges the atria and vena cava and attracts blood to them. The filling of the atria during ventricular systole depends on the quantity and pressure of blood available in the venous reservoir and the vigor with which ventricular systole moves the AV junction. Thus, ventricular myocardial contraction is a very important means of actively filling the atria during systole and, therefore, in determining the extent of ventricular filling during the rapid filling phase

Finally, attention is directed to the dotted and abruptly dipping line which represents an alternate decline of ventricular pressure, and at times indicates a negative intraventricular pressure has developed (*vis a fronte*, p 3-200) Such a dip in the pressure curve of ventricular relaxation, although recorded for many years and considered an artifact, is now given more credence since *1)* it can be recorded with a micromanometer (which is supposedly immune to

artifacts), 2) recent experimental evidence indicates that the relaxing ventricle can develop suction under certain artificial experimental conditions For example, in the beating mammalian heart, a moderate volume of fluid can be drawn into the ventricular cavity in the absence of a positive ventricular filling pressure and in the presence of an empty ventricle or one with some systolic residual volume The time available during which suction could act is approximately 0 1 sec , i e , the earlier part of the rapid inflow period The quantitative contribution of the ventricle to ventricular filling under normal conditions is still unknown and, hence, the physiological significance of diastolic suction for the return of blood to the heart cannot be evaluated Wiggers, in summarizing the problem, states, "crucial evidence is still required that the small remnant of elastic recoil still operative at the end of relaxation can create sufficient suction to be of significance in filling the normally beating heart Dynamically it must be shown that the concordant declines of atrial and ventricular pressures are due to a more rapid rate of ventricular relaxation than of filling from the atrium " However, there are significant restoring forces during the early part of diastole which probably aid diastolic filling (Tyberg et al , 1970)

Atrial Contraction. The dynamic importance of atrial contraction on ventricular filling has been much debated The older view that the chief function of the atria is filling the ventricles is not now acceptable since it is known that such filling occurs chiefly during the earlier portion of diastole when the difference between atrial and ventricular pressure is maximal However, in hearts slowed by vagal stimulation to separate atrial and ventricular contraction and in hearts with 2 1 or more block, it can be demonstrated that atrial contraction has a small but significant effect on the ventricular volume curve obtained with a cardiometer In open-chest dogs with surgically induced complete atrio-ventricular block and a fixed, slow ventricular rate, there is an increase in left ventricular end-diastolic pressure, stroke volume, stroke work and aortic systolic pressure when atrial systole precedes ventricular systole by an interval of 0 085 to 0 125 seconds, indicating enhanced ventricular filling through atrial contraction (see also p 3-25) Finally, atrial contraction and relaxation are instrumental in bringing about closure of the atrioventricular valves (see below)

Pressure Pulse Values. Aortic pressure throughout the cardiac cycle is uniformly higher than in the pulmonary artery The peak aortic pressure during systole of 120 mm Hg is approximately five times that of 25 mm Hg in the pulmonary artery, the relative end-diastolic pressures are 80 mm Hg versus 10 mm Hg, the relative pulse pressures are 40 mm Hg vs 15 mm Hg The diastolic pressure in both cavities is quite low with a small pressure gradient from the left ventricle (0 to 5 mm Hg mean diastolic, 5 to 12 mm Hg end-diastolic) to the right ventricle (0 to 3 mm Hg mean diastolic, 0 to 5 mm Hg end-diastolic) The atrial pressure values are only a few mm Hg and are uniformly somewhat higher in the left atrial (mean 2 to 12 mm Hg) than in the right atrial (mean 0 to 5 mm Hg) curve

Asynchronisms of Pressure Pulses While dynamic events on the two sides of the heart are generally similar, there is considerable asynchronism and some difference in duration of parts of the cardiac cycle The onset of contraction of the right atrium precedes that of the left atrium while the onset of contraction of the right ventricle follows that of the left ventricle Right ventricular ejection begins earlier and is completed later than left ventricular ejection (Fig 3 111)

Electrocardiogram vs. Onset of Pressure Events In man the interval between the onset of electrical and mechanical activity in the left atrium (rise of P wave vs onset of rise of atrial A wave) is of the order of 0 08 sec , for the right atrium, the interval approximates 0 06 sec For the left ventricle, the interval between the onset of ventricular depolarization (Q wave)

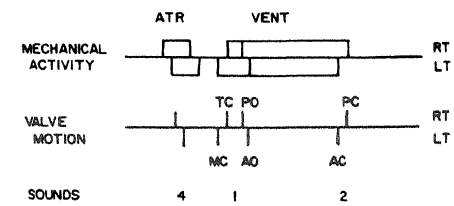

Fig 3 111 Sequence of valve motion as related to mechanical activity during the cardiac cycle Right heart events above the line left heart events below the line ATR atrium VENT, ventricle RT, right LT left MC mitral closure TC tricuspid closure PO pulmonic opening AO aortic opening AC, aortic closure PC pulmonic closure 4 1 2, fourth, first second heart sounds Duration of isometric contraction for each ventricle is indicated in each ventricular rectangle by a verticle line (Redrawn from Lewis, 1962)

and onset of left ventricular contraction (onset of pressure rise) approximates 0 04 sec , for the right ventricle, the interval is about 0 05 sec The T wave has a variable relation to the end of systole but terminates usually before the incisura of the aortic pressure curve

Aortic Flow. The relationship between left ventricular pressure pulse and aortic flow in a dog is seen in Figure 3 112 The flow rate at the root of the aorta increases rapidly during the phase of rapid ejection when most of the systolic output of the heart is expelled, then flow falls off during the phase of reduced ejection and reverses at the time of protodiastole During diastole the aortic flow remains at about zero However, forward flow continues in the more peripheral arteries under the impetus of its initial momentum and the elastic recoil of the larger arteries

The Ventricular Pressure-Volume Diagram (Work Diagram). For a complete representation of mechanical activity of the heart, the coordinates of pressure, volume, and the time must be employed In Figure 3 110, pressure and volume curves are plotted separately against time The relationships between ventricular pressure and volume changes during the cardiac cycle can be displayed as functions

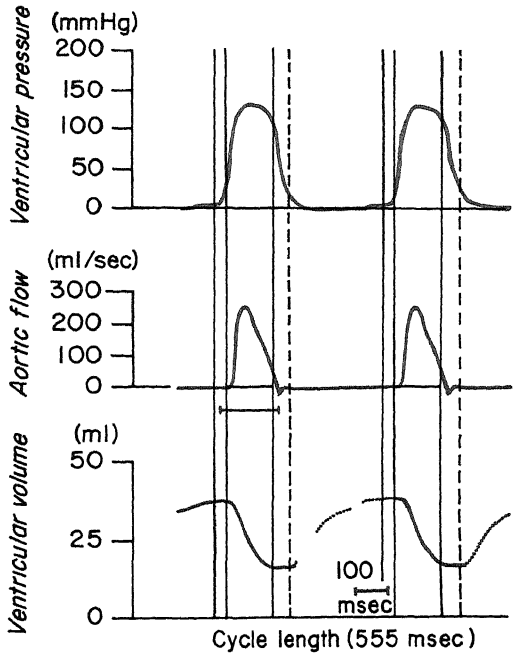

Fig 3 112 Aortic flow in relationship to ventricular pressure and volume changes during the cardiac cycle (23-kg dog) (Redrawn from Jacob 1968)

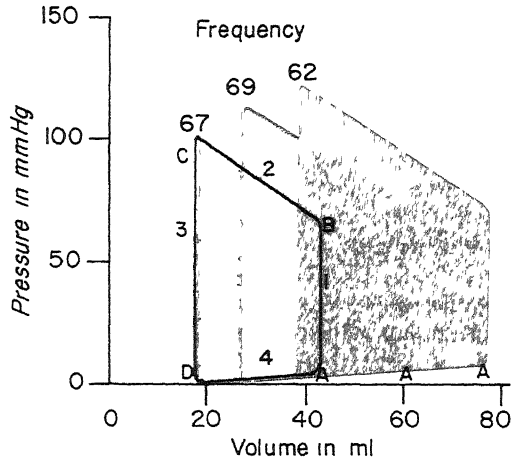

Fig 3 113 Ventricular pressure volume diagrams Data from a 20-kg dog The letters and numbers identify the following phases of the cardiac cycle *A* onset of ventricular contraction (beginning of isovolumetric contraction) level of end diastolic pressure and volume *B* onset of ventricular ejection (end of isovolumetric contraction) *C* end of ventricular ejection (onset of isovolumetric relaxation) level of end-systolic pressure and volume *D* end of isovolumetric relaxation (beginning of diastolic period) *1* isovolumetric contraction period *2* ventricular ejection (for purposes of simplification the pressure during ejection is depicted as continuously increasing) *3* isovolumetric relaxation period *4* diastole The effect of increasing end-diastolic pressure and volume (*A*) is illustrated Note the increase in area of the work diagram as the levels of end-diastolic pressure and volume (*A*) increase (Redrawn from Bauereisen 1970)

of one another In Figure 3 113, pressure and volume values during the cardiac cycle are plotted at three different rates of cardiac filling The area bounded by the sides of each quadrangle represents work (pressure × volume) The effect of increasing end-diastolic pressure and volume on stroke work is indicated (Frank-Starling mechanism)

The Pressure-Volume-Time Diagram. The relations between pressure and volume changes with time during a ventricular cycle are diagrammed three-dimensionally in Figure 3 114 The temporal changes in pressure and volume are diagrammed on the left and base planes, respectively, and the work diagram on the right plane The three dimensional curve in the center represents power (rate of work or work per unit time), since the time course of the work diagram can be determined

MOVEMENTS OF HEART VALVES

Atrioventricular Valves (Tricuspid and Mitral). The valve leaflets or cusps, three in

number on the right and two on the left side, are attached by their bases to the fibrous rings surrounding the atrioventricular openings Their free margins are connected through delicate tendons (chordae tendineae) to the papillary muscles which prevent inversion of the valves into the atrium during ventricular systole The chordae tendineae are tightened at the commencement of systole by the contraction of the papillary muscles The leaflets are composed mainly of a double layer of the endothelial lining of the heart, strengthened by fibers of connective tissue Their attached bases are thicker and contain more connective tissue, small blood vessels and delicate strands of smooth muscle The latter, however, play no part in valve closure which is effected, as mentioned above, in a passive manner

The Mechanism of Valve Closure According to traditional concept, an advancing gush of blood thrusts the AV valves widely open during early ventricular diastole During atrial systole the leaflets do not lie back against the ventricular wall but occupy a midposition as a result of two opposing currents. The inflowing blood pressing upon their atrial surfaces keeps them open, while eddies reflected in the reverse direction from the ventricular walls strike their ventricular surfaces and tend to close them Thus, they float in a position of delicate balance When, as a result of the fall in intra-atrial

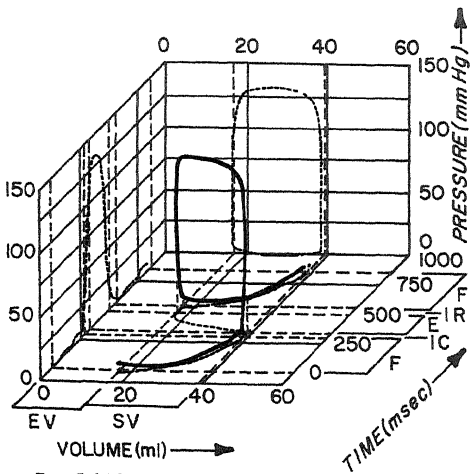

Fig 3 114 Pressure-volume-time diagram of the left ventricle Base volume changes with time Left vertical plane pressure changes with time Posterior vertical plane pressure volume diagram (Redrawn from Jacob 1968)

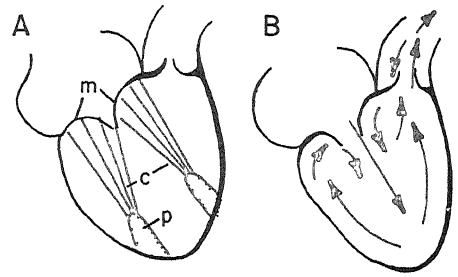

Fig 3 115 Two diagrams showing mechanisms concerned in valve closure *A* showing relations of papillary muscles and chordae tendineae to valve flaps *B* partial closure due to eddy formation (After Wiggers 1954)

pressure at the end of atrial systole, the incoming jet is diminished in force and finally ceases, the back eddies persisting for a brief space and being unopposed, approximate the valves or bring them gently into apposition (Fig 3 115) The importance of atrial relaxation in closing the valves has been shown in open-chest dogs with surgically induced atrio-ventricular block, where a negative atrioventricular pressure difference was demonstrated during atrial diastole The fact that the first heart sound has been found to be significantly delayed in the absence of atrial systole supports this view that normally the atrioventricular valves are closed or nearly so, before ventricular systole They are not, however, firmly closed This is effected by the rise in pressure in the ventricle when it contracts Dean (1916) has shown by attaching a hair to the septal leaf of the valve and recording its movements, that if ventricular systole does not follow almost instantly upon the cessation of the flow of blood from the atrium, the valves start to reopen In instances, therefore, in which ventricular systole is delayed, that is, when the A-V interval is prolonged, the reopening of the valves proceeds for an appreciable time Then, when ventricular contraction occurs, a small amount of blood regurgitates into the atrium before the valves are swung closed by the rising intraventricular pressure The backward flow of blood through the orifice may then give rise to a murmur just preceding the first heart sound (presystolic murmur)

These concepts have been derived mainly from observations and direct photography of valve action in isolated hearts and from correlation of heart sound with mechanical and electrical events of the cardiac cycle However, cinefluorographic observations of the motions of

the mitral valve cusps by means of attached radiopaque markers in intact anesthetized dogs, showed the edges of the valve cusps to be only slightly separated during ventricular filling Since in both instances, it is not possible to rule out certain experimental artifacts, no choice can be made at present between the concept of wide valve excursion in isolated hearts and restricted valve movements in intact animals

The Semilunar Valves. The dynamics of aortic and pulmonary closure are essentially the same in principle as those described for the AV valves The valves and sinuses of Valsalva form three small pockets open toward the arterial lumen Back eddies which are set up during the ejection phase of systole prevent the contact of the valves with the arterial wall When ejection ceases, the centripetal currents carry the valves into apposition and firm closure is effected by the higher pressure at this time upon their arterial surfaces

HEART SOUNDS

The sounds produced by the heart during a cardiac cycle consist of waves of greatly varying frequency Because of the intervening tissue, the intensity of the sounds is generally decreased and some components are accentuated and others depressed

Graphic registration of the heart sounds has been used to give a permanent record for study and to permit precise relations to be established between them and the events of the cardiac cycle, as recorded by other graphic methods such as the electrocardiogram and intracardiac and intravascular pressure curves

For obvious reasons, sounds picked up from the surface of the thorax are not a true representation of the actual vibrations of the cardiac valves and walls Thus, attempts have been made to move the pick-up device closer to the source of sound by placing microphones in the esophagus, by suturing microphones to the myocardium in experimental animals, by applying suction microphones directly to the surface of the human heart, and finally, by introducing the microphone into the cardiac chambers themselves The latter technique aids in locating the site of production of normal heart sounds and serves as a valuable diagnostic tool in disease states in locating the origin of abnormal sounds and murmurs However, use of data obtained thereby must be tempered by knowledge of the fact the catheter mounted device may itself, through the motion imparted to it in the cardiac cavities, produce sounds which are recorded as naturally occurring

Characteristics of Heart Sounds. Two distinct sounds are heard by direct auscultation and occasionally a third is also audible during a cardiac cycle A fourth sound is revealed by graphic methods The first two sounds occur mainly during ventricular systole, the other two sounds take place during ventricular diastole (Fig 3 110)

Origin of Heart Sounds and Time Relations These vibrations arising in the heart and great vessels are fundamentally the result of sudden displacement of blood (acceleration) or abrupt stoppage of blood (deceleration), and turbulence

The temporal relations of human heart sounds to central hemodynamic events are illustrated schematically in Figure 3 110 The large vibrations of the first sound begin with the rapid rise in intraventricular tension and by the beginning of ejection they have already reached a maximum The beginning of the second sound coincides with the trough of the incisura of the aortic pressure The third sound occurs near the end of the rapid inflow phase of diastole of the ventricles The fourth sound begins near the middle of the atrial pressure wave and extends to the isometric phase of ventricular contraction

First Heart Sound The first sound is of relatively long duration, soft in quality and low in pitch The second sound is shorter, sharper and of higher pitch These characteristics can be imitated vocally by the syllables "lub" and "dup" separated by a brief pause The two heart sounds mark the beginning and end of ventricular systole and the determination of the interval between their commencements (as determined by the phonocardiogram) is a reliable method for arriving at the length of ventricular systole in man although intracardiac phonocardiographic techniques indicate a time lag of the order of 0 02 seconds between the closure of the atrio-ventricular valves and the beginning of the first heart sound (see below) The pause between the end of the second sound and the beginning of the first coincides with ventricular diastole

The *First Sound* is heard most clearly and at maximum intensity over the fifth left inter-

costal space, i e , with an area centered over the "apex beat " Here the mitral element of the sound predominates Any abnormal sound produced at the tricuspid valve is detected by listening over the lower end of the sternum

Four components of the first heart sound have been identified The first component is associated with the earliest phase of ventricular contraction which shifts blood toward the atrioventricular valves, approximating them It precedes elevation of intraventricular pressure The second component begins with closure and tension of the atrioventricular valves as intraventricular pressure begins to rise The third component begins as intraventricular pressure starts to exceed arterial pressure with the onset of ejection It is associated with opening of the semilunar valves and abrupt distention of the arterial trunks The fourth component probably results from flow turbulence in the arterial trunks during early ejection

The record of the first sound is composed chiefly of a series of from 9 to 13 vibrations, and has a duration of from 0 9 to 0 16 sec The vibrations are in general irregular, which places the sounds in the category of noises rather than of musical tones The frequency is low varying from 33 to 110/sec

The Second Sound results from the vibrations set up in the blood column and arterial walls as the aortic and pulmonary valves are placed under tension following their closure The duration of the second sound is about 0 10 sec It commences about 0 09 sec after the summit of the T wave of the electrocardiogram The average frequency is about 50 per sec In the pulmonary area (along the left upper border of the sternum) two components of the second sound can normally be heard ("split second sound") Phonocardiographic records show that the first of the two components is synchronous with the dicrotic notch of the carotid arterial pressure pulse and therefore represents aortic valve closure, the second component is caused by closure of the pulmonary valve The relative delay of pulmonary vs aortic valve closure is enhanced during inspiration when the increased venous return to the right heart prolongs right ventricular ejection time, the situation is reversed during subsequent expiration, when the blood ejected by the right ventricle reaches the left side of the heart and causes prolongation of left ventricular ejection, moving aortic valve closure closer to pulmonary valve closure Thus the splitting of the second heart sound widens during inspiration (average 0 05 sec) and narrows or even disappears during expiration (average 0 02 sec) The relationships of valvular opening and closure, mechanical activity of the atria and ventricles and heart sounds are shown in Figure 3 111

The Third Heart Sound Sometimes a faint third sound is heart in normal hearts which follows the second sound by about 0 08 sec and lasts for about 0 04 sec It is heard at the apex and is commonly found in young adults It may be made to appear or is intensified by procedures which increase the venous flow into the atria, e g , exercise, recumbent position, etc Several explanations have since been given to account for it By intracardiac phonocardiography it was demonstrated that the sound coincides with rapid, early ventricular filling and is recordable from the ventricular cavity and the ventricular surface but not from the atrium It is suggested that the sound is produced by the vibrations of the ventricular wall as blood rushes into the ventricle

The Fourth Heart Sound, as a rule, is inaudible in normal subjects Often, however, the phonocardiogram records a few small pre-systolic vibrations, usually consisting of two components The first of these coincides with the atrial "a" wave and, by intracardiac phonocardiographic techniques, it can be recorded from within the atria, indicating that it is caused by atrial contraction The second component follows the peak of atrial contraction and can be recorded more often from the ventricles than from the atria, suggesting that it is due to the impact of blood, expelled from the atria, against the ventricular wall There is also evidence, however, from studies on horses (Patterson et al, 1965) that this late component results from transient reversal of the pressure gradient between atria and ventricles at the end of atrial systole, resulting in presystolic tensing and perhaps closure of the atrioventricular valves

Variations in the Intensity of the Heart Sounds. It is the general belief that the first sound varies in intensity with the force of ventricular systole and the loudness of the second sound with the height of the arterial blood pressure The intensity of the first sound is directly related to the rate of the pressure rise within the ventricle during the isometric period The intensity of this sound is not dependent upon

the volume of the systolic discharge but rather upon the diastolic pressures in the pulmonary and systemic circuits. Wiggers found that when the heart was slowed and the systolic discharge consequently increased but the diastolic pressure lowered, the intensity of the first heart sound was reduced while acceleration of the heart (reduced systolic discharge with raised diastolic pressure) increased its intensity. These experiments together with the observations that the first heart sound is believed to be largely on a valvular basis and is greatly influenced by the length of the P-R interval, strongly suggest that the intensity of the sound is ultimately conditioned by the position of the AV valves at the onset of ventricular systole.

The intensity of the second sound, aortic or pulmonary, is increased by an elevation in the systemic or pulmonary pressures, respectively. Among the cardiovascular conditions associated with intensification of the second sound are, mitral stenosis and failure of the left ventricle which raise the pulmonary arterial pressure, and arterial hypertension which raises the aortic pressure.

5 / REGULATION OF THE HEART

Regulation of cardiac output is effected through mechanisms which operate within the myocardium itself (*intrinsic* or *autoregulation*) and factors outside the heart (*extrinsic regulation*) These mechanisms adjust cardiac frequency and stroke volume, thus altering cardiac output The functional properties of myocardial fibers affected include force, velocity, duration, and extent of contraction Conductivity is adjusted to maintain proper timing of atrial and ventricular systole and the temporal sequence of ventricular activation Finally, the output of the left and right hearts is coordinated so that they remain equal

Intrinsic Regulation of Ventricular Function

Control mechanisms within the myocardium itself make it possible for isolated myocardial preparations to adapt to changes in work load In dogs with denervated hearts, cardiac output adjusts appropriately during exercise and rest The mechanisms responsible reside within the heart and thus are called *intrinsic* The best known such adaptive response is that to changes in resting myocardial fiber length, the Frank-Starling mechanism Since this involves a change in myocardial fiber length, it has been termed *heterometric autoregulation* The term *homeometric autoregulation* is used to designate other intrinsic adaptive mechanisms which do not involve myocardial fiber length

HETEROMETRIC AUTOREGULATION

As described for isolated papillary muscle (p 3-110 et seq) and the entire isolated heart (p 3-119 et seq), increasing fiber length or diastolic volume of the heart, within physiological limits, increases contractile force and ventricular stroke work Thus, the denervated heart can respond appropriately to alterations in filling pressure, duration of diastole (filling time), and its own distensibility

HOMEOMETRIC AUTOREGULATION

Myocardial tension, frequency of contraction, and temperature influence contractile strength for any given fiber length

Myocardial Tension. The isolated heart may maintain its increase in stroke volume in response to an increase in venous return even after its diastolic volume has returned to the control level Similarly, if the ejection resistance (afterload) is increased in such a preparation, the stroke volume at first decreases, but can return to control values Then the same stroke volume is maintained against an increased aortic pressure This response, which is not dependent on changes in fiber length, is sometimes called the Anrep phenomenon Anrep (1912) first demonstrated that when aortic resistance was elevated in the heart-lung preparation (see p 3-121, Fig 3 120), ventricular volume first increased, then returned to its control value, presumably maintaining comparable stroke volume against elevated pressure Increased myocardial wall tension triggers some unknown mechanism which can elevate contractile strength Possibly, the initial stretch alters the viscous properties of the series and parallel elastic elements of the myocardium, allowing alterations in the degree of contractile filament overlap (Braunwald et al , 1968) Local release of norepinephrine by the increased stretch has also been suggested as a possible factor, and in conscious dogs infusion of isoproterenol (a β-adrenergic receptor stimulant) increases the positive inotropic response of the left ventricle (Bugge-Asperheim and Kiil, 1969)

Rate and Rhythm Effects. The strength of myocardial contraction is markedly influenced by the time interval between beats The earliest demonstration of this effect was that of Bowditch (1871), who described the staircase (Treppe) phenomenon in the frog ventricle, after a period of rest, subsequent contractions increase stepwise in strength until a plateau is reached

In mammalian ventricular muscle a premature contraction is weaker than the preceding beats Then, for several regular beats following the premature beat, the contractions are increased in strength This potentiation cumulates if premature contractions are continually repeated This phenomenon has been called *postextrasystolic potentiation* or *premature activation potentiation* (*prematurity potentiation*) The latter terms are preferable In ventricular muscle of most mammals, rate of tension development, peak tension developed, and maximum shortening increase with frequency over the physiological range This is termed *frequency potentiation* Frequency potentiation requires many beats to reach a steady state while prematurity potentiation is almost complete with the first potentiated contraction

Details on the influence of the time interval between beats on papillary muscle contraction are illustrated in Figure 3 116 According to the analysis of Blinks and Koch-Weser (1961), two interval-dependent processes influence myocardial contractility in opposite directions

Negative inotropic effect of activation (*NIEA*) is a temporary effect tending to decrease the strength of contraction in subsequent beats Each beat has a relatively large NIEA which disappears rapidly within a few seconds after contraction ceases

Positive inotropic effect of activation (*PIEA*) is a temporary effect tending to increase the strength of contraction in subsequent beats Each beat has a smaller PIEA than NIEA and the effect disappears slowly with a half time of decay to the order of 0 5 to 1 0 min

Both NIEA and PIEA are cumulative The strength of a given contraction is that of the rested-state contraction plus cumulated PIEA, minus cumulated NIEA Under steady-state conditions at regular frequency the PIEA and NIEA produced by each beat decay during each interval between beats Each beat produces more NIEA than PIEA, but the NIEA decays much more rapidly Premature beats occur in the presence of more of both PIEA and NIEA than regular beats, but NIEA predominates, causing premature beats to be weaker than regular beats The longer lasting PIEA is predominant at the end of the longer interval between regular beats

In Figure 3 116, various effects of interval changes on tension development of a mammalian papillary muscle are shown In record A, the points are steady-state tensions developed at various frequencies (interval between contractions of 0 2 to 300 sec) This illustrates frequency potentiation In B, prematurity potentiation is illustrated The contractions following the premature contractions are stronger for several beats owing to PIEA, which finally decays and the contraction returns to control levels In C, shortening of the interval from 20 to 0 63 sec produces initially potentiation due to prematurity At first, this is followed by a progressive decline in contractile force for a few beats, caused by NIEA Then *Treppe* (staircase phenomenon) follows owing to accumulation of the longer lasting PIEA When the frequency of contraction is again slowed, the time course of PIEA decay can be determined (C)

The effect of PIEA accumulation can be produced by so-called *paired pacing*, in which the heart is driven by paired pulses (Kelly, 1969, Cranefield, 1965) The time interval between paired stimuli is short so that the second stim-

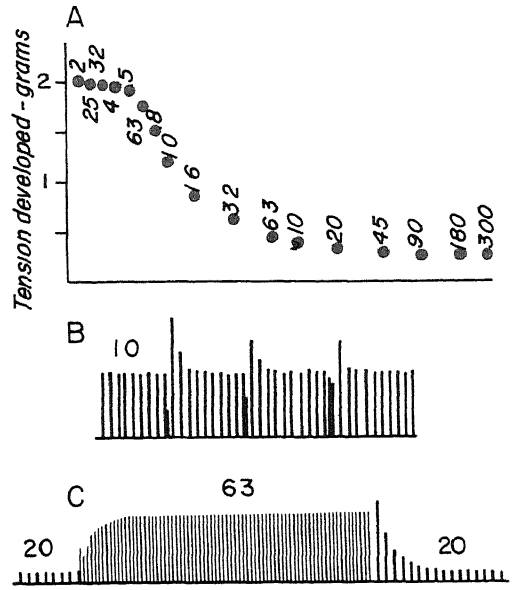

Fig 3 116 Tension responses in an isolated papillarly muscle as the interval between contractions is varied *A* graph of the steady-state tensions developed at the between contraction time intervals (seconds) indicated above each point *B* the influence of premature contractions in a preparation stimulated at 1 0-sec intervals *C* the effects of changing the interval between contractions from 20 sec to 0 63 sec (Redrawn from Koch-Weser and Blinks 1963)

ulus of each pair occurs just after the absolute refractory period following the first induced contraction The second stimulus produces negligible mechanical effect, but the following beat is potentiated (PIEA) When the premature activations are continually repeated, PIEA cumulates and cardiac action improves even in the presence of congestive heart failure The use of paired pacing in cardiac patients with failure, while effective, has not produced impressive clinical results

The mechanisms accounting for these inotropic effects are not known There is increasing evidence that PIEA of frequency potentiation is caused by increasing Ca^{++} influx and greater availability of Ca^{++} at contractile sites The NIEA seen in the premature beat may be caused by changes associated with the relaxation process and membrane repolarization

The inotropic effects of activation described in the foregoing are characteristic of the ventricle of most mammalian species The interval-strength relations are very different in most types of atrial muscle and in ventricular muscle of various species

Temperature. In isolated preparations of mammalian heart, hypothermia augments contractile strength In contrast, moderate hypothermia (body temperature 25° to 30° C) and pyrexia (body temperature 41° to 43° C) decreased ventricular contractile capacity in intact dogs (Goodyer, 1965) The direct stimulant effect of hypothermia observed in isolated preparations is replaced by a depressant effect in intact hearts A possible explanation for this is that cooling depresses cardiac sympathetic tone in the intact heart, since adrenergic blocking agents largely prevent this effect Pyrexia, on the other hand, enhances ventricular contractile capacity even after autonomic blockade The thermal limits of the human and dog heart are between 26 ° and 44° C, near these limits myocardial contractility and conduction are depressed

Extrinsic Regulation

NERVOUS CONTROL OF THE HEART

The Heart Rate. The average rate in adult man is around 70/min , but there is a rather wide variation between individuals, a rate considerably below or above this average being not uncommon Muscular training tends to reduce the cardiac rate, athletes not infrequently having a pulse rate between 50 and 60 On the other hand, a rate between 80 and 90 is sometimes seen in other healthy persons The rate diminishes progressively from birth, when it is around 130/min , to adolescence, but increases slightly again in old age Among physiological conditions which temporarily increase the heart rate are *muscular exercise, emotional excitement, and high environmental temperature* It also increases somewhat during *digestion* The rate is lowered during *sleep* (55 to 60) Among pathological conditions which cause an increase in cardiac rate are *hemorrhage, surgical shock, hyperthyroidism, fever* (an increase of 10 beats/1° F rise in temperature), and certain *cardiac arrhythmias,* e g , paroxysmal tachycardia, atrial fibrillation, etc

Tachycardia and *bradycardia* are general terms used to denote, respectively, any considerable increase in heart rate above, or reduction below the normal average

The heart, as we know, beats rhythmically after its complete separation from the central nervous system, but in the intact animal this automatic action is under the continuous influence of nervous impulses Where these were blocked experimentally with appropriate drugs in man, the heart beat intrinsically at a mean rate of 107 5/min (standard deviation 9 3) at rest (Jose and Taylor, 1969) The nervous mechanism comprises groups of nerve cells in the medulla—the *cardiac centers,* various *afferent pathways* along which impulses are conveyed to these centers from numerous regions of the body, and the *vagus* and *accelerator* or *augmentor* nerves which transmit impulses from the centers to the heart

Innervation of the Heart. The vagus nerves are cardio-inhibitory This action was discovered by the Weber brothers in 1845 They convey fibers, belonging to the parasympathetic division of the involuntary nervous system, from a center in the medulla (*cardio-inhibitor center*) to the special tissues of the heart The medullary center was located by Miller and Bowman (1915) in the dorsal nucleus of the vagus situated in the floor of the fourth ventricle. Weak electrical stimulation of this area produced slowing of the beat, and stronger currents, complete arrest of the heart The cardiac fibers of the vagus separate from the trunk of the nerve in the neck between the origins of its superior and inferior laryngeal branches Inter-

mingling with fibers of the accelerator nerves, they enter into the formation of the deep and superficial cardiac plexuses, whence they are continued to the atrial muscle Here they make connection with ganglion cells Postganglionic fibers pass to the specialized tissue of the sinoatrial and atrioventricular (AV) nodes where they are prolonged between the muscle fibers They form a rich plexus and are seen to end as ring-shaped or club-shaped structures (boutons") upon the fibers of the specialized tissue Many postganglionic fibers do not enter the nodal tissues but terminate in the atrial myocardium proper Some vagal fibers are distributed to the ventricular myocardium as well as to coronary arteries With vagal stimulation, negative inotropic effects on both atria and ventricles can be demonstrated In dogs, greater cardiac acceleration follows section of the right vagus than of the left, and stimulation of the right vagus has a greater tendency to cause sinus arrest than does left vagal stimulation Left vagal stimulation causes atrioventricular conduction block preferentially, however, with stimulation, left and right vagal effects on AV conduction time were about equal (Hamlin and Smith, 1968)

Accelerator or Augmentor Nerves The accelerator fibers were described by von Bezold in 1863 They belong to the thoracolumbar division of the involuntary nervous system and arise from cells situated in the lateral horns of the upper thoracic segments of the spinal cord These cells constitute a spinal cardio-accelerator center The preganglionic fibers enter the gangliated cord of the sympathetic to connect with cells in the *inferior*, *middle*, and *superior cervical ganglia* In many animals and also often in the human subject the inferior cervical and the first thoracic ganglia are fused into an irregularly shaped structure called the *stellate ganglion* from which accelerator fibers pass directly to the heart The heart also receives accelerator fibers *directly* from the sympathetic chain as far down as the fourth or fifth thoracic ganglion In order, therefore, to remove all accelerator influence from the heart it is necessary to interrupt these connections as well as to remove the stellate ganglia The axons of the cells of the cervical ganglia (postganglionic fibers) form the *inferior*, *middle*, and *superior cardiac nerves* (Fig 3 117) These fibers, especially those forming the nerves of the right side, terminate in the sinoatrial node Those of the left side are distributed mainly to AV node and bundle According to Nonidez (1943), sympathetic efferent fibers which reach the heart are contained mainly in the middle cardiac nerve The superior cardiac nerve is distributed to the large arteries at the base of the heart while the inferior cardiac nerve is mainly afferent The spinal accelerator center is subordinate to higher centers

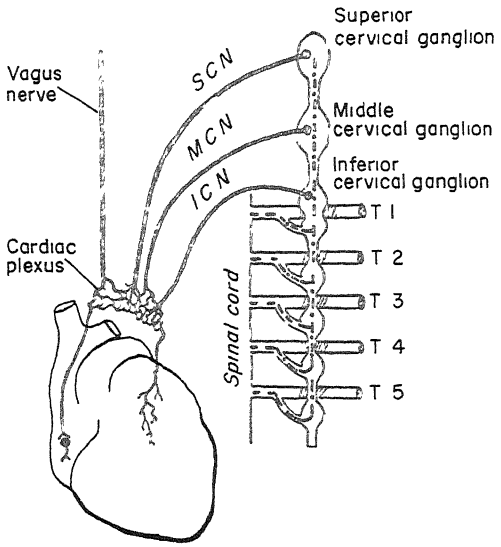

Fig 3 117 Diagram of the cardiac nerves Broken lines = preganglionic sympathetic fibers

In dogs, stimulation of the left stellate ganglion produces a greater effect on ventricular contractility (augmentor fibers) than on heart rate (accelerator fibers) while with stimulation of the right stellate ganglion these relative effects are reversed (Levy et al , 1966) Selective right and left sympathetic denervation studies also indicate that the SA node and atria are innervated primarily from right, and the ventricles from left sympathetic fibers (Priola, 1969)

Tonic Action of Nerves The functional properties of the heart affected by extrinsic nerve impulses, chemical mediators, hormones, drugs, etc , are contractile strength, rate, conductivity, and excitability Classically, the following qualitative terms have been applied to these effects *chronotropic action* (*chronotropy*), influence on heart rate, *inotropic action* (*inotropy*), influence on contractile strength, rate of

pressure development (dP/dt), ejection velocity, *dromotropic action* (*dromotropy*), influence on conduction velocity, and *bathmotropic action* (*bathmotropy*), influence on excitability or irritability (stimulation threshold)

An increase in action is termed *positive* and a decrease *negative* Thus, a *positive inotropic* effect is one which increases strength of contraction, a *negative chronotropic* effect is one which slows heart rate

The sympathetic fibers stimulate the heart and thus affect the aforementioned properties in a positive sense, the parasympathetic fibers inhibit the heart and affect these properties in a negative sense The chemical mediators of these autonomic effects, norepinephrine (sympathetic) and acetylcholine (parasympathetic), act on the specific adrenergic (sympathetic) and cholinergic (parasympathetic) receptor sites in effector cells Of the two types of adrenergic receptor sites recognized, α and β, the heart contains chiefly β-receptors Activation of the α-receptors causes vasoconstriction but few primary cardiac effects There is evidence for the presence of vasoconstrictor α-receptors in the coronary arteries (Feigl, 1968) and negative chronotropic α-receptors in the SA node (Priola, 1969, James et al, 1968) Activation of the β-receptors causes vasodilatation and positive chronotropic and inotropic cardiac effects (see also p 3–115)

The Tone of the Vagus At rest, the vagus nerves exert a continuous restraint upon the action of the heart Thus, the vagus, or rather the cardioinhibitory center, possesses tone, impulses passing from it in a continuous stream to the heart This effect can be readily demonstrated in animals by cutting or freezing the nerves The heart's action then immediately becomes greatly accelerated The increase in rate following the removal of the vagal influence also occurs though the stellate ganglia have been previously excised, the result therefore cannot be due to an increased action of the accelerator nerves The tonic action of the vagus nerves may be annulled by atropine, the heart rate then increasing to 150 or 180/min The difference between this rate and the normal resting rate of 70/min , therefore, represents the vagal effect which is being constantly exerted under ordinary circumstances Various conditions, physiological and pathological, alter the tone of the vagus center The tone is naturally higher in some species, e g , the horse, which is capable of feats of endurance, than in others, e g , the domestic rabbit It also shows individual variations in man, athletes usually showing a higher tone than those who lead sedentary lives

Vagal tone is apparently reflex in nature and dependent upon afferent impulses flowing to the vagus center especially along the sinus and aortic nerves Section of these nerves causes an increase in heart rate and little further acceleration occurs, as a rule when the vagi themselves are subsequently severed

Sympathetic Tone The existence of a tonic action of the sympathetic nerves has been postulated on the basis of experiments showing that excision of the stellate ganglia was followed by a slowing of the heart rate A criticism of these experiments is that they were not performed under truly basal conditions—i e , in conscious, fasting animals resting comfortably, with external visual and auditory stimuli reduced to a minimum and, in addition, apprehension of the animal eliminated through previous training to lie quietly during observation of the heart rate Yet only under these circumstances can the presence or absence of true accelerator tone (as opposed to accelerator nerve activity under various experimental conditions) be ascertained Murphy (1942) studied dogs in this manner The average "resting" heart rate before training was 90 to 112/min After several weeks of training, the resting rate slowed and stabilized at 47 to 57/min Cardiac sympathectomy was then performed Following recovery of the animals from this procedure the basal rate was 50 to 58—i e , not different from that observed prior to interruption of the accelerator fibers It was concluded that in the truly resting state the accelerator nerves are not in tonic activity, but that the accelerator mechanism is more or less constantly involved in adapting the heart rate to the changing bodily conditions

Cardiac Reflexes. A variety of reflexes affect both cardiac activity and vascular tone simultaneously They are therefore discussed together (see chap 8)

Under ordinary conditions, the activities of the cardio-inhibitory and cardio-accelerator centers which result in the continuous discharge of impulses along the corresponding cardiac nerves are in turn dependent to a very large extent, if not entirely, upon the reception of impulses by afferent paths In other words,

the maintenance of the tone of the centers, and so of the normal resting rate of the heart, and the alterations in rate which occur under various physiological conditions are in large measure either reflex in nature or due to impulses received from cerebral centers The impulses which stream into the nervous centers arise in all parts of the body, the heart itself included By these influences the tone of either center may be exalted or depressed, and corresponding changes produced in the cardiac rate If the cardiac vagus on one side be cut and its central portion (i e , the end leading to the brain) stimulated, a reflex through the cardioinhibitory center and the opposite vagus occurs which alters the cardiac rate The nature of the change in rate—whether acceleration or inhibition—which will result from stimulation of the central end of the vagus or of most other afferent nerves cannot always be foretold Reflex slowing of the pulse can usually be demonstrated in the human subject by pressure upon the eyeball at the outer canthus (oculo-cardiac reflex), carotid sinus, or by the stimulation of nasal branches of the fifth nerve Stimulation of afferent fibers in the respiratory passages as by the inhalation of irritating vapors, e g , anesthetics, is particularly likely to cause reflex inhibition of the heart Extrasystoles and bradycardia have been demonstrated electrocardiographically in man during abdominal operations, the irregularities being the consequence, apparently, of visceral stimulation Excitation of the central end of various peripheral nerves, e g , the sciatic, causes reflex changes in the pulse rate In these last instances acceleration is more readily obtained than inhibition The irradiation of impulses on to the cardiac centers from the cerebral centers, e g , from the motor area at the commencement of muscular exercise or from regions concerned with emotional manifestations, are held responsible for the changes in pulse rate which occurs under these conditions

The pulse rate is generally inversely related to the arterial blood pressure, a rise or fall in pressure causing, respectively, a decrease or increase in heart rate These adjustments are believed to be subserved by *1*) a reflex whose afferent limb is constituted of afferent vagal fibers (aortic nerve) ending in the aortic arch and heart, 2) a reflex in which the sinus nerve forms the afferent limb These mechanisms have been considered in chapter 8 Presumably such changes in heart rate are brought about not simply by an increase or a decrease in tone of one or the other cardiac centers, but by reciprocal variations in the tone of both For example, the slowing of the heart which results from a rise in arterial pressure is much less pronounced if impulses from the cardio-inhibitory center have been prevented from reaching the heart by section of the vagi After removal of the stellate ganglia on the other hand, the cardiac response to a rise in blood pressure is reduced to a lesser extent Other mechanisms are concerned, since a fall in blood pressure causes an increase in the rate of the heart even after it has been completely denervated

CHEMICAL CONTROL OF THE HEART

The *adrenal medullary catecholamines* exert positive inotropic chronotropic, dromotropic, and bathmotropic actions on the myocardium and induce glycogenolysis These are β-adrenergic receptor effects, it has been suggested that the β-receptor may be adenyl cyclase (p 3-114), since a close correlation has been found between the positive inotropic and chronotropic effects of catecholamines and their adenyl cyclase activating potency Adenyl cyclase catalyzes the conversion of adenosine triphosphate (ATP) to 3',5' cyclic adenosine monophosphate (3',5' AMP), this 3',5' cyclic AMP then promotes the conversion of inactive phosphorylase *b* to active phosphorylase *a* Enhanced glycogenolysis and increased energy supply in cardiac muscle is the result Epinephrine stimulates 3',5' cyclic AMP production and Ca^{++} mobilization in the heart Both are necessary for the increase in phosphorylase *a* activity and the resultant enhancement of glycogen breakdown it catalyzes Increased Ca^{++} permeability at the cell surface occurs and 3',5' cyclic AMP increases efficiency of Ca^{++} mobilization from stores in the sarcoplasmic reticulum Thus, the positive inotropic effect of catecholamines can be attributed to an increase in Ca^{++} availability Such a mechanism of activation may operate in other cells and it has been proposed that 3',5' cyclic AMP and Ca^{++} are two interrelated intracellular messengers which function in both muscle and secretory cells (Rasmussen, 1970) (see also p 3-34) The way in which this system could operate in heart muscle is illustrated in Figure 3 118

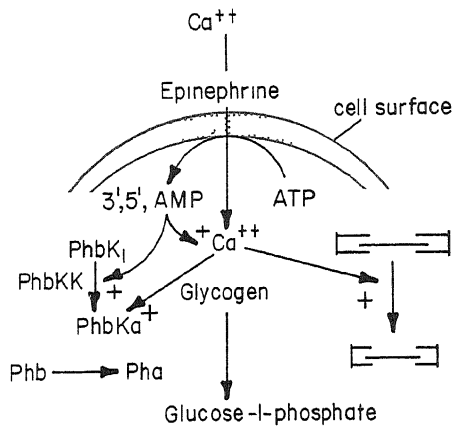

Fig 3 118 Hypothetical mechanism of epinephrine inotropic and glycogenolytic effects in heart muscle Epinephrine stimulates 3' 5' cyclic AMP production and calcium mobilization These sequentially activate phosphorylase *b* kinase kinase (PhbKK) and inactive phosphorylase *b* kinase (PhbKi) to active phosphorylase *b* kinase (PhbKa) Inactive phosphorylase *b* (Phb) is then converted to active phosphorylase *a* (Pha) and glycogenolysis is increased The positive inotropic effect results from greater availability of Ca^{++} made possible by increased Ca^{++} uptake by the cell This is induced by epinephrine and by more efficient Ca^{++} mobilization from the sarcoplasmic reticulum stimulated by cyclic AMP (Modified from Rasmussen 1970)

Glucagon causes a similar activation of glycogenolysis and a positive inotropic effect, possibly by a similar mechanism It does not act at a β receptor site, but appears to stimulate cardiac adenyl cyclase at a different receptor site This suggests there are at least two receptor sites affecting catalytic activity of the cyclase, one responding to adrenergic β stimulation and one to glucagon (Mayer, 1970)

Adrenal cortical hormones have positive inotropic effects as do *angiotensin* and *serotonin* *Thyroxin* possesses positive chronotropic actions, but whether or not it is directly inotropic is uncertain

Hypoxemia, *hypercapnia*, and *acidosis* of sufficient degree depress myocardial contractility

Cardiac Output and Cardiac Work

The most important external manifestation of the heart is its output of blood and the work it performs These measurements are obtained by the Fick procedure, by the dilution principle, and in some instances, by the foreign gas methods (pp 3-158 to 3-161)

DEFINITIONS AND GENERAL CONSIDERATIONS

The output of the heart per beat is spoken of as the *systolic discharge* or the *stroke volume*, and the output per minute as the *minute volume* The value of the latter is simply the product of the stroke volume and the pulse rate (pulse rate $\times$ stroke volume = minute volume), the minute volume divided by the pulse rate, therefore, gives the stroke volume The quantity of blood ejected by each beat of the left ventricle in the average healthy man during rest is from 70 to 80 ml An equal quantity is, of course, discharged at the same time by the right ventricle, making a total for the whole heart of from 140 to 160 ml The contents of the left ventricle are ejected against a much higher mean arterial pressure than the contents of the right, the mean pressure in the pulmonary artery being about one-sixth of that in the aorta The minute volume is expressed in terms of one ventricle The output of one ventricle obviously represents the quantity of blood flowing through the lungs, or through the systemic vessels, during the same period An adult of sedentary occupation pumps at least 5500 liters of blood through his body daily—from left to right ventricle through the systemic vessels, and from right to left through the lungs

The portion of the energy output of the left ventricle that appears as useful work can be roughly calculated from the product of mean aortic blood pressure and cardiac output The work done by the right ventricle can be similarly calculated, except that the mean pressure is that in the pulmonary artery The end diastolic pressure in the left or right ventricle should be subtracted from the measured aortic pressure or pulmonary arterial pressure since the end diastolic ventricular pressure does not have its origin from ventricular systole Preferably, the transmural pressure should be subtracted, but this is difficult to obtain in man Ordinarily the end diastolic pressure is small, approximating up to 5 mm Hg in the right ventricle and up to 10 mm Hg in the left Yet under some conditions of heavy ventricular loading such as an arteriovenous fistula, or congestive heart failure, the value may reach 30 to 40 mm Hg, and hence, the correction is important The simpler calculation also assumes that the velocity factor is but a very small part of the external work of the heart

Normally, this is of the order of 1 to 2% When cardiac output is quite large in the presence of a decreased systemic pressure, or especially if aortic or pulmonary stenosis occurs, the kinetic factor can be up to 50% of the cardiac work (see also pp 3-96 to 98)

To compare better the cardiac output and cardiac work in different individuals, the values are generally expressed in terms of surface area and are spoken of as flow or work indices Thus, the cardiac index (CI), stroke volume index (SVI), cardiac work index (CWI), and stroke work index (SWI) are obtained by dividing the cardiac output, stroke volume, cardiac work, and stroke work by the surface area of the body An average surface area is 1 7 m^2 Normal values for the right and left heart obtained in man during catheterization studies are in Table 3 13 The reason for relating cardiac output to body surface area in man is that, just as in the case of basal metabolic rate, the correlation with body size is better when based on body surface area than when based on body weight Actually, the basic determinants of cardiac output are the oxygen requirement of the tissues, the volume of oxygen carried per unit volume of blood, and the percentage extraction of oxygen from the blood in tissue capillaries (i e , the arteriovenous oxygen difference) The oxygen requirement depends on metabolic rate and blood oxygen content on the concentration of respiratory pigment (e g , hemoglobin) The arteriovenous oxygen difference (i e , percentage oxygen extraction by tissues) is governed by the blood-tissue oxygen gradient, the capillary surface area available for gaseous exchange, and the time the blood remains at these surfaces In mammalian species (mouse to elephant) "metabolic weight" is an exponential function of body weight (e g , $kg^{0.75}$) In larger mammals (dog to horse) cardiac output is linearly related to body weight, the output in liters per minute approximates 0 1 times the body weight in kilograms [more precisely cardiac output (liters/min) = (0 1017) × (body weight in $kg^{0.99}$)(Patterson et al , 1965b) However, if other species are considered (e g , fish and crustaceans), body weight and body surface area are no longer useful as a reference for comparison of oxygen requirements as related to circulatory flow rates of blood Much higher relative blood flow rates are required in those species which have blood with low oxygen carrying capacity (Dejours et

al , 1970) Thus, for comparative purposes, as between species, the relationship between circulatory requirements as reflected by cardiac output, must include consideration of arterial oxygen concentration Similarly, in man, if the oxygen carrying capacity of the blood is diminished (as with the low hemoglobin concentrations seen in anemia), cardiac output must increase to maintain optimal tissue oxygen supply for metabolic needs In man the ratio of cardiac output (Q) to oxygen consumption Vo_2 approximates (in absolute terms) 20 1 (e g , $\dot{Q}/Vo_2$ = 6000 ml /300 ml) If the oxygen carrying capacity is reduced, as in anemia, this ratio increases as blood flow increases to carry the required oxygen The general trend of change is similar to that observed in fish and crustacea, and further displays the importance of oxygen requirement as a basic determinant of circulatory volume flow

OUTPUT OF THE HEART NORMAL STANDARDS, PHYSIOLOGICAL VARIATIONS

The minute output of the heart under basal conditions[1] for the average size male adult is about 5 5 liters, and the CI is 3 2 liters The CI is slightly lower for the female and considerably higher for children Cardiac output can be quite variable in the same person from day to day unless extreme precautions are used to maintain the resting state

Conditions in Which Cardiac Output Is Not Changed. The cardiac output is apparently the same when a person is asleep as when he is awake and in the horizontal position It is unaffected by menstruation, by metabolic acidosis produced by the infusion of ammonium chloride or lactic acid, and by moderate variations in the external temperature, although it may be increased up to 30% at environmental temperatures above 30° C , or by low temperatures that are associated with shivering The native indigenous to high altitude undergoes considerable acclimatization by changes in his cardiovascular and respiratory systems, so that at altitudes of, at least, 15,000 ft , the cardiac output is normal as are his heart rate and systemic blood pressure and systemic arteriovenous O_2 However, the slightest exertion will increase his cardiac output which will be considerably higher in the sitting rather than in the reclining position, whereas in persons indigenous to sea level, such change in posture at sea level may decrease cardiac output

Conditions in Which Cardiac Output Decreases.

Normal The cardiac output is decreased about 30% in changing from the recumbent to the upright posture

Pathological States Atrial fibrillation and a very rapid heart rate may reduce cardiac output up to 50% In complete heart block and with an efficient myocardium, the output may be approximately normal, but when this exists in the presence of coronary sclerosis, myocardial degeneration, or after open heart surgery (cutting of the atrioventricular bundle), the output may be greatly reduced In other subjects, although the output at rest is normal, the inability of the heart to accelerate properly prevents an adequate output during muscular exertion In congestive heart failure, cardiac output very often is reduced, and the increase in cardiac output which normally follows muscular effort does not occur or is slight This type of failure is to some extent compensated for by a greater increase in the systemic arteriovenous O_2 difference than occurs in healthy persons doing a similar amount of external work

Conditions Which Increase Cardiac Output. Cardiac output may be increased 50 to 100% by anxiety and excitement and, at least, 30% by eating (during first 3 hr) Anemia, pregnancy (in later months), metabolic alkalosis produced by infusion of sodium bicarbonate, and low oxygen or high CO_2 in the inspired air are conditions which increase cardiac output up to 100% In maximum exercise the cardiac output may be increased five, seven, or even ninefold

Effects of Drugs upon the Cardiac Output. *Adrenaline* and *histamine* increase the oxygen consumption and the cardiac output, the effect upon the minute volume is, however, proportionately greater than that upon the oxygen consumption *Acetylcholine*, whose effects in general are very evanescent, causes a slight increase in the minute volume A decided rise in the cardiac output is produced by *nitrites* which, like acetylcholine, cause arteriolar dilation The increase in the cardiac output caused by nitrites is probably a compensatory effect of the lower peripheral resistance, whereby the

[1] Body recumbent, at rest and at 20° C for 15 to 20 min and 12 hr after food and drink

blood pressure is maintained near the normal level *Digitalis* produces no immediate effect upon the minute volume in normal persons In subjects with congestive heart failure and atrial fibrillation the output is as a rule, though not invariably, increased as the cardiac condition improves *Atropine* which increases the heart rate to 150 or 180 beats/min does not increase, as a rule, the cardiac output *Alcohol* in moderate dosage (35 ml) causes no more than a slight rise in the cardiac output

REGULATION OF CARDIAC OUTPUT AND CARDIAC WORK DURING EXERCISE AND EXCITEMENT

In strenuous exercise, the cardiac output may reach 35 to 45 liters/min (Table 3 13) or increase 7 to 9 times, while the body oxygen usage may increase 10 to 12 times

Heart Rate. At the transition from rest to work, the pulse frequency rises very rapidly with heavy exercise, reaching levels of 160 to 180/min During short exhaustive work, heart rates as high as 240 to 270 have been recorded in normal young people This increase in heart rate is attributed to some form of autonomic control, but the mechanisms have not been established The suspect Bainbridge reflex probably does not apply since this requires for its operation cardiac distension from increased venous return As we shall see later, the heart is more apt to decrease in size The tachycardia during exercise is attributed to a reflex through the carotid sinus and aortic baroreceptors resulting from a reduced arterial pressure as the result of vasodilation in the active muscle However, the systemic blood pressure rises, not falls, during exercise Finally, tachycardia is explained as related to direct regulation from the higher centers

Ventricular Pressure-Volume Relations. It has long been believed that the output of the heart is governed by its venous blood supply, and that the increase in minute output during muscular work requires a regulating mechanism by which venous return is augmented To effect this, the venous blood supply and pressure in the central veins must increase to such a height that the increased venous flow and ventricular filling pressure will dilate the heart and increase the length of its fibers during each diastole, and by this stretch cause a greater ventricular response in the following systole

A very large amount of experimental work has stressed this viewpoint Howell and Donaldson (1883) first showed the intrinsic adaptation of the heart of the dog to an artificially increased venous return Frank (1895) in the frog heart, came to the conclusion that the magnitude of ventricular contraction is determined by the intracavity volume at the end of systole In 1914, Patterson, Piper, and Starling measured the pressure and volume of both ventricles with a cardiometer in a heart-lung preparation of the dog, while the venous return was passively and progressively increased by elevating a blood infusion reservoir connected to the right atrium As the atrial pressure or ventricular filling pressure rose, the heart dilated and with each systole ejected a greater stroke volume at a greater ventricular pressure This relationship, called "Starling's Law of the Heart" or the "Frank-Starling" mechanism, indicated in a more formalized way that "the energy of contraction, however measured, is a function of the length of the muscle fibers," before contraction (Fig 3 119*A*) (pp 3–88 to 92, and 3–44) As these investigators indicated, this relationship is little more than the application to cardiac muscle of what was already known about skeletal muscle by Blix in 1891 and Fick in 1882 This relationship of ventricular pressure and volume has been confirmed for the whole heart in the open-chest dog and for the left ventricle in the open- and closed-chest dog (Fig 3 119*B*).

Because of the difficulty of estimating volume of a single ventricle and the relative ease of pressure measurement, attempts have been made to correlate mean atrial pressure or end-diastolic pressure of the associated ventricle with the stroke volume or stroke work A useful experimental preparation for this type of study by Sarnoff et al (1958) is in Figure 3 120 Sarnoff has found that the curves expressing the relation of mean atrial pressure and stroke work are shifted in one direction by conditions improving myocardial performance (stimulation of cardiac fibers from the stellate ganglia, reflex stimulation of the myocardium by a decrease in carotid sinus perfusion pressure, injection of epinephrine), while unfavorable conditions such as vagal stimulation, increase in carotid sinus perfusion pressure and coronary insufficiency shift the curves in the opposite direction These ventricular function curves provide important objective evidence

that ventricular control can involve changes in myocardial contractility, a concept now widely accepted (Fig 3 119*C*, *D*)

As one approaches the normal state, however, the evidence is equivocal for this relationship The peripheral venous pressure in man during heavy work (2 8 liters oxygen/min) can increase up to 7 mm Hg Variations of filling pressure, however, cannot be deduced from peripheral venous pressure because of the unknown pressure gradient from the periphery to central veins In the dog exercising on the treadmill, in the human following injection of a small amount of epinephrine or exercising mildly while lying down, there may be no direct correlation between the increased cardiac output or cardiac work and the atrial or ventricular end diastolic pressure Furthermore, intracardiac end-diastolic pressure measurements alone do not necessarily represent the effective transmural pressure, since it was shown in the closed-chest dog that under certain experimental conditions a rise in ventricular end-diastolic may be accompanied by a

concomitant increase in the intrapericardial pressure On the other hand, in subjects with an artificial pneumotherax, a linear relation was found between effective or transmural atrial pressure and stroke volume with an increase of 2 mm Hg providing an increase in stroke volume of 40% In humans whose autonomic nervous system has been inhibited by a ganglionic-blocking drug elevation of the left ventricular end-diastolic pressure, induced by blood transfusion, was accompanied by an increase of the cardiac output and stroke volume This relationship also apparently holds in patients with high output failure and very large ventricular volumes

Ventricular Volume and Stroke Volume. As already indicated, comparisons of direct measurements of ventricular volume with pressure or with stroke volume or stroke work have not been made in the normal state in which the aggregate complications of venous resistance, intrathoracic pressure, vascular volume, changing heart rate, neurogenic factors, and humoral influences exist However, highly suggestive evidence has been obtained by estimating the ventricular volume in systole and diastole The essential findings follow,

In man and the dog, the left ventricular diastolic volume and stroke volume increase in the recumbent position as compared to the more or less upright position Concurrently, the central blood pool or thoracic blood volume increases by about 400 ml The cardiac output and heart rate change in opposite directions on alteration of position, i e , in the supine position the cardiac output increases and the heart rate decreases Correspondingly, assuming the upright position is accompanied by a reduction in heart size and stroke volume

In the resting dog, an increase in venous return induced by a rapid infusion of blood or by displacing blood from the splanchnic area into the thorax by abdominal compression increases the left ventricular dimension without significantly altering stroke volume or stroke work Excitement or startle or the anticipation of exercise just before treadmill activity can lead to a transitory increase in stroke volume with enlargement of the left ventricle

Nonexhaustive exercise by healthy dogs and normal untrained supine human subjects may be accompanied by increased cardiac output, primarily resulting from tachycardia with little or no progressive increase in stroke volume as the level of exertion increases Stroke volume during such exertion may only occasionally exceed the resting recumbent values in healthy dogs or untrained human subjects, although with exercise performed in the upright position (when the resting stroke volume is smaller), a definite increase in stroke volume accompanies the increasing heart rate and cardiac output Concurrently, the left ventricular dimension of the dog's heart remains the same or becomes smaller However, trained athletes and patients with chronic volume loads, such as in valvular insufficiency, may increase cardiac output with a significant augmentation of stroke volume and a lesser degree of tachycardia The relatively small hearts of untrained persons may show a tendency to reduce their diastolic size during exercise but the end-diastolic size of the large hearts of athletes gets much smaller The larger capacity of athletes, as compared to untrained subjects, for increasing cardiac output during exercise is explained by the larger stroke volume

Evidence for increased contractility of the

myocardium during exercise is in the increasing rate of tension development, rate of blood ejection, and rate of relaxation as seen in the ventricular pressure curves and the aortic flow curves

The preceding evidence suggests, but does not offer quite certain proof, that the fundamental property of cardiac muscle of a relation between end ventricular diastolic size and energy release is not dominant, but rather that in the normal dog and man, an increase in cardiac output during exercise is achieved mainly by an increase in heart rate with a constant or slightly increased stroke volume A little reflection will indicate, however, that this is a self-regulating mechanism and cannot alone explain the observed changes in cardiac output When the heart accelerates, the output per beat can be kept constant only if the venous inflow is adequate, only under such circumstances can the minute volume be increased

The contribution which cardiac acceleration can make toward the minute volume is, therefore, strictly limited, for rates from 180 to 200 are about the maximums to which the healthy heart can be speeded up This is only about 2½ to 3 times the normal rate With a constant stroke volume, therefore, cardiac acceleration could not increase the minute volume more than about 3 times Yet reliable data have shown that the cardiac output of untrained man doing strenuous exercise may increase ninefold (from 5 to 6 liters/min at rest to 35 to 45 liters) and the oxygen consumption 12 times (from 250 ml oxygen at rest to 3000 ml) In this circumstance, it must be concluded that the stroke volume increases 2 to 3 times (even at a maximum pulse rate) to account for up to 50% of the cardiac output increase This is borne out by some of the data in Table 5 13

In summary, it can be stated that both changes in stroke volume and heart rate contribute significantly to regulation of cardiac output in man, but no firm conclusion can be drawn as to the relative role that stroke volume, heart rate, and diastolic and systolic volumes play under various conditions of stress

Body Arteriovenous (AV) O_2 Difference. Since the body oxygen usage can increase 12 times in exercise, it is important to know the mechanisms by which this amount of oxygen is supplied to the tissues The AV O_2 difference is generally calculated from the oxygen usage divided by the cardiac output, the former being determined by collection and oxygen analysis of the expired air and the cardiac output by the dilution technique, which does not require cardiac catheterization The oxygen extraction rises but considerably more slowly than does the cardiac output, reaching in very heavy exercise a calculated maximum of 13 to 16 ml /100 ml of blood Since most of the increase in blood flow is presumably through the exercising muscle, this means that the oxygen extraction at times must be very nearly complete in the latter, a situation similar to that which has been observed in the heart muscle with maximal activity In well-trained subjects, it appears that the rise in AV O_2 difference, as well as heart rate, are somewhat smaller, while the stroke volume is larger (see p 3-221)

Other Hemodynamic Variables in Exercise In addition to the heart rate and stroke volume alterations occurring in exercise, many other changes are involved which may be mild or almost insignificant in light exercise, or which may be massive is strenuous activity (Table 3 13) In the presence of heavy exercise and a very large increase in cardiac output, the CWI of the left ventricle may increase four times, the systemic blood pressure may increase considerably, the arterial pressure pulse may increase from 50 to 100 mm Hg, the total peripheral resistance may decrease greatly Presumably, the latter results mainly from vasodilation in the metabolically active beds for, since splanchnic blood flow in man is decreased in the presence of an elevated systemic blood pressure, resistance in the splanchnic bed must be increased In the pulmonary circulation, the arterial pressure rises moderately, while the resistance decreases or undergoes little change Finally, as pointed out earlier, the central venous, atrial, and ventricular end-diastolic pressure do not necessarily increase The alterations in many hemodynamic parameters during exercise is indicated in Figure 3 121

The Role of Catecholamines. The importance of the sympathetic nervous system in the regulation of the heart's performance has already been mentioned on several occasions throughout this section The effects of sympathetic nerve stimulation are in all likelihood mediated through the release of norepinephrine from the nerve endings Evidence for this view may be summarized as follows

The mammalian heart, including the human, like several other tissues and organs possessing

a rich adrenergic innervation, contains significant stores of norepinephrine The norepinephrine content of the tissues is closely related to the number of adrenergic fibers supplying them It disappears completely following postganglionic sympathetic denervation Similarly, the administration of reserpine results in practically complete disappearance of norepinephrine from the heart, and, in animals so treated, the positive chronotropic effect of accelerator nerve stimulation is blocked The cardiac effects of stellate ganglionic stimulation can be mimicked by norepinephrine infusion Finally, during stellate ganglionic stimulation, norepinephrine can be recovered from coronary venous blood, in an amount proportional to the intensity of the stimulus

REGIONAL DISTRIBUTION OF OXYGEN CONSUMPTION AND BLOOD FLOW

The preceding discussion indicates that despite much study of long familiar functions, their operation in the adjustments of oxygen and cardiac output to exercise is poorly understood The response of oxygen usage and blood flow, of course, represents the average requirements of organs and regions of the body The advent of implantable sonar and electromagnetic flowmeters now makes it possible to measure blood flow simultaneously in a limited

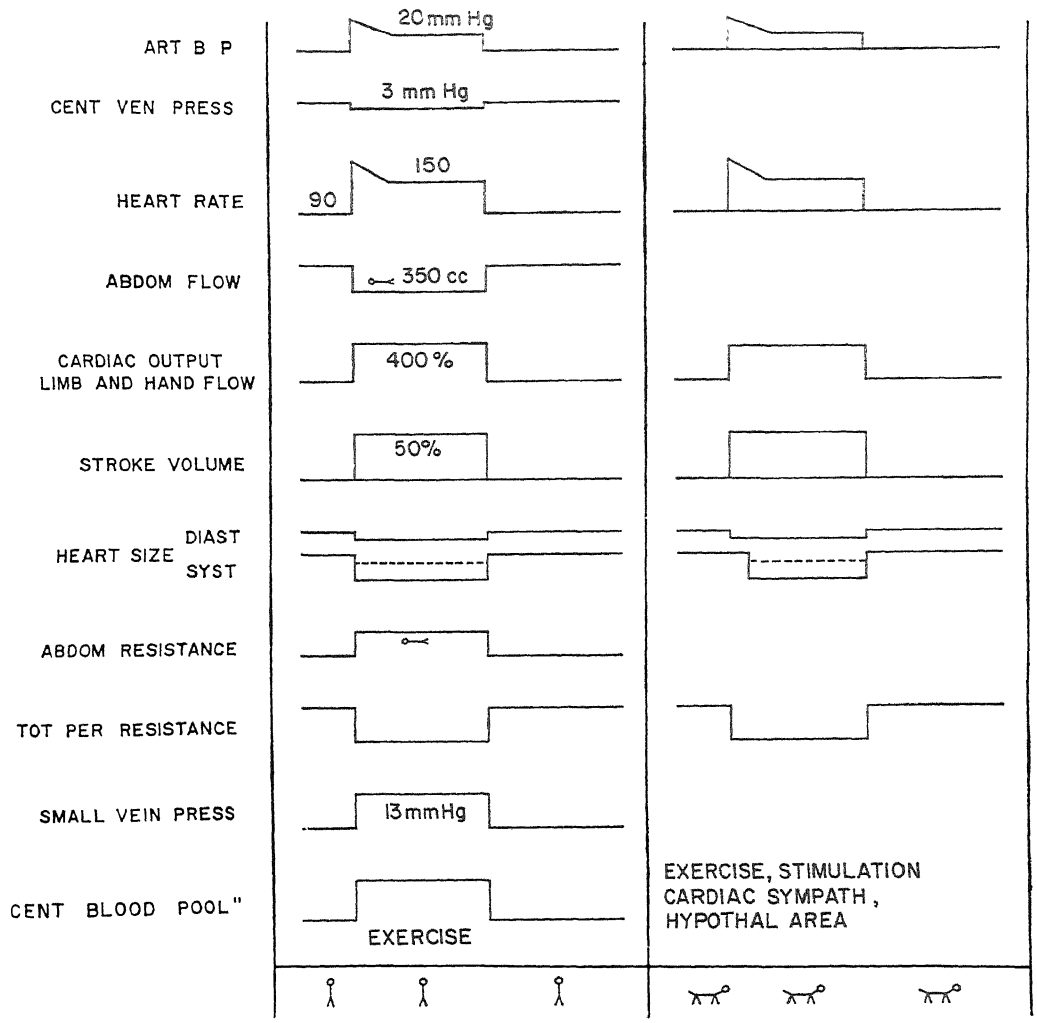

Fig 3 121 Left side hemodynamic responses in exercising man and right side hemodynamic responses in the unanesthetized dog to exercise to stimulation of the cardiac sympathetic fibers and of the hypothalamic area Dotted lines represent the less usual responses

number of different vascular beds in intact, conscious animals under a variety of physiological conditions Table 3 14 is presented showing data on distribution of flow and oxygen consumption in resting and exercising man, obtained by different types of measurement by different observers on different subjects (In some instances, values are extrapolated from animals) The values are certainly not absolute but the general pattern of distribution may be right The kidney blood flow of 400 ml /100 g of tissue is about six times greater than that of any other organ (nearest is the heart with a flow of 70 ml) The heart per unit of tissue, on the other hand, uses considerably more oxygen than any other organ Four regions—brain, heart, liver and intestine, and kidney, make up about 7% of body weight but receive 65 to 70% of the output of the heart and account for 60% of the total oxygen used at rest The skeletal muscles representing 50% of body weight receive only 20% of cardiac output at rest and account for only 15% of body oxygen usage, but during exercise they may account for 80 to 90% of the oxygen consumption and cardiac output The brain which is only 2% of body weight requires more than 20% of the total oxygen used by the body and during convulsions (observed in monkeys), this fraction may increase to 40% and the brain fraction of cardiac output from 14 to 20% Thus, the cardiovascular response is not limited to an adjustment of the cardiac pump, complicated as this may be Certainly, real changes occur in the distribution of the output of the pump

Coordination of Right and Left Heart Activity

As shown in Figure 3 122, the outputs of the left and right ventricles must be maintained in equilibrium if the blood volume and hemodynamic relations between the pulmonary and systemic circulations are to be preserved The cardiac factors which serve to interrelate right and left ventricular activity are

1) Frank-Starling Mechanism This serves to adjust each ventricular output to its inflow

2) Ventricular End-Diastolic Volume The ventricles do not empty completely with each beat A change in stroke volume induced by sudden alterations in sympathetic tone can occur from beat to beat through alterations in the ratio of stroke volume to end-diastolic volume In dogs, abrupt onset of exercise induces a simultaneous increase in both right and left ventricular stroke volumes (Franklin et al , 1962), presumably because of increased sympathetic activity Any disparity between venous returns of the two ventricles can thus be buffered by changes in end-diastolic volume

These factors, in turn, are aided by mechanisms which effect coordination of right and left heart volume output and accommodate temporary differences

1) Storage Function of the Pulmonary Circulation This permits moderate increases in pulmonary blood volume for a time Experimentally, rapid intravenous infusion of saline increases right ventricular output first The left ventricular output is increased similarly after a

Table 3 14

lag time of at least three cardiac cycles During this period the blood volume in the pulmonary circuit increases temporarily

2) *Flow Transmission through the Pulmonary Vasculature* Right ventricular flow pulse is transmitted with little storage of volume in the lung circulation The pulmonary venous flow pulse is synchronized with the period of rapid filling of the left ventricle Therefore, the end-diastolic volume of the left ventricle can be directly influenced by right ventricular stroke output, which is transmitted to the left atrium in about 0 1 sec (Morkin et al , 1965) An increase in right ventricular stroke volume can cause an increase in left ventricular stroke volume at the next heart beat (Franklin et al , 1962) The transmission of this stroke flow is related to the stiffness (compliance) of the pulmonary vasculature Increased stiffness (sympathetic activity) increases flow wave transmission, thus aiding in ventricular coordination (see pp 3-22 and 3-210)

3) *Bronchial Circulation* There is free communication between the capillaries of the pulmonary vascular bed and the bronchial circulation The bronchial flow (part of left ventricular output) returns in part to the left atrium through the pulmonary veins, a smaller fraction returns to the right atrium via the azygos vein and superior vena cava Thus, a shunt is provided which could serve to equalize pressure and flow between the two circulatory systems The possible importance of this mechanism in health and disease has not been established

COORDINATION OF ATRIAL AND VENTRICULAR ACTIVITY

Atrioventricular conduction time decreases with the interval between heart beats so that the timing of atrial and ventricular contraction remains sequential An increase in rate of spread of excitation over ventricular musculature and shortening of the action potential duration accompany cardiac acceleration Thus, systole is shortened and the sequence of activation of the myocardium as a whole (i e , both ventricles) is maintained with changes in heart rate

THE HEART AND VESSELS AS A COORDINATED SYSTEM

The right and left sides of the heart are connected to their respective vascular systems at

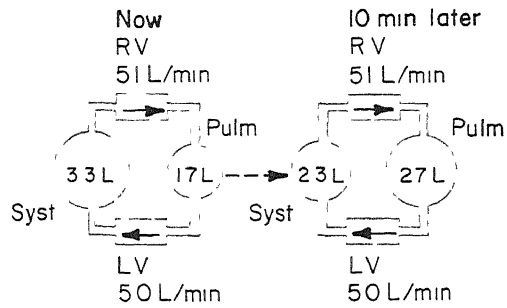

Fig 3 122 Diagram illustrating the consequences of a 2% difference in right (RV) over left (LV) ventricular outputs if mechanisms did not come into play to keep the mean outputs of the two ventricles the same Actually death would supervene before a shift of blood volume of the magnitude depicted could occur (Volumes and figure from Burton 1965)

both their input and output ends Cardiac output is adjusted to its venous return and to arterial pressure The arterial side is hemodynamically coupled with the heart only during systole, the venous side at all times Through these couplings, circulatory flow volume and pressure directly influence the intrinsic regulatory factors of the heart More remote influences from the vascular system are transmitted to the heart by nerve impulses and humoral agents (extrinsic regulation) Primary changes in cardiac output similarly affect vascular function Thus, the volumes, flows, resistances, and pressures in all parts of the circulation are capable of affecting function in all other regions of the system

Cardiac function curves (so-called Starling curves) relate factors governed in part by venous return (e g , mean right atrial pressure, end-diastolic ventricular volume, end-diastolic pressure) to cardiac output or some function of the ventricle which is a determinant of cardiac output (e g , stroke volume, ventricular pressure, rate of pressure development dP/dt, power, work) Figure 3 123 illustrates a group of such curves relating cardiac output to right atrial pressure Usually left ventricular output is determined, so that the curves describe a relationship between left ventricular function and right atrial pressure Such a simplified model of the circulation is shown in Figure 3 123*A* As can be seen from the normal curve in Figure 3 123*B*, when right atrial pressure increases, cardiac output increases When right atrial pressure falls sufficiently below zero (e g , −2 0 mm Hg), cardiac output is 0, at 0 0 mm Hg it is 5 liters/min and at 5 0 mm it is 12 5

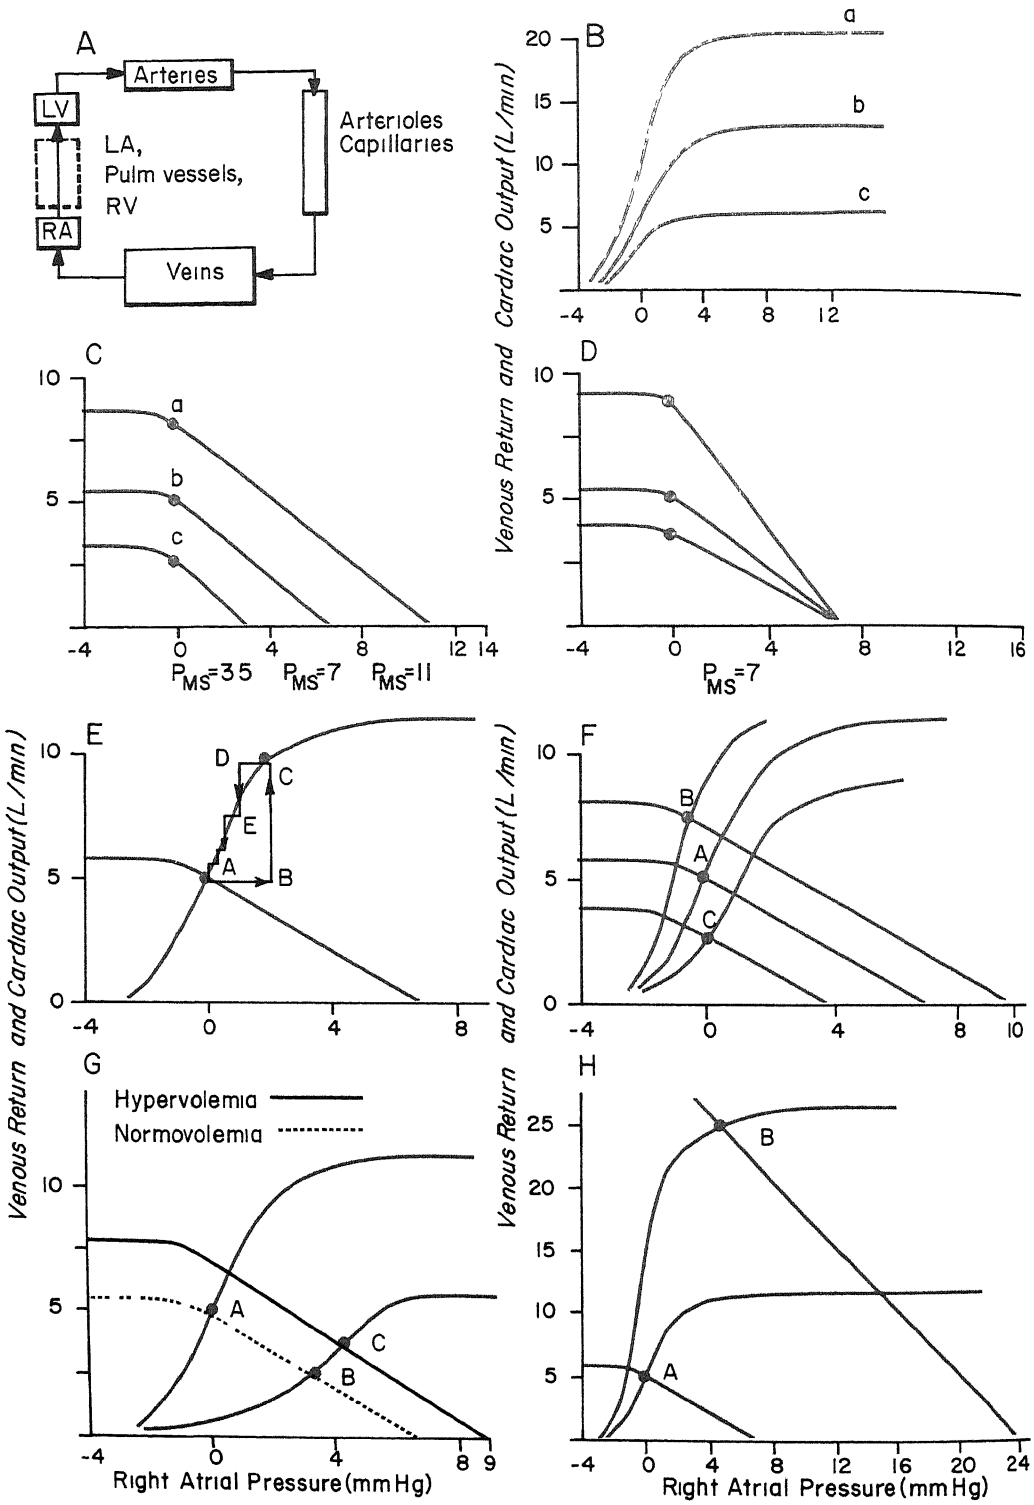

Fig 3 123 Cardiac and Systemic Function Curves *A* simplified model of the circulation Cardiac function curves may be plotted from determinations of right atrial pressure (RA) and left ventricular output (LV) The resultant curves characterize steady-state flow through the heart and lungs When the only parameters measured are LV output and

liters/min Lines *a* and *c* are for hyperdynamic (*a*) and hypodynamic (*c*) hearts The former represents the direction of change with, for example, sympathetic nerve stimulation or cardiac hypertrophy of lengthy physical training, the latter represents the direction of change associated with inhibition of sympathetic tone, vagal stimulation or myocardial disease

These curves permit an evaluation of the functional state of the heart based on the measurement of two factors e g , right atrial pressure and left ventricular output Any influence of the right ventricle, pulmonary circulation, or left atrium would alter the relationships between these two variables, but would not be distinguished from changes in left ventricular function by this analysis

Venous return or *systemic function curves* (Guyton, 1955, 1963) are employed to relate right atrial pressure and venous return (Fig 3 123*C*, *D*) The same two coordinates used in the Starling curve are here related right atrial pressure and volume flow But in this case flow is expressed as venous return rather than cardiac output Note, however, that now the relationship between flow and pressure is the inverse of that described by Starling curves In the Starling curve a rise of atrial pressure is associated with an increase in cardiac output In venous return curves, increasing atrial pressure decreases venous return The systemic function curves represent right atrial pressure (dependent variable) as a function of venous flow (independent variable) In the systemic function curves, contrary to convention, the dependent variable is plotted along the abscissa, whereas in the Starling curve convention is followed and the dependent variable (cardiac output) is plotted along the ordinate The fact that the relationship between pressure and flow is reversed in the two types of curves is not contradictory It simply means that the variables are interdependent and both relations operate simultaneously in the system (see pp 3-8 to 3-12) By considering flow first as the dependent variable (Starling curve) and then as the independent variable, (systemic function curve) the individual roles of factors determining right atrial pressure, venous return, and cardiac output are emphasized Starling curves deal with circulation through the heart and lungs, systemic function curves with circulation through the systemic vessels In the former, the heart (with the lungs and pulmonary circuit remaining to provide blood oxygenation) is allowed to respond functionally as the dependent variable to controlled alterations in pressure, flow, and resistance of the systemic vascular system which affect atrial pressure (independent variable) In the latter, the heart and lungs are replaced by a pump oxygenator (independent variable) and flow in the systemic vascular system becomes the dependent variable Figure 3 123*C* depicts a series of systemic function curves Note that in the normal curve, blood flow into the right atrium reaches zero at an atrial pressure of 7 mm Hg This is the expected pressure in all parts of the systemic circulation when equilibrium occurs following cessation of flow It is the mean filling pressure of the systemic circulation and is termed *mean systemic pressure* (P_{ms}) The value 7 mm Hg has been determined in dogs by stopping the heart, and within 2 to 3 sec pumping blood from the arterial to the venous side until the pressure is equalized (Guyton et al , 1954) The

---

RA pressure the possible effects of hemodynamic influences of the right ventricle pulmonary vessels and left atrium (dotted square) are ignored *B* cardiac function curves for the heart *a* Hyperdynamic cardiac state *b* Normal state *c* Hypodynamic cardiac state *C* Systemic function curves the effect of changing mean systemic pressure (P_{ms}) *a* P_{ms} of 11 mm Hg *b*, P_{ms} of 7 mm Hg *c* P_{ms} of 3 5 mm Hg *D* Systemic function curves the effect of changing resistance to venous return *E* Cardiac function (cardiac output) and systemic function (venous return) curves plotted on the same axes *A* the equilibrium point with coordinates of 5 liters/min cardiac output and venous return (ordinate) and 0 mm Hg right atrial pressure (abscissa) These coordinates represent stable values at which the system is operating When a perturbation occurs (such as a sudden shift of right atrial pressure from *A* to *B*) the coordinates for cardiac output reach a new point (*C*) In a stable system, a series of changes is initiated (*D E* etc) and the original equilibrium value (*A*) is regained *F* the effect of altering sympathetic tone *A* control cardiac function and systemic function curves *B* the effect of sympathetic nerve stimulation *C* The effect of sympathetic nerve inhibition (e g with spinal anesthesia) *G* Shifts in cardiac and systemic function curves in congestive heart failure *A* equilibrium point of control curves *B* new equilibrium point when the heart fails (decrease in cardiac output and increase in right atrial pressure) *C* equilibrium point established when the increase in blood volume which is expected in heart failure occurs Cardiac output is substantially increased owing to this shift in the equilibrium point *H* The effect of exercise on cardiac and systemic function curves *A* the control equilibrium point *B* the new equilibrium point when cardiac output and right atrial pressure are increased during strenuous exercise

P_{ms} is determined by the volume capacity of the vascular system and its degree of filling (blood volume) In the systemic function curves an increase of venous return is seen as atrial pressure falls (Fig 3 123*C*, *D*) until a plateau is reached This is the maximum venous return which is not exceeded as atrial pressure continues to fall The plateau is caused by progressive collapsing of the veins (at the thoracic entrance) which increases resistance to flow This automatically limits the rise in venous return with further fall in atrial pressure When the P_{ms} is increased (increased blood volume, decreased vascular capacitance) the curve is shifted upward and to the right, while with a fall in P_{ms} it shifts to the left and downward (Fig 3 123*C*) If the P_{ms} remains constant when vasodilatation occurs, venous return increases as resistance to flow decreases and the function curves rotate about the point of right atrial pressure which equals P_{ms} (Fig 3 123*D*)

Figure 3 123*E* illustrates the relationship between right atrial pressure, venous return, and cardiac output These two function curves cross at point *A*, the *equilibrium point* The coordinates of this point represent the cardiac output and mean right atrial pressure which characterize the state of the heart and circulatory system at the time the curves are derived

As long as the system is operating along these cardiac output and systemic function curves, it will tend to stabilize at this equilibrium point For example, a sudden increase in right atrial pressure from point *A* to *B*, all other factors remaining unchanged, would result in increased cardiac output (point *C*) This could be induced experimentally by withdrawing a given volume of blood from the arterial side and injecting it during ventricular systole into the venous side The increase in right atrial pressure would increase cardiac output (point *C*) while decreasing venous return The cardiac output would then exceed venous return and during the next four or five heart beats, blood from the heart and pulmonary circulation would be transferred into the systemic circulation Thus, atrial pressure would be reduced (points *D*, *E*, etc) as cardiac output decreases also The process would continue until the stable equilibrium point for the two function curves would be reached

With alteration in sympathetic tone, shifts occur as depicted in Figure 3 123*F*, increased sympathetic tone shifts the ventricular function curve to the left and the systemic function curve upward and to the right New coordinates are then established for the equilibrium point (*B*) representing an increase in cardiac output and venous return and decrease in mean atrial pressure Decreasing sympathetic tone has the opposite effect and the new equilibrium point (*C*) shows that flow into and out of the heart is less for a given right atrial pressure Marked reduction in cardiac output, as occurs in heart failure, shifts the cardiac output curve to the right and the equilibrium point lower on the systemic function curve (from *A* to *B*, Fig 3 123*G*) Even if cardiac function does not improve, fluid retention with hypervolumia increases P_{ms}, shifting the systemic function curve upward and to the right, establishing a new equilibrium point (*C*)

With exercise marked shifts in the function curves occur In Figure 3 123*H*, the steady state attained during strenuous exercise is depicted *A* represents the equilibrium point at a resting cardiac output of 5 liters/min and mean right atrial pressure of 0 0 mm Hg *B* is the equilibrium point attained with a fivefold increase in cardiac output and elevation of right atrial pressure to about 5 mm Hg Mean systemic pressure has increased to 24 mm Hg, the result of sympathetic contraction of capacitance vessels The systemic function curve slope is steeper than the resting curve because vasodilatation in the active muscles reduces resistance to flow through part of the systemic circuit The cardiac output curve is shifted to the left as the result of inotropic cardiac effects of sympathetic nerve activity and elevation of myocardial tension (Anrep effect, p 3-110), caused by increased arterial pressure (afterload) which accompany exercise The two curves equilibrate at *B*, a point on the cardiac output curve which is near its maximum

The foregoing type of analysis is only a rough approximation based on simplified assumptions regarding the vascular system and reasonable presumptions regarding the course of the cardiac output curves However, it serves to illustrate the complex interactions between cardiac output, arterial pressure, right atrial pressure, and venous return in cardiac regulation In this way the analyses have predictive value and agree with experimental observations (Guyton, 1963)

Cardiac Reserve

Present knowledge of the reserves available to the heart to cope with various stress impacts permits little more than their enumeration. The potential reserves are its heart rate, its systolic and diastolic volume, its blood flow, the oxygen content of the body mixed venous blood, the cardiac work, the changing efficiency of the heart, and possibly the stores of catecholamines.

The reserve in heart rate is about 130 to 140 beats/min., resulting in a maximum heart rate of 210. The reserve in stroke volume is 80 to 100 ml. since each ventricle normally contains about 150 to 170 ml., of which 60 to 70 ml. is ejected during systole. This figure is somewhat lower than the measured figure of 190 ml. for maximum stroke volume in Peruvian natives in the mountains, exercising to exhaustion on a treadmill. Attainment of such an increased stroke volume indicates an increased contractility of the myocardium. The reserve in blood flow approximates 30 liters/min., since maximum cardiac output is about 35 liters/min. in man working to exhaustion, and the resting cardiac output is about 5 liters. The potential reserve of oxygen within the body is about 900 ml. This is based upon the fact the body mixed venous blood contains 15 to 16 ml. oxygen/100 ml. blood, and the blood volume is 5500 ml. However, neither normal persons nor persons with heart disease utilize this oxygen to the full. With maximum exertion, the oxygen extraction approximates 14 to 16 volumes %. This is supplemented by the ability of the human body to take up a maximum of 3000 ml. oxygen/min., or an excess of about 2700 ml. over that in the basal state. The reserve work of the heart is at about 75 kg. m./min., since the maximum left ventricle work recorded is about 80 kg. m./min., and the resting left ventricle work approximates 5 to 6 kg. m./min.

6 THE CORONARY CIRCULATION

Anatomy

Two coronary arteries, the right and left, carry blood to the myocardium About 2 mm from its ostium, the left coronary artery divides into the left circumflex and the anterior descending branches The former runs in the atrioventricular (AV) groove to the left, ending in a posterior descending branch The anterior descending branch runs downward in the interventricular groove toward the apex Near its origin, septal branches are given off The right coronary descends in the right (AV) sulcus and ends posteriorly as several descending branches on the right and left ventricles The subdivisions of the main coronary rami descend superficially in the general direction of the apex and give off myocardial branches which course directly into the ventricular muscle At or near the apex, where the superficial muscles form a spiral and penetrate to form the innermost (subendocardial) layer of muscle, the terminal coronary arteries go along with the muscle to supply the inner layer of both ventricles and the papillary muscles Anatomical studies in both the dog and human heart indicate that vessel branching within the myocardium is related to muscle bundles, but numerous communications exist between the different muscle layers

As in any other vascular system, each of the two coronary arteries connects with its capillary bed, its superficial myocardial venous bed, and eventually with the right atrium (Fig 3 124) The epicardial branches of the coronary arteries and coronary veins also anastomose with each other and with extracardiac arteries and veins There are numerous arteriovenous shunts In addition to these pathways, the arterioles as well as the capillaries and superficial veins connect directly with both ventricular cavities by discrete, deep drainage channels, the arteriolu-minal, the arteriosinusoidal, and the Thebesian vessels which together comprise the deep coronary drainage circuit

In man, approximately 50% of hearts have the right coronary artery predominant, 30% have a balanced coronary circulation, and 20% have the left coronary artery predominant

The experimental animal most frequently employed in studying coronary vascular function is the dog despite certain anatomical differences In the dog, in contrast to man, there is a higher incidence of left coronary artery predominance and differences in detail of arterial and venous distributions (Detweiler et al , 1970)

MYOCARDIAL CAPILLARY CIRCULATION

The coronary microcirculation is organized as in other tissues True capillaries (endothelial tubes) arise from metarterioles whose walls have smooth muscle cells at irregular intervals Precapillary sphincters (or cuffs of smooth muscle) are located at the origin of the true capillaries The ratio of capillaries to myocardial fibers approaches 1 1 in the adult myocardium This "ratio" is the same for skeletal muscle However, in the latter fiber diameter is much greater—50 μ in skeletal muscle versus 20 μ in cardiac muscle—and there are about six times more capillaries per unit cross-section of myocardium

Coronary Circulation and Cardiac Metabolism

LEFT CORONARY ARTERY FLOW AND CHEMICAL COMPOSITION OF CORONARY SINUS BLOOD AS INDICES OF LEFT VENTRICULAR METABOLISM

It is not possible to quantitate accurately the metabolism of the right ventricle in the dog because its superficial anterior cardiac veins have many exits into the right atrium and because their contained blood is grossly contaminated by blood from the left coronary artery However, a large percentage of the drainage of the left myocardium is accessible In most in

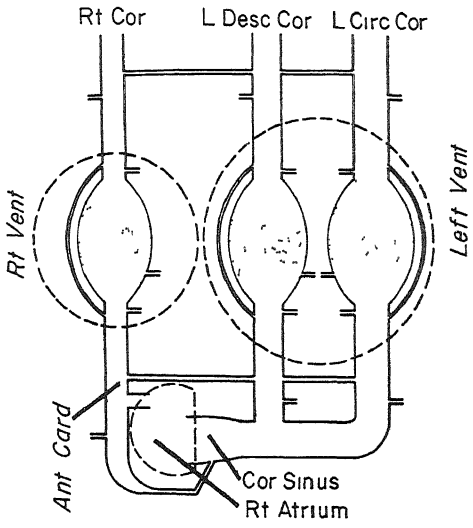

Fig 3 124 Schematic representation of the coronary circulation The areas enclosed within the circles depict the capillary beds collateral communications and AV shunts (Gregg and Sabiston 1956)

stances quantitative changes in the metabolism of the left ventricle can be obtained from measurement of the chemical composition of the coronary sinus blood together with measurement of the left coronary inflow This is because *1*) coronary sinus blood is almost entirely from the left coronary artery, *2*) by means of a special cannula which permits collection of all blood draining into the coronary sinus, the percentage of left coronary artery inflow recovered in the coronary sinus is quite high (80 to 90%) and reasonably constant during the induction of a variety of physiological variables and drug injections, *3*) the O_2 content of the venous blood from the left coronary artery not draining into the coronary sinus is generally only slightly less than that in the coronary sinus

Basal Data. In the resting state, the coronary data for dog and man agree With the left ventricular cardiac work index approximately 3 5 to 4 6 kg -m /min /m ^{2}, left coronary flow approximates 72 to 85 ml/100 g of left ventricle/min In anesthetized and unanesthetized dogs, under stress conditions, values as high as 600 ml /100 g of left ventricle/min have been recorded Although the heart can remove essentially all oxygen from the coronary blood in its passage through the myocardium, normally about two-thirds is extracted with an arteriovenous difference of 12 to 14 ml. and a coronary sinus value of 4 to 5 ml /100 ml of blood This extraction changes little with increased stress, signifying that the oxygen supply is well balanced with metabolic demands

Oxygen uptake per 100 g of left ventricle is 8 to 10 ml /min Oxygen consumption during systole averages about three times that in diastole

Myocardial Response to Anoxia. The coronary vascular bed is very reactive to the stimulus of anoxia, occlusion of a cornary artery for as short a time as 5 sec is followed by a temporary increase in blood flow Reactive hyperemia is considered to be the excess blood flow (over the control flow that normally would have occurred) which follows release of an arterial occlusion (Fig 3 125) The amount and duration of the reactive hyperemic blood flow increase with lengthening periods of left circumflex artery occlusion up to 120 sec , peak flows also increase but to a lesser degree The theoretical blood flow "debt" (control blood flow multiplied by the duration of occlusion) is usually greatly overpaid. Reactive hyperemia in skeletal muscle vascular beds shows these same characteristics except the blood flow "debt" is variably under or overpaid (see p 3–221) Coronary vasodilator agents do not consistently affect myocardial reactive hyperemia while Pitressin usually decreases the response

The *contracting* myocardium cannot withstand as long periods of arterial occlusion and oxygen deficit as *resting* skeletal muscle, and repays its oxygen "debt" with an increased blood flow but a decreased AV oxygen difference

DETERMINANTS OF CORONARY FLOW

Consideration of the mechanisms that control the blood supply to the myocardium involves certain difficulties not encountered in similar investigations in other organs of the body The myocardial wall of the left ventricle not only furnishes the pressure head for driving blood into the coronary arteries but also may either offer phasic resistance to coronary flow or actually aid flow by its muscular contraction around the coronary vascular bed Similarly, the right ventricle rapidly changes resistance to right coronary flow at the same time that left ventricular contraction presents blood to it under a pulsatile head of pressure However, coronary flow is related to the pressure difference (effective pressure) between the central coronary artery (identical to aortic pressure) and the right atrium divided by the sum of the

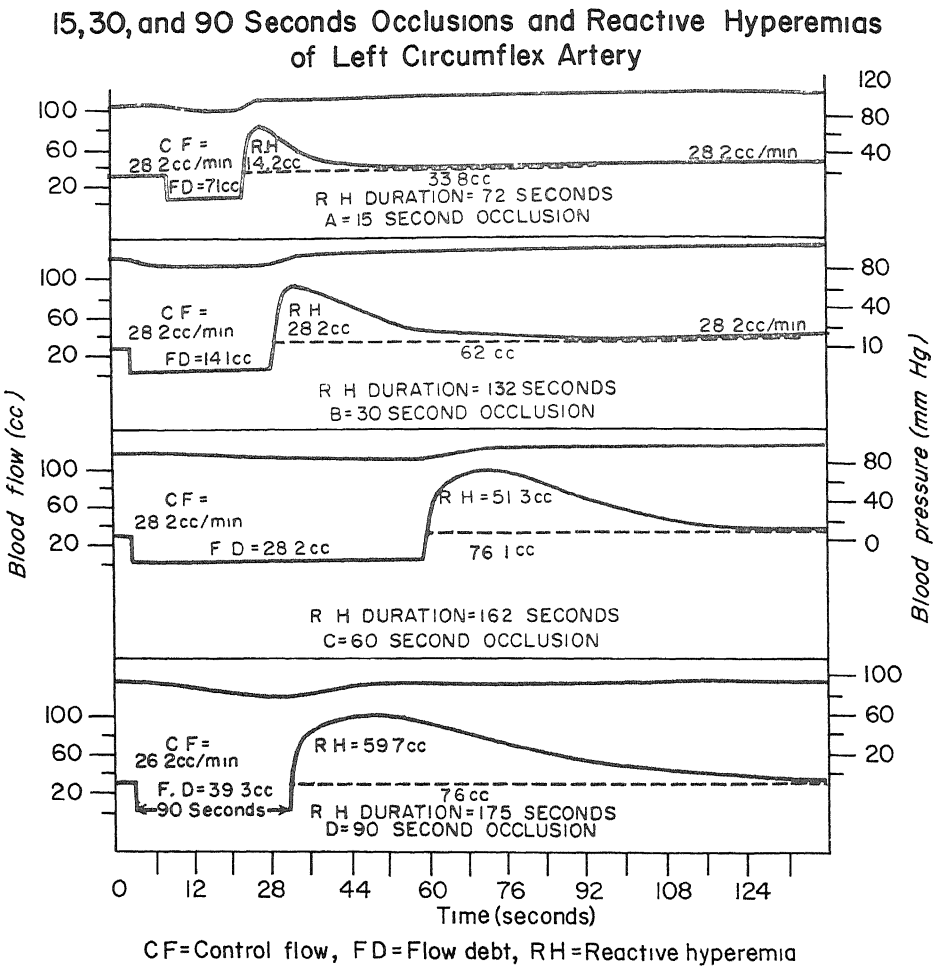

Fig 3 125 Myocardial response to anoxia Tracings redrawn from original experiment (Coffman and Gregg 1960)

viscous resistances to flow in the epicardial portion of the artery and in the peripheral coronary bed Viscous resistance to flow (aside from change in hematocrit) is mainly governed by the mean caliber of the coronary vascular bed The mean coronary diameter and, hence, flow are controlled by the effective intravessel pressure and by two peripheral mechanisms, i e , active changes in the state of the small mass of intravascular smooth muscle built into the coronary vessels, and the mechanical or passive effect on flow exerted during ventricular systole by the large muscle mass around the coronary vessels The peripheral mechanisms are regarded as more important in controlling coronary flow than the central coronary or aortic pressure which does not change greatly even in exercise It is estimated that doubling the aortic pressure might double the coronary flow, but doubling the average radius of the coronary bed might increase coronary flow about 16 times

Insight into the complexity of the integrating action of these three flow determinants has been obtained from recording of the peripheral coronary pressure and the phasic, or moment-to-moment changes, in coronary inflow and outflow in the epicardial arteries and veins (Fig 3 126) At the onset of isometric contraction of the left ventricle, there is an abrupt decrease in left coronary inflow (*solid line*) or even the appearance of backflow With the rise in aortic pressure, forward flow increases initially and rapidly, only to decrease to a new intermediate level in late systole With the onset of isometric relaxation, coronary flow increases significantly, peaking at early diastole and then declining progressively The velocity of coronary inflow differs somewhat from the

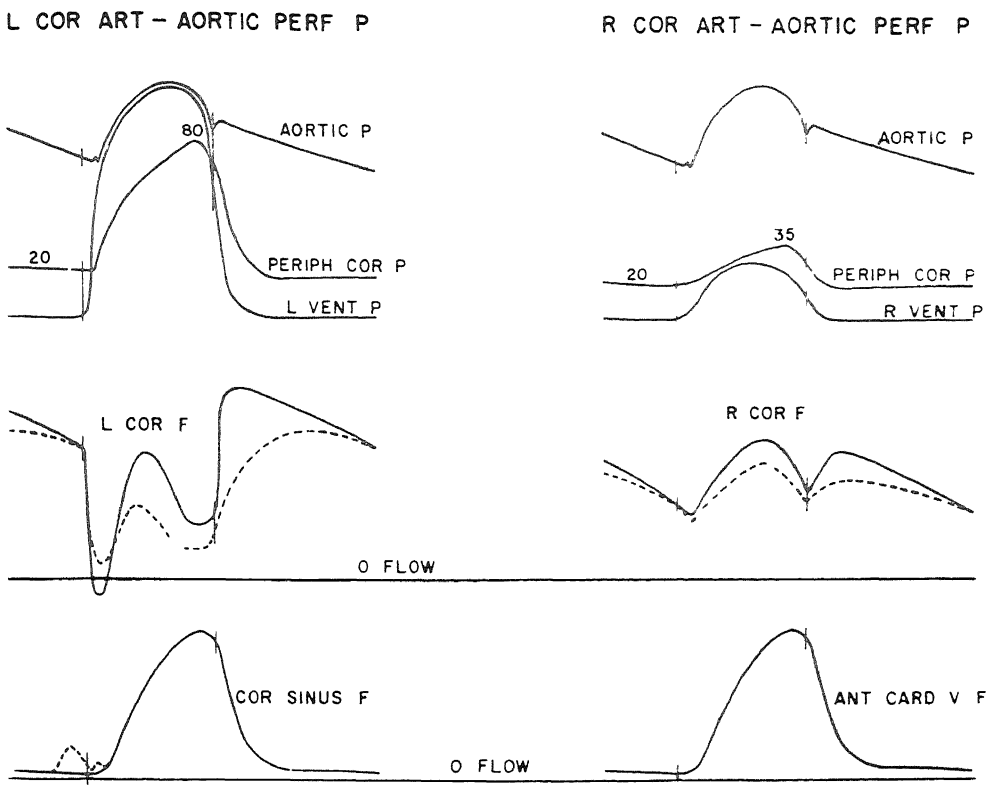

Fig 3 126 Series of curves relating phasic variations in left and right coronary inflow and coronary sinus-anterior cardiac vein outflow to aortic pressure ventricular pressure and peripheral coronary pressure Coronary inflow (*solid lines*) and anterior coronary vein flow obtained with orifice meter coronary sinus flow with pitot tube *Broken lines* estimated intramural velocity curves (Gregg 1959)

estimated intramyocardial flow (*dotted line*) The deficit during isometric contraction is caused by the compressing action of the myocardium on the coronary capillaries, forcing blood into the superficial vessels Early in the period of ejection, the flow excess is caused by the uptake of blood in the superficial coronary arteries, in diastole, the excess is caused by the uptake of blood to fill the previously compressed capillaries These demarcations of flow are much less obvious in the right coronary inflow pattern, which roughly resembles the prevailing aortic pressure curve. Thus, blood is flowing through the myocardium throughout the cardiac cycle, except possibly for a brief period in early systole in the left coronary artery In the left coronary artery, the systolic rate of flow is less than that during diastole, in the right coronary artery, the systolic rate equals or exceeds the diastolic In contrast to the left coronary inflow pattern, the flow curves in the coronary sinus and anterior cardiac veins rise and fall smoothly, with most flow occurring during systole and very little during diastole In unanesthetized dogs, using electromagnetic flowmeters, data have been obtained clarifying left coronary blood flow during systole and diastole In the resting dog, left coronary inflow during systole was 15 to 60% of diastolic inflow Under stress conditions (during excitement, chronic cardiac sympathetic nerve stimulation, or irreversible hemorrhagic shock), both the systolic and diastolic flow per heart beat increased by 300 to 400%, the ratio between them remaining the same, approaching unity, or even reversing, so that systolic flow surpassed diastolic flow Thus the strong contractions of the left ventricle, although impeding coronary flow, permit a large, but variable, systolic flow

The preceding account indicates that the coronary bed has a fluctuating resistance to coronary flow For the left coronary artery, the peripheral intracoronary pressure values at the height of systole and the low point of diastole approximate 80 and 20 mm Hg, respectively, and inflow is cut off at these pressure levels

when the left coronary artery is perfused under constant pressure In the right coronary artery, the contour and time relations of the peripheral coronary pressure curve are similar, but the values for systole and diastole and for the cutoff of flow are considerably lower

Elevation of right atrial pressure must increase coronary venous pressure and decrease the flow of blood in the coronary arteries provided no compensatory change occurs However, mild elevation of the pressure in the coronary veins draining the left coronary artery, by coronary sinus constriction, may decrease coronary flow and increase coronary arteriovenous oxygen difference only slightly Even marked constriction, or clamping, of the coronary sinus may cause only moderate reduction in arterial pressure and left coronary flow The smallness of the effect on coronary flow, despite elevation at times of the coronary venous pressure to near aortic systolic level, is presumably caused by the compensatory increased functioning of collateral venous communications with the anterior cardiac veins, in which flow increases considerably Similarly, right coronary inflow is not greatly reduced by clamping most of the anterior cardiac veins, presumably for the same reason

The relation of coronary perfusion pressure to coronary flow (*P/CF*) is generally such that the calculated coronary resistance decreases as the coronary flow rises This holds for almost any dynamic state of the coronary system (excised fibrillating or beating heart, heart in situ) and also for the pulmonary artery and certain peripheral vascular beds In the heart, it is impossible to say what fraction of flow change is caused by passive dilation from the perfusion pressure per se, since oxygen consumption per minute and per heart beat is elevated without any other observable systemic dynamic change Accordingly, if a physiological variable alters coronary pressure and flow by about the same amount and hence the ratio is unaltered, it is impossible to know whether the change in coronary flow is due to a change in effective head of pressure alone or whether the variable directly affected resistance However, a gross change in the vasomotor state of the bed occurs when coronary flow changes considerably with a constant pressure, or when flow and pressure change considerably in opposite directions.

Separation and quantitation of the determinants of coronary flow lying within the myocardial wall, i e , the intravascular and extravascular muscle, are of extreme importance To do this, continuous measurements are made in the open-chest dog while the left coronary artery is perfused with blood under a constant pressure, first it is done in the beating heart, and then during ventricular asystole induced by vagal stimulation or by disconnecting an external pacemaker which drives the ventricles, the latter manifesting complete atrioventricular heart block which had been surgically produced earlier By either means, the mechanical effects of ventricular contraction are largely removed Figure 3 127 illustrates that induction of ventricular asystole by vagal stimulation always increases immediately (within 1 second) left and right coronary inflow, in this instance from 56 to 78 and from 9 to 11 ml /min , respectively Thus, ventricular contraction acts to impede coronary flow through the ventricular wall The extent of the rise of flow is taken to represent the magnitude of the mechanical or passive factors limiting coronary flow The magnitude of this mechanical throttling effect on coronary flow during systole normally varies from 31 to 300% and averages about 50% The new flow level represents that state of coronary dilation related to the condition of the intrinsic smooth muscle of the coronary vessels at the prevailing coronary pressure The relative contribution of extravascular and intravascular re

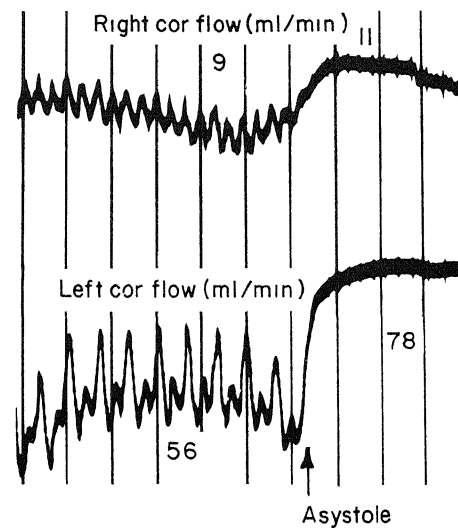

Fig 3 127 Response of left and right coronary flow to vagal induced asystole Note the prompt increase with the induction of asystole Time lines are 1 sec apart (Sabiston and Gregg 1957)

sistance to an increase of coronary flow has been tested under the different conditions of increasing heart rate, decreased arterial blood oxygen saturation, aortic constriction transfusion and drug injections In all instances, the major portion of a flow increase is through active dilation and not through reduction in extravascular resistance The largest reduction (40%) in extravascular resistance came from a decrease in arterial oxygen saturation

DETERMINANTS OF NORMAL CARDIAC METABOLISM

Metabolic Patterns in the Heart. The ability of the heart to do work depends basically on its biochemical activity leading to muscular contraction Cardiac muscle has been found to have basic chemical patterns similar to those of skeletal muscle The catabolism of fat, carbohydrate and protein produces free energy, about half of which is dissipated as heat and half is captured as phosphate bond energy which is used for muscle cell work and for various anabolic activities such as synthesis of glycogen, lipids, proteins and enzymes These catabolic and anabolic reactions proceed simultaneously under the influence of a complex system of enzymes, coenzymes (from the vitamin B complex), and hormones

Coronary sinus catheterization studies in man and dog have indicated that the heart is able to choose its fuel from a variety of foodstuffs These include mainly glucose, lactate, pyruvate, esterified and nonesterified fatty acids and, to a lesser extent, acetate, ketone bodies, and amino acids To determine their quantitative contribution to the energy production of the heart, i e , its oxygen consumption, measurements have been made of their cardiac extraction (coronary artery-coronary sinus difference), their total uptake [coronary flow times (coronary artery-coronary sinus difference of substance)], and the myocardial respiratory quotient (coronary sinus-arterial carbon dioxide difference) divided by (coronary artery-coronary sinus oxygen difference) Excellent correlation has been demonstrated between the myocardial respiratory quotient and the myocardial uptake of substance The extent to which each substrate contributes to the energy requirement of the heart in vivo is influenced by its concentration (above threshold) in arterial blood In addition, the state of nutrition of the organism markedly influences the kind of substrate used for energy production of the heart Under postprandial conditions, or after glucose infusion, myocardial metabolism is mainly glucose, lactate, and pyruvate, since its respiratory quotient approximates 0 9 with a high extraction of carbohydrate and a negligible uptake of amino acids Even the substitution of 5 to 10% oxygen for the normal 21% in the inspirated air does little to change carbohydrate uptake by the normal heart During overnight fasting, the heart derives much of its energy from fat, as indicated by a myocardial respiratory quotient of 0 8 with a low extraction and uptake of carbohydrate (see sect 3, chap 2, p 3-39) With prolonged fasting, the extraction coefficient for carbohydrate practically disappears, those for fatty acids and ketones are maximal, and the respiratory quotient is 0 7 With regard to the uptake of oxygen, the coronary A-V O_2 differences in man vary linearly with the arterial oxygen content through a range from mild anemia to marked polycythemia, so that the myocardial extraction coefficient (AV)/(A) is constant

Determinants of O_2 Usage of the Myocardium. Estimation of the metabolism of the myocardium in the absence of a heart beat, that is, during prolonged diastole, has been made in the vagal arrested heart as previously described under determinants of coronary flow Tht oxygen saturation of the arterial blood and coronary sinus blood is also measured continuously This permits left coronary arteriovenous oxygen differences as well as coronary inflow to be measured continuously first in the beating heart and then in the stopped heart until a new equilibrium is established, usually within 20 to 25 sec

Typical results are shown in Figure 3 128 As coronary inflow rises immediately with asystole from 70 to 90 ml /min , the oxygen saturation of blood in the coronary sinus also rises from a low control value of 44% to a very high value of 81%, thus greatly reducing the coronary arteriovenous oxygen difference The O_2 usage at rest is 35% of that in the beating heart Calculations in many experiments show that as the result of the combination of increased coronary flow and decreased coronary arteriovenous oxygen difference, the average oxygen usage per 100 g of left ventricle/min decreases from the average control level of 8 1 in the beating heart to 2 3 ml in the resting heart Individual values for the resting heart range from 1 0 to 4 0 ml This

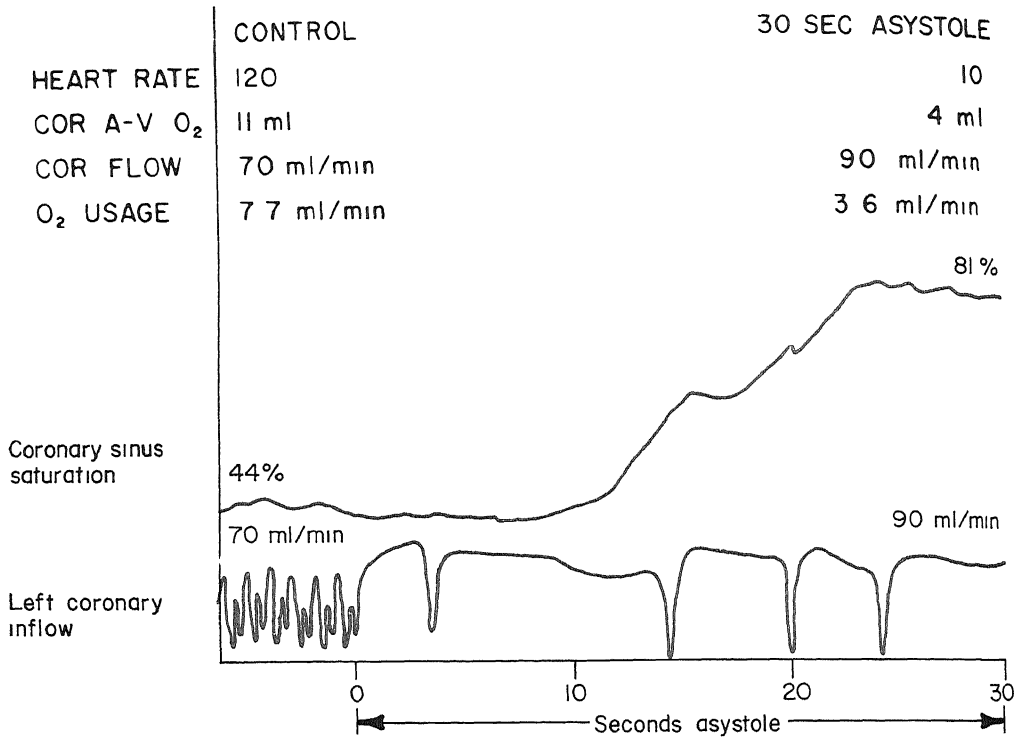

Fig 3 128 Reproduction of tracing from original record showing changes in left coronary inflow and coronary sinus oxygen saturation during prolonged ventricular asystole (Gregg 1955)

oxygen consumption in diastole is about one-third that in systole for an equivalent time period

Patterns of Response of the Coronary Circulation

The preceding gives some idea of the fractionation of the control of coronary flow and oxygen uptake within the myocardium during a cardiac cycle There are certain general patterns of hemodynamic responses of the heart and coronary circulation which follow primary changes in stress The information has been obtained from both humans and animals and has been assembled from many laboratories (Table 3 15)

METABOLITES

The coronary flow is greatly increased and the coronary arteriovenous oxygen difference decreased by some chemical constituents of the blood, while others produce no response or a decrease in coronary flow, in any case there is little or no change in systemic dynamics (blood pressure, cardiac work, heart rate) or myocardial oxygen consumption The coronary response to carbon dioxide and decreased pH is minimal, intracoronary injection of some intermediate metabolites will increase coronary flow and decrease oxygen extraction Although it has not been possible to demonstrate in the coronary sinus blood substances which would increase coronary blood flow, such metabolites could be metabolized or degraded rapidly and not be recoverable in venous blood Adenosine and adenine nucleotides are very active coronary vasodilators Although they are not found in coronary sinus blood, their derivatives, inosine and hypoxanthine, appear in measurable quantities during periods of myocardial hypoxia If adenosine is added to coronary arterial blood, only inosine and hypoxanthine are recoverable in the coronary sinus blood Thus it is possible that some metabolites may induce the vasodilation seen in myocardial hypoxia and yet not be recoverable in the coronary sinus blood

Autoregulation. As in other vascular beds, the coronary system tends to minimize the effects of alterations in perfusion pressure by

appropriate changes in resistance As illustrated in Figure 3 129, when the coronary perfusion pressure is increased or decreased, flow at first follows suit, but then resistance changes and flow returns toward the control level (see autoregulation (pp 3-6 and 3-164)

TACHYCARDIA

When the heart rate is increased considerably by electrical stimulation of the myocardium, aortic blood pressure, and minute cardiac output and work increase while the stroke volume and stroke work decrease Simultaneously, minute coronary flow and oxygen usage increase, coronary resistance decreases, oxygen extraction is unchanged but the coronary flow and oxygen consumption per beat decrease Since acceleration of the heart means proportionally greater time per beat and per minute in systole than in diastole and since in systole coronary flow is less than in diastole, it would be anticipated that increased heart rate per se should reduce coronary flow Since it does not, it must be that increased flow is due to arteriolar dilation from the increased metabolic activity The same trend of flow and oxygen usage per beat and per minute also occurs at the faster heart rate when minute cardiac work is held constant or when comparisons are made at the same stroke work This means that cardiac acceleration can augment the energy metabolism of the myocardium without manifestations of the extra energy as work

TRANSFUSION

Augmentation of ventricular load by increasing venous return and hence circulating blood volume through infusion has a clinical counterpart in the load placed upon the human heart by transfusion or by an aortacaval fistula The increasing coronary flow is partially explainable on a mechanical basis, since the slowing of the heart, which occurs under these circumstances, should increase coronary flow per beat and per minute by increasing diastolic time in which flow is greater However, active dilation presumably results from the increasing local chemometabolic activity associated with the increased cardiac work The coronary flow and oxygen are used economically, for the ratio

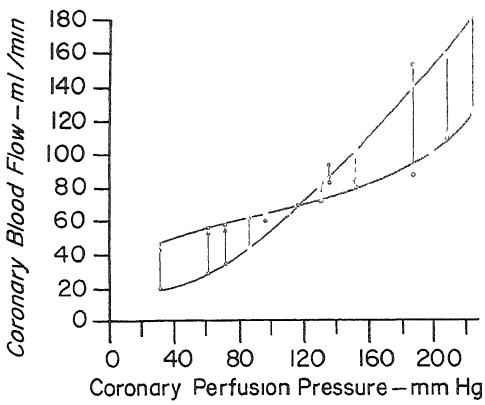

Fig 3 129 Pressure flow relationships in the coronary vascular bed The control level of coronary perfusion pressure and flow is at the point where the two lines cross Abrupt changes in perfusion pressure changed flow immediately to new levels (*closed circles*) which returned toward the control level (*open circle*) before becoming fixed at a new steady state (autoregulation of blood flow) (Redrawn from Berne and Levy 1967)

of cardiac work to oxygen consumption increases

AORTIC COARCTATION

With simulation of clinical coarctation by acute mechanical constriction (moderate) of the thoracic aorta just beyond the left subclavian artery, venous return to the heart by way of the inferior vena cava is decreased, but compensatory flow through various branches of the aortic arch may increase, so that cardiac output is maintained at the same level while the left ventricular workload is elevated With greater aortic constriction, the net cardiac output decreases, causing the cardiac work to decrease In either case the coronary dilation and increase flow arise in large part from *active* changes in the bore of the coronary bed related to the metabolic demands and in part passively from the increased blood pressure and moderately decreased heart rate The cardiac oxygen consumption is increased much more by this augmentation of pressure work than with an equal increase of volume work following transfusion No chronic studies of aortic coarctation have been made, because, owing to development of collateral circuits, the aorta may be first partially and then completely constricted at the arch without permanent development of hypertension proximal to the occlusion In human coarctation not much change has been reported in coronary flow and oxygen uptake per unit of muscle, but this might be expected because systemic pressure was only mildly elevated However, if true, the difference from the animal experiments might be explained by the fact that in these hearts, which are hypertrophied, there are fewer capillaries per unit of muscle to carry the oxygen and flow

HORMONES

Thyroid The myocardium participates in the increase in oxygen consumption characteristic of all body tissues in thyrotoxicosis This hypermetabolism is accompanied by an increase in coronary blood flow, a decrease in coronary vascular resistance, and an increase in oxygen consumption per minute and per beat Since there is an increase in oxygen usage per beat, cardiac oxygen utilization is presumably related not only to the increase in heart rate but to the general hypermetabolism of the myocardium as well

Epinephrine and Norepinephrine. The response of the systemic and coronary circulation to intracoronary artery injection of a minimal amount of epinephrine is similar to that indicated for stellate stimulation (see "Nervous Influences") Probably the coronary changes can be similarly explained With doses of 0 0002 mg or less, coronary flow may increase without any change in blood pressure or heart rate and with an increased coronary arteriovenous oxygen difference With the same or larger doses, as the systemic effects of the substance (increased aortic blood pressure, cardiac output, and changing heart rate) become evident, the coronary effects are exaggerated In those instances in which it has been tested, norepinephrine affects the coronary circulation similarly The circulatory responses to cigarette smoking or nicotine (i e , increased heart rate, systemic blood pressure, cardiac output, cardiac work, left coronary blood flow, and decreased coronary vascular resistance), parallel those with epinephrine or norepinephrine injection and are presumably related to the release of norepinephrine However myocardial oxygen consumption may increase, decrease or remain unchanged

Acetylcholine. This hormone, when infused into a coronary artery, increases coronary blood flow in the anesthetized dog If the dose is properly chosen, this response in the beating heart occurs without a significant change in blood pressure, heart rate, cardiac output, or

cardiac work, myocardial oxygen consumption per beat and per minute have been shown to increase However, when the hormone is fused intravenously into dogs with a constant heart rate and peripheral resistance, a decrease in myocardial oxygen consumption and ventricular contractility accompany the increased coronary blood flow The oxygen consumption of the myocardium for a given amount of cardiac work is not changed Although mechanical factors have been excluded, whether the effect of acetylcholine on coronary blood flow is directly on the intrinsic smooth muscle of coronary vessels or is induced through metabolic changes of the heart cannot be determined from the experimental data

Pitressin and Angiotensin. Of the hormones used clinically, pitressin and angiotensin increase coronary resistance to flow Coronary flow decreases during pitressin infusion, the reduction occurring throughout the cardiac cycle in the presence of an increased central coronary pressure There is a decrease in myocardial oxygen consumption and contractility, and in stroke work Although a reduced metabolic influence is presumably the cause of the decrease in coronary blood flow, a direct effect on the coronary vascular bed has not been ruled out Angiotensin produces an increase in coronary vascular resistance, its mode of action is unknown An initial cardiac depression is followed by a positive inotropic effect Blood pressure and cardiac work are increased

NEURAL INFLUENCES

Experimentally, vagal stimulation causes parasympathetic coronary vasodilatation independent of the chronotropic and inotropic actions of the vagus (Feigl, 1969) The extent to which parasympathetic vasodilatation contributes to coronary artery regulation has not been determined Stimulation of the cardiac fibers from a stellate ganglion in the anesthetized dog increases mean left coronary flow as the result of a decrease in systolic flow and a large increase in diastolic flow This is in contrast to the unanesthetized dog where the ratio of systolic to diastolic flow is variable Concurrently, left ventricular metabolism, cardiac output, and cardiac work increase while the systolic and diastolic sizes of the heart decrease The decreased ratio of pressure to flow indicates an increased mean coronary bore The major part of the dilation is explained by active changes in the coronary bed resulting from the release of an epinephrine-like substance (presumably norepinephrine) which directly enhances myocardial metabolism

Experimental evidence has been accumulated that alpha and beta adrenergic receptors are present in the coronary vascular bed Norepinephrine, which presumably acts only on alpha receptors, and epinephrine, which acts on alpha and beta receptors, produce a relaxation of helical strips of coronary vessels (200 to 500 μ in diameter), this relaxation can be prevented by beta adrenergic blockers (Zuberbuhler and Bohr, 1964) Also the decrease in coronary vascular resistance induced by intracoronary infusion of isoproterenol in the potassium arrested heart can be blocked with beta adrenergic blocking agents (Klocke and associates, 1964)

There is evidence that the alpha receptors mediate vasoconstriction, but the physiological importance of this has not been established (Hirche, 1967)

Carotid sinus (q v) reflex sympathetic control of the coronary circulation has been demonstrated (Feigl, 1968) and in the cat stimulation of sympathetic C fibers causes coronary vasodilatation (Brown, 1968)

ANEMIA

The coronary system participates actively in the circulatory adjustments to anemia For hemoglobin values of 10 g or more, the systemic circulation is essentially unaltered, and the compensation of the coronary system to the decreased oxygen-carrying capacity is similar to that with hypoxia, i e , an increased coronary flow without change in oxygen uptake When the hemoglobin values reach 6 to 8 g , the response of the systemic circulation is manifested by tachycardia, increased cardiac output, cardiac work, and a fall in peripheral resistance The coronary flow may now triple, coronary venous blood may contain less than 2 volumes % oxygen, the coronary arteriovenous oxygen difference may be 4 ml or less, and oxygen uptake is considerably increased The increase in coronary flow is related in part to the decreased blood viscosity and in larger part to the active dilation associated with myocardial hypoxia, which arises from the low hematocrit and from the increased metabolism Ultimately, myocardial failure will occur in severe anemia when the coronary vessels have approached maximal dilation and cannot further

compensate for the decreased oxygen-carrying capacity of the blood either by increased flow or by increased oxygen extraction In the presence of coronary stenosis associated with anemia, the effect of coronary arteriolar dilation in increasing coronary flow is minimized by the high fixed resistance of the stenotic artery, and myocardial depression and failure occur at lesser degrees of anemia

VALVULAR LESIONS

Acute elevation of right ventricular pressure by pulmonary artery constriction initially decreases right coronary flow, to be followed quickly by a sustained increase in systolic, diastolic, and mean flow in the right coronary artery and, to some extent, in the left coronary artery Upon release, right coronary flow temporarily increases still further During the sustained response, the systemic blood pressure can be fairly well maintained At the same time both the right ventricular work and metabolism increase, the former arising from the increased pulmonary artery pressure and cardiac output, the latter indicated by the increased right coronary flow and greater oxygen extraction from the coronary blood The coronary response to elevation of left ventricular pressure by aortic constriction central to the coronary ostia is similar to that with pulmonary artery stenosis In both instances, the sustained flow increase indicates a dominant influence of active coronary dilation over the increased mechanical flow-inhibiting effect of increasing extravascular compression which earlier was dominant However, in dogs with congenital subaortic stenosis, reduced coronary flows have been recorded (Pyle, Patterson, and Gregg, unpublished) In such instances the flow-inhibiting effect of extravascular compression is probably not compensated for by arteriolar dilatation This would account for the evidences of myocardial anoxia (myocardial necrosis and fibrosis, sclerosis of intramyocardial arteries, sudden death) in such hearts

HEART FAILURE

The heart shares with other types of muscle the characteristic that an optimum exists beyond which further stretching reduces the force of contraction and leads to myocardial failure In acute heart failure with progressive deterioration of the myocardium from pulmonary artery stenosis, the changes in coronary flow and oxygen usage per minute and per beat may be in the same direction as those described for the right myocardium during pulmonary artery constriction, but of lessor magnitude If the heart failure is severe enough, extravascular compression can become dominant over any active coronary dilation from metabolic proc esses, and coronary flow and oxygen usage may be normal or decrease, with the oxygen extrac tion at times reaching 90% The coronary circu lation in the heart failing with severe aortic stenosis undergoes similar changes When acute heart failure and chronic congestive failure simulating the human condition are induced by surgical complete heart block, changes in left coronary flow and ventricular oxygen consumption rather closely parallel alterations in the reduced left ventricular work In chronic left heart failure due to rheumatic, arteriosclerotic, and hypertensive heart disease, the coronary circulation apparently responds by a slight increase in oxygen usage through maintenance of the left coronary flow and increased coronary arteriovenous oxygen difference The increased oxygen usage corresponds with that indicated above for the right heart in one stage of failure Such hearts have considerable difficulty in transforming released energy into realizable work Studies of the coronary circulation in high-output failure from excessive transfusion or a chronic aortacaval fistula are not available

HYPOTHERMIA

Hypothermia is often used during open heart surgery The associated changes that occur which tend to reduce the coronary flow are a diminution in blood and muscle temperatures, cardiac output, heart rate, cardiac work, and oxygen usage by the heart, and an increased blood viscosity, and a greatly lengthened period of ventricular systole Opposing these factors are the relaxation of the major coronary vessels, which is known to occur with hypothermia, and dilation of the coronary bed caused by the hypotension per se As a result of these determinants, coronary flow is decreased at low temperature However, the percentage of reduction is greater in cardiac output than in coronary flow, which results in an increase in the coronary fraction of cardiac output at temperatures of 25° to 26° C There may be a decrease, an increase, or no change in peripheral resistance

in the coronary bed, whereas in the systemic bed an increase in peripheral resistance occurs Myocardial function appears to be adequate However, many hearts are apparently not too far from failure, because if total venous inflow occlusion (which decreases coronary flow close to zero) is now added to permit open cardiotomy, myocardial failure supervenes, as evidenced by elevation in mean right atrial pressure and postmortem findings This trend can be reversed by perfusion of the coronary system with small volumes of oxygenated blood

SHOCK

Standardized oligemic shock in dogs is characterized during the hypotensive phase by a decrease in cardiac output, systemic blood pressure, cardiac work, stroke volume, stroke work, and by an increase in heart rate and an adequate central venous pressure Coronary flow and coronary resistance are greatly decreased Coronary flow is generally greater and the resistance generally less than can be accounted for by a simple decline in arterial blood pressure At the same time, the oxygen uptake decreases, and the coronary arteriovenous oxygen difference is generally unchanged (The coronary response to sustained hypotension through spinal anesthesia or injection of procaine and Etamon is similar) With restoration to normal systemic blood pressure by reinfusion (intraarterial and intravenous routes are equally effective), coronary flow is greater and flow resistance is less than at an equivalent arterial blood pressure in the preshock state, and the augmented flow is maintained even if circulatory failure subsequently intervenes

The fact that early in the hypotensive phase ventricular end-diastolic pressure does not rise indicates that the functional capacity of the heart is adequate for the work performed At times after prolonged hypotension there may be evident cardiac dilation and elevated left and right atrial pressures, with the heart eventually proceeding to ventricular fibrillation or standstill, suggesting that myocardial depression or failure is partially responsible for the hemorrhagic shock syndrome Gross and microscopic evidence of myocardial injury appears in both reversible and irreversible shock Such myocardial depression could be caused by an insufficient coronary flow during either the hypotensive or the restoration periods The high coronary flow during the restoration period would seem to preclude an insufficient coronary flow during this phase as an adequate explanation During the hypotensive period, the actual coronary flow is greatly curtailed The problem is whether the associated sizable reduction in coronary resistance is sufficient to permit enough blood to reach the myocardium to prevent it from failing In some instances, at least, this loss of myocardial contractility is consequent upon an insufficient coronary flow, since the relation of atrial pressure to cardiac size can be reversed by increasing mildly with a pump left coronary flow without change in either the hypotension or blood volume

HYPERTENSIVE CARDIOVASCULAR DISEASE

An exception to the general picture of coronary compensation to increased systemic stress appears to be the response of the chronically hypertensive heart In essential hypertension with a normal cardiac output and elevated systemic blood pressure, the coronary flow and oxygen consumption per 100 g of ventricular muscle are unaltered while coronary resistance increases This increased resistance is also present in the renal and cerebral circulations Since these hearts are generally hypertrophied, *total* coronary flow and oxygen usage are increased This deviation (increased cardiac work with little change in coronary flow and oxygen usage per 100 g of ventricular muscle) is explainable if it is assumed that such hearts with known coronary artery disease have an increased amount of perfused fibrotic tissue

EXERCISE

Direct measurements of coronary flow have been made in normal unanesthetized dogs by applying chronically an appropriate electromagnetic flow meter (a somewhat modified Kolin type) directly to the circumflex branch of the left coronary artery Illustrated in Figure 3 130 are the changes in phasic and mean coronary flow. First, the dog stood on a treadmill, then ran for 3 min at 12 miles/hr at a 5% grade, and finally, stood at rest Although not measured, the blood pressure and cardiac output obviously rose in this dog as they have in other dogs A pulse pressure pattern has been sketched in for orientation purposes The control flow is 46 ml /min , with most of this oc-

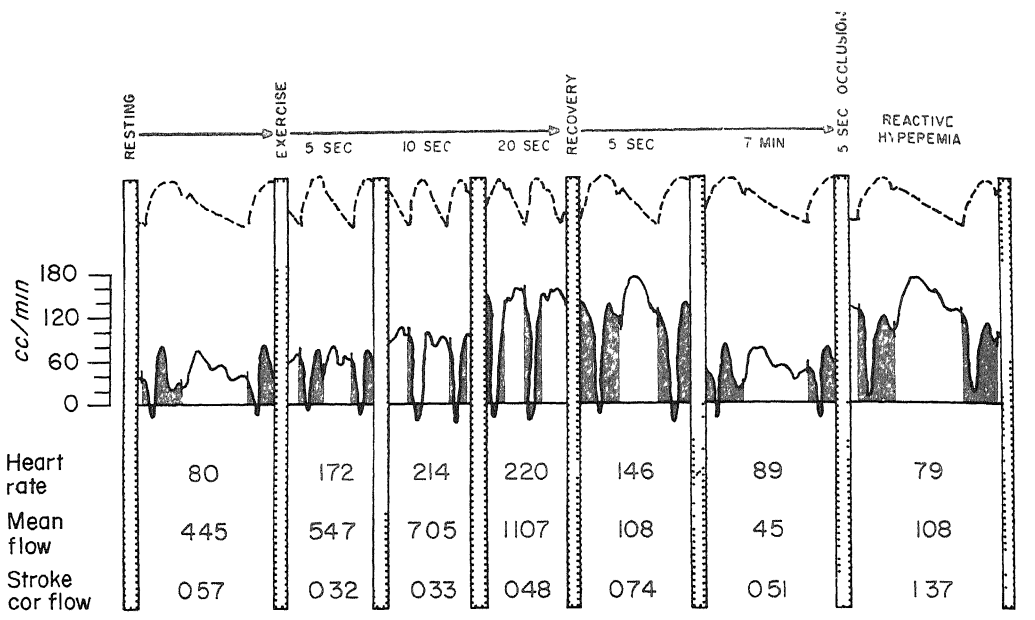

Fig 3 130 Response of the unanesthetized intact dog to exercise Curves are redrawn from the original experiment Phasic flow curves obtained with an electromagnetic flow meter monitoring an internal mammary-circumflex coronary anastomotic shunt *Upper curve* aortic pressure *Lower curve* phasic circumflex coronary flow (D E Gregg unpublished data)

curring during diastole Within 15 to 20 sec after the onset of exercise, the changes in the coronary flow response are complete and do not change further during the 3-min period of exercise The changes include an increase in heart rate from 80 to 220/min , a reduction in duration of both systole and diastole per beat and an increase in mean flow from 46 to 111 ml /min Calculation shows that the flow per heart beat is mildly decreased, and, hence, the mean flow increase is entirely on the basis of the increase in heart rate Within 5 sec after sudden stoppage of the treadmill, the patterns and flow have started to revert toward normal, the return to normal is completed within about 7 min The last record was taken so that a comparison could be made between the maximum diastolic rate of flow during exercise and that during reactive hyperemia It was taken shortly after the 7-min recovery period and immediately following a 5-sec occlusion by a pneumatic cuff of the coronary artery in which flow was being measured Despite the slower heart rate, maximum diastolic flow during reactive hyperemia is about the same as that during exercise

In other experiments, left coronary artery flow (electromagnetic flowmeter), cardiac output (a second flowmeter probe on the aorta), blood pressure (from a catheter in the aorta), and coronary sinus oxygen (from a catheter in the coronary sinus) have been monitored In *mild* to *moderate* exercise with little change in stroke cardiac output, with doubling of the heart rate, and with a mild blood pressure rise, coronary blood flow and myocardial oxygen usage *per heart beat* increased slightly, remained the same, or even decreased During induced excitement of the dog or stimulation of the cardiac sympathetic nerves, there was a massive dilation of the left coronary vascular bed, an increased heart rate with a greatly increased myocardial flow and oxygen usage per heart beat occurred Thus the coronary flow response to *mild* to *moderate* exercise is not similar to sympathetic stimulation of the heart in that stroke coronary flow and stroke oxygen usage are not always increased in the former The exercise response does resemble the effects resulting from a mechanical increase in heart rate by means of an artificial pacemaker (see also p 3–220)

SUMMARY

From the preceding discussion, it is apparent that when the primary change is an increase in

cardiac work and cardiac oxygen usage, concurrently, the coronary flow increases while coronary vascular resistance decreases In situations where the cardiac work and oxygen consumption decrease, so does the coronary inflow An exception to this general picture of coronary compensation to changing stress is that of complete aortic coarctation which may be characterized by a reduction in the output and work of the heart but an increased left coronary flow and oxygen usage A second exception is that of chronic hypertension in which the cardiac work is increased, but cardiac output, oxygen usage and left coronary flow are unaltered while coronary resistance to flow increases Thus, in most instances, coronary flow follows a primary change in cardiac stress However, coronary flow correlates best with oxygen usage This relationship is understandable since the oxygen consumption is derived from the product of the coronary flow and the coronary arteriovenous oxygen difference

Coronary Artery Collateral Circulation

The state of the human heart in the presence of naturally occurring coronary insufficiency or occlusion, or the state of the dog's heart in which coronary insufficiency has been experimentally induced, can be improved by augmentation of the naturally occurring coronary artery collateral circulation (by retrograde perfusion of the ischemic coronary bed with arterial blood) or by elevation of the ventricular fibrillation threshold In addition, in man, positive and subjective benefit from drugs or surgical procedures could arise through psychogenic effects which are not necessarily related to the heart

The measurement which is most important, least subject to error, and which has yielded most information, is that of the collateral flow This is determined by collecting the volume of blood that flows externally from a tube inserted into the peripheral end of an occluded coronary artery (retrograde flow) This is done acutely in the open-chest dog before, and sometime after, a variable has been chronically induced to improve collateral flow This is collateral flow before it passes through a capillary bed Collateral flow can also be measured after it has passed through a capillary bed and has appeared in the coronary sinus This can be done when extracardiac tissue with a vascular stalk has been previously placed on the heart to stimulate collateral development The coronary sinus flow is measured before and after clamping the potential extracardiac source of collateral blood Any difference in flow would represent that which has traversed the capillary bed

NATURAL RESPONSE OF THE CORONARY COLLATERAL CIRCULATION

The natural responses of the coronary system during experimental coronary artery constriction and occlusion (which presumably also occur in the heart of man) have been studied extensively Within 1 min after occlusion of a left coronary artery branch, the intracoronary pressure beyond this point drops to about 35/25 mm Hg, the ischemic muscle lengthens during systole of the left ventricle and useful function is lost When the peripheral end of this ligated coronary artery is permitted to bleed externally, collateral arterial blood appears immediately, averaging about 3 0 ml /min for about 50 g of potentially infarcted myocardium Probably not more than 2 4 ml of this blood (containing 0 5 ml of oxygen) would perfuse the myocardial bed if the collateral flow were not permitted to bleed externally This is because of the peripheral resistance existing beyond the point of occlusion This level of collateral flow and oxygen content is estimated to be up to 40% of that calculated as necessary to maintain indefinitely the viability of this myocardium (The oxygen uptake of 50 g of a heart with perfused coronary arteries at rest and doing no external work approximates 1 2 ml as compared to the immediately available collateral oxygen supply of 0 5 ml)

Hence, it is important to try to increase immediately this collateral or retrograde flow The level of retrograde flow does not naturally increase and cannot be made to increase for 8 to 10 hr by drugs or by any known physiological means such as increased heart rate, increased flow in the other coronary arteries or induction of hypoxia or hypoxemia in the other coronary arteries It can, however, be increased by passive elevation of arterial blood pressure (Fig 3 131) Why the collateral flow remains fixed, why the anastomoses function as a set of inert tubes, and why they do not participate in the vasodilatory response of the normal coronary bed is not known It contrasts with the rapid development of collaterals in other vascular beds.

This retrograde flow can be greatly reduced

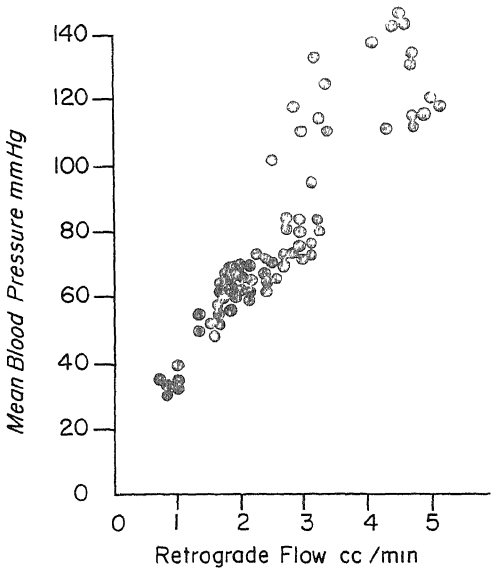

Fig 3 131 Relation of retrograde coronary flow to mean arterial perfusion pressure in dogs (Kattus and Gregg 1959)

by at least two conditions, namely, by excessive stretch of the nonischemic myocardium and by the presence of reactive hyperemia in the other coronary arterial branches One suspects that the reason for the decreased collateral flow in an occluded coronary artery branch while reactive hyperemia exists in the other coronaries is also the excessive stretch of the nonischemic myocardium Thus, the improvement that occurs in the human heart with drugs such as Neosynephrine in the presence of coronary insufficiency and infarction arises because of a good dynamic response in the non-ischemic but over-stretched myocardium This would increase the collateral flow by increasing the coronary perfusion pressure and by decreasing the size of the heart

Most hearts with an occluded coronary artery branch die within a number of hours If they survive the first few hours, then within 12 hr, for some completely unknown reason, collateral flow starts to rise, doubling within 2 days, and within 3 to 4 weeks it may approximate 40 to 100% of normal inflow into that coronary artery At the same time, the peripheral coronary pressure pulse beyond the point of ligation of the coronary artery branch may approximate, in pattern and ordinate values, the aortic pressure pattern simultaneously recorded

This is the usual course of events In other cases, stresses, some known but most unknown, prophylactically enhance the potential collateral circulation without the stimulus of coronary insufficiency or occlusion (Table 3 16) This enhancement is exemplified in man by the increase in the incidence of the injectable collateral bed in the presence of hypertrophy, valvular disease, cor pulmonale, anemia, and probably high altitude It is exemplified in animals by an increase in both the injectable and functional collaterals in the presence of high altitude and transfused anemia No good experimental evidence exists to indicate that physical exercise per se augments prophylactically the collateral flow as measured in a normal coronary artery immediately after its occlusion Even with a combination of moderate coronary artery constriction and exercise, the retrograde flow does not increase

DRUGS VS CORONARY COLLATERAL FUNCTION

Since the vascular bed beyond an occluded coronary artery is presumably maximally dilated by anoxia, it is unlikely that a drug could improve a heart by immediately increasing flow to this area Actually, the best experimental evidence offers no support for the belief that any drug penetrates the connecting collaterals or exerts any beneficial influence in the ischemic bed It has not been possible to increase

Table 3 16
Prophylactic augmentation of coronary artery collaterals by natural stimuli

	Known Stimuli	Incidence of Injectable Collaterals
		%
Man	None	9
	Hypertrophy	26
	Valvular disease	28
	Cor pulmonale	73
	Anemia	39
	Coronary constriction	11-63
	Coronary occlusion	90-100

Pig	Anemia	100
Dog	Transfused anemia	↗
Dog	Mild coronary constriction and exercise	→

the flow of blood into this ischemic area within a short time after coronary artery occlusion, or to retain myocardial shortening by the use of drugs that are known to dilate the normal coronary bed, such as papaverine, nitroglycerine, epinephrine, aminophylline, Coramine, and khellin In chronic experiments, cortisone and ACTH do not promote collateral flow or reduce the size of infarcts The hypothesis that coronary occlusion reflexly decreases flow in other nonoccluded coronary arteries is negated by the experimental fact that flow in nonoccluded coronary arteries generally rises with coronary artery ligation The alleged favorable effect on survival of prophylactic and therapeutic drugs, such as papaverine and quinidine, is best explained by their known action in raising the fibrillation threshold and in reducing the excitability of the myocardium

NATURAL RESPONSE OF THE NORMAL BUT OVERSTRESSED PORTION OF THE MYOCARDIUM

Since the collateral flow does not increase for some hours, any early natural compensation must occur, not by improvement of the circulation in the affected area, but through enhanced action of the normal myocardium which is not involved Nonfunction of involved muscle following coronary artery occlusion reduces the total myocardial force available for raising intraventricular tension The immediate consequences, which lead to a hypodynamic ventricle, are a reduction in left ventricular systolic pressure, aortic pulse pressure, systolic and diastolic pressures, duration of systole, stroke volume and stroke work In this situation, left coronary inflow decreases considerably because of the mechanical reduction in size of its peripheral vascular bed However, within a few minutes, the nonischemic portion of the heart puts into operation compensatory mechanisms by means of which dynamic conditions are largely restored to normal, provided the nonischemic myocardium is in a good responsive condition Briefly, as the result of the lesser expulsion of blood with hypodynamic beats, the accumulating systolic remainder added to the oncoming blood stretches the viable muscle more and raises the ventricular end diastolic pressure or left atrial pressure This combination of increased pressure in and increased radius of the ventricular cavity causes the normal muscle to contract more vigorously, thereby restoring normal hemodynamics In this situation of increased cardiac work per unit of functioning myocardium, coronary flow, arteriovenous oxygen difference, and metabolism of the left ventricle increase The increase in oxygen uptake is equal to, and at times can be much more than that lost by the deletion of noncontractile muscle

However, not all hearts react as well because the viable portion of the myocardium may not respond to stretch, or may respond only temporarily This has been most thoroughly studied when the coronary obstruction has been induced by intracoronary injection of microspheres This leads to acute or progressive heart failure associated with a profound hypotension with a decreased cardiac output, and the clinical signs and symptoms of shock The clinical inference that this is due to the supervention of peripheral circulatory failure has not received heavy experimental support On the contrary, experimental work favors the view that, in this situation, circulatory failure not due to severe irregularity of the heart beat is due, successively, to defection of useful contractions in the ischemic area, a loss of contractile energy through expansion of the affected area, and failure of the still viable fractions to compensate adequately

ATTEMPTS TO IMPROVE CORONARY COLLATERAL CIRCULATION

The coronary arteries of the normal human heart are not "end arteries," but possess numerous collateral connections with adjacent vascular areas which can be increased by a variety of procedures (Gregg, 1969, Baroldi, 1969)

The state of the heart following coronary artery occlusion can be improved considerably by various physiological and surgical procedures The principles of the procedures used, together with the surgical manipulations, are shown in Table 3 17 These approaches include section of the cardiac sympathetic nerves, induction of myocardial hypoxia by various manipulations of the coronary venous system, production of chronic epicardial granuloma by mechanical and chemical means, application of extracardiac tissue to the heart, internal mammary artery ligation, sham operations, irradiation of the heart, coronary endarterectomy and coronary artery bypass

Animals. In the dog the coronary arteries function chiefly as end arteries and collateral

flow is normally negligible (Hammond et al , 1969) Hypoxemia (e g , coronary artery occlusion) activates interarterial anastomoses, increasing the effectiveness of collateral circulation (Blum et al , 1970)

Many of the procedures in Table 3 17 in the experimental animal are of positive benefit to the heart and give immediate or sustained protection against subsequent ligation of a major coronary artery ramus This is illustrated in the data obtained in many laboratories (Table 3 18) Ligation of a major ramus of the left coronary artery causes about a 70% mortality within the first 1 to 2 hr , and chronically there is considerable infarction When partial or complete occlusion of the coronary sinus precedes coronary artery ligation, or when a portion of the coronary bed is perfused in retrograde fashion by connecting the coronary sinus to an artery, the immediate mortality is reduced considerably With the exception of section of cardiac sympathetic fibers and internal mammary artery ligation, all other procedures listed—chronic coronary venous maneuvers, application of various

chemical and mechanical irritants, separately or in combination, and application of extracardiac tissue to the heart lead to a significant reduction in mortality and infarction

Man. All of the procedures listed in Table 3 17 designed to promote collateral development, including the sham operation, have been applied to the heart of man suffering from coronary artery disease All appear to increase to some extent the work and exercise tolerance and to decrease the cardiac pain These observations are not necessarily explained on the same basis as the improvement in the collateral circulation which follows such procedures in the dog This is because, in the dog, surgery precedes coronary artery ligation, whereas in the human, surgery follows coronary artery occlusion Surgery in the dog is designed to promote collaterals in the presence of a normal coronary circulation Surgery in the human is designed to promote collateral circulation after the coronary insufficiency has been naturally established In man, hypoxia, the greatest known vessel dilator, and a natural stimulus to collateral development, has already been working for many months To be effective, the surgical procedure must supply a stimulus to collateral development far more potent than hypoxia This has never been demonstrated in animals in which coronary insufficiency has previously been induced

The explanation of the results in man is not clear It may be that some subjects are protected and live longer because of the known experimental fact that handling the heart enhances the ventricular fibrillation threshold Some may be improved by procedures such as de-epicardialization which could obliterate the afferent pathways for pain However, results of the sham operation of Adams and of others, involving only a skin incision, strongly suggest that much of the positive benefit is on a psychogenic basis

Coronary endarterectomy, which has been applied to man, is on a sound physiological basis, and its purpose is entirely different from the preceding The surgeon directly re-establishes coronary flow through the original coronary artery by removing its atherosclerotic plug It does not require collateral development and should be effective provided there exists a gross coronary insufficiency of blood beyond the obstruction, provided the vessel remains patent and thrombi do not form, and provided there are no sizeable atherosclerotic lesions beyond the region of the occluded coronary artery Only a small group of patients have benefited from this type of operation and long term evaluation is not available Patients must be chosen carefully for this procedure with the above criteria in mind

Finally, bypass of a length of an occluded coronary artery by anastomosis of its peripheral patent end to a systemic artery has been recently applied therapeutically in man (Green et al , 1970) In dogs, a nonsuture anastomosis by intima to intima contact between the left coronary artery and the left internal mammary artery has been highly successful In almost all of the dogs, the anastomoses have been demonstrated to be patent as evidenced by gross observation, angiography, and measurement of coronary blood flow through the anastomosis up to the time of dog sacrifice (12 to 24 months after operation) End-to-side anastomoses of the internal mammary artery to 1 0 mm diameter segments of the anterior descending coronary artery is feasible in dogs, and results in long term patency and high flow Such a procedure was shown to relieve anginal symptoms and to increase exercise capacity in a small series of patients (Green et al 1970)

There is, however, a possible late complication to successful coronary endarterectomy or coronary bypass in man which must not be overlooked In the presence of such a large new blood supply, the existing collateral flow might disappear If another coronary occlusion subsequently occurs, the patient would be in difficulties because he had lost his collaterals

SUMMARY

From the preceding, it would appear that in the normal heart a moderate collateral circulation exists which functions immediately following a coronary artery occlusion Different prophylactic procedures are successful experimentally in preserving life either by compensating for a deficit in the supply of collateral oxygen or by preventing ventricular fibrillation This protection against occlusion of a coronary artery may be dependent upon a collateral development on the arterial side of the order of magnitude of that essential for viability Human coronary surgery which follows coronary insufficiency has no counterpart in animal experiments and these human coronary experiments cannot as yet be interpreted on a physiological basis

7 / MEASUREMENT OF BLOOD PRESSURE AND FLOW

Direct Measurement of Blood Pressure

In the direct approach, a catheter or needle is inserted into a vessel or heart cavity and connected to a hydrostatic column of fluid or to a special device Miniature transducers for implantation within the artery have been developed and employed for both hard wire recording and telemetering of blood pressure signals from free ranging animals (Van Citters and Franklin, 1969) Pressures thus obtained in almost all parts of the cardiovascular system of animal and man have been quantitated and studied Direct pressure measurements have value in determining certain aspects of function of the circulation They should not, however, as is pointed out elsewhere, be used as an index of change in flow through or volume of a blood vessel or heart cavity Whenever a change in volume is empirically deduced from a change in pressure, potentially active changes in caliber are ignored which are known to occur in every vessel except the capillaries

MEASUREMENT OF NONOSCILLATORY OR NEARLY NONOSCILLATORY PRESSURES

A vertical column of fluid with attached millimeter scale, and with some form of anticoagulant between it and the vessel whose pressure is being tapped, is the only device needed to determine the pressure in most intravascular pressure regions To measure the pressure, the column is filled from a side tube, and the column is then allowed to seek its own level by drainage into the vessel For measuring cerebrospinal fluid pressure, intravascular pressure in arterioles, capillaries and venules, and extravascular pressure in the tissue space in skin, muscle, kidney, subcutaneous tissue, etc , water or saline manometers are used in which little or no fluid enters or leaves the manometer This method yields higher values for tissue pressure, (+1 to +3 mm Hg) than those obtained with implanted perforated capsules, or in fluid spaces beneath the skin Interstitial fluid pressure measured by these methods is actually negative (−3 to −9 mm Hg) The existence of negative interstitial fluid pressure, although controversial, has its counterpart in negative pressures (−5 to −10 cm H_2O) measured in the peripheral cavity, joint spaces, and in subcutaneous spaces (Gauer et al , 1970) Obviously, the usual values employed in the Starling ratio for forces acting across the capillary wall must be modified to account for fluid exchanges where the interstitial pressure is negative (See sect 4, chap 12)

MEASUREMENT OF PRESSURE PULSES

Basically, all types of pressure apparatus involve measurement of the displacement of some type of elastic membrane which is moved by generation of pressure in a vessel or cavity In one group of manometers, an essentially nondistensible conduit (needle, lead tube, cannula, or catheter) is filled with fluid and connected to the membrane outside the body, this, in turn, is connected to a form of amplification and recording, in the other, a micromanometer membrane or its equivalent is mounted in a catheter tip at the pressure source, and the catheter serves only as a conduit for wires to the amplifying and recording assembly (Fig 3 132) The detection and transmission of the movements of the membrane can take place by mechanical, optical, or electrical means, or by a combination of these principles Owing to their technical imperfection, purely mechanical systems are now only of historical interest Pretty much in the same category are manometers which combine optical and electrical systems

Manometers Mounted in an Empty Catheter Tip. In this type of gauge, the pressure sensitive element is mounted in the catheter tip, the catheter contains no fluid, and merely

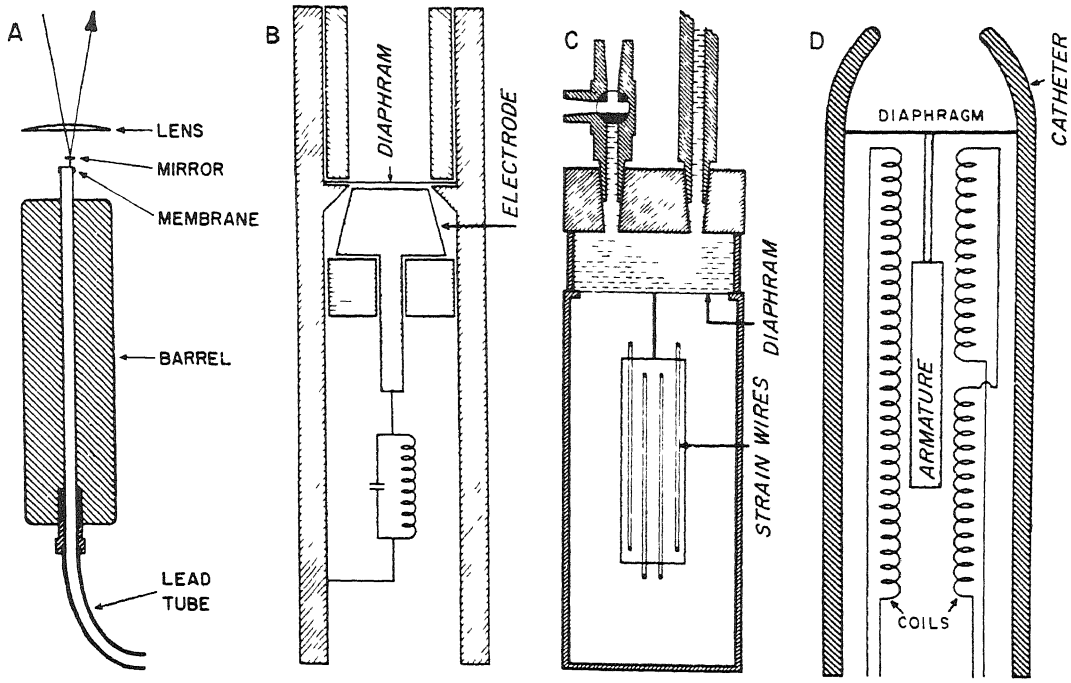

Fig 3 132 Externally recording pressure gauges *Left* principle of the classical optical method for determining biological pressures A flexible short nondistensible lead tube offering little damping effect connects to the pressure source *Center left* capacitance transducer *center right* strain gauge transducer and *right* catheter mounted inductance transducer

functions as a conduit for wire leading to an amplifier Inductance pressure gauges of this type are used in which the variable mutual inductance between a pair of coils can be altered by changing the position of an iron core within its magnetic field If the iron core connected to the center of an elastic membrane is mounted between two coils, movement of the membrane moves the core within the coils, changing their inductance Change in inductance, monitored by an appropirate bridge circuit indicates the extent of membrane displacement (Fig 3 132) This instrument was first devised by Wetterer (1954) and has been considerably modified and improved by others The strain gauge principle has also been applied to a micromanometer mounted in the end of a catheter In this, a strain wire wrapped around a metal reed with multiple longitudinal slits is stretched by the pressure source

Both the inductance and strain gauge type of micromanometer faithfully record the pressure pattern but are difficult and expensive to build Inductance gauges have been used in animals and, at times, in humans, but their use has been limited because it has not been possible to determine accurately the zero pressure with the Wetterer type Although the strain gauge type does not have this disadvantage and has been used with some patients, its initial expense is higher than the inductance type, and it has the added drawback that no way has been found to disconnect it from its catheter which wears out first

For precise quantitation, the intravascular pressure should be measured against the extravascular or tissue pressure which is around the vessel The terms, *effective*, *transmural*, and *net pressure*, have been introduced to indicate the pressure difference between the intravascular and extravascular pressure Precise determination of extravascular pressure, however, is unreliable

Indirect Blood Pressure Measurements

Although the blood pressure can be determined by inserting a hollow, wide-bore needle into an artery and connecting it with a suitable manometer, such a method is usually reserved for human cardiopulmonary diagnostic

work Convenience and safety demand that any method for general clinical use must be indirect The principle employed involves the balancing of air pressure against the pressure of the blood in the brachial artery The air pressure is estimated by means of a mercury or an aneroid manometer

The instrument used for this purpose includes an inflatable flat rubber bag covered by a nondistensible envelope of fabric, called the cuff The cavity of the bag is connected to both the manometer and a hand bulb or small pump by rubber tubing By this means the bag can be inflated to any desired pressure A small valve between the bulb or pump and the bag permits the escape of air, and the reduction of the pressure as required The uninflated rubber bag is wrapped snugly around the upper arm just above the elbow The bag is then inflated until the air pressure within it overcomes the arterial pressure and obliterates the arterial lumen The pressure is increased a little beyond this point and is then cautiously reduced again,[1] by the release of the valve, until the arterial pressure just overcomes the air pressure and blood escapes beyond the cuff into the peripheral section of the artery At this instant the pressure in the bag is read from the manometer Since the air pressure practically balances the systolic arterial pressure the manometer reading must indicate the value of the latter It is essential to the method that the manometer reading be taken at the instant when the blood escapes beneath the cuff

One of three methods, the *palpatory*, *oscillatory*, or *auscultatory*, may be employed to determine when the blood first escapes beneath the cuff In all three procedures the value for the lateral pressure in the brachial artery is obtained, whereas direct methods (which entail the introduction of a straight, unbranched cannula, or a large-bore needle into an artery) measure the end pressure The latter is greater because it includes not only the lateral pressure on the elastic arterial wall, but also that derived from the conversion of the kinetic energy of the moving blood column as it meets the obstruction, and the increment of pressure caused by the reflected wave from the obstruction

AUSCULTATORY METHOD

This procedure is the one generally employed clinically, It was introduced in 1905 by the Russian physician Korotkoff Certain sounds heard during auscultation over the brachial artery distal to the cuff are taken as the criteria for the systolic and diastolic pressures Under ordinary circumstances if a stethoscope is placed over the brachial or any other artery, no sound can be heard as the flow of blood through the channels is inaudible If, however, the artery is compressed by the manometer cuff so as to completely arrest the flow of blood, a sharp light tapping sound, in rhythm with the heart beat, will be heard when the pressure in the cuff is released and falls just sufficiently to permit the arterial lumen to open As the pressure in the cuff is progressively lowered the sound undergoes a series of changes in quality and intensity

Four phases of the sound, each having its distinctive character, may be heard in succession in the normal individual, as the pressure is gradually reduced from about 120 to 80 mm Hg or less These are described below with the average pressures at which they are normally heard (Fig 3 133)

Sounds of Korotkoff Phase I Sudden appearance of a clear, but often faint, tapping sound growing louder during the succeeding 10 to 14 mm Hg fall in pressure

Phase II The sound takes on a murmuring quality during the next 15 to 20 mm fall in pressure

Phase III Sound changes little in quality but becomes clearer and louder during the next 5 to 7 mm fall in pressure

Phase IV Muffled quality lasting throughout the next 5 to 6 mm Hg fall After this all sound disappears

Phase V Point at which sounds disappear

The muffling and disappearance are commonly referred to as the fourth and fifth points If there is a detectable difference between these, it is recommended (Kirkendall et al, 1967) that they be recorded e g , 142/82/78 mm Hg (142 = systolic, 82 = fourth phase, 78 = fifth phase) If the fourth and fifth points

[1] Should deflation be carried out too rapidly the mercurial type of clinical manometer shows a considerable lag, due to the time required for the air above the mercury column to reach atmospheric pressure With rapid deflation, particularly when the heart rate is slow, the actual point at which arterial pressure overcomes cuff pressure may be missed The rate of deflation should not exceed from 2 to 3 mm Hg/sec

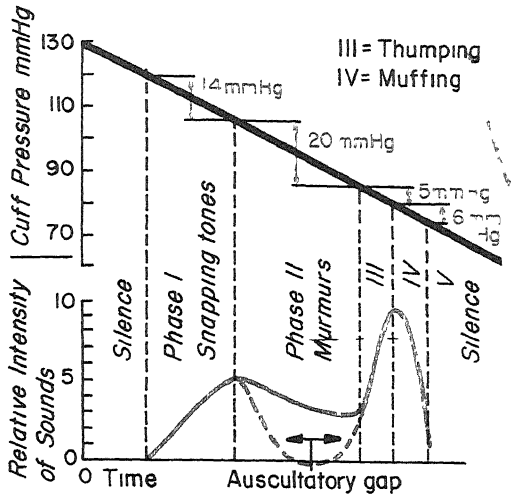

Fig 3 133 Characteristics of the auscultatory method of measuring blood pressure (Redrawn from Geddes 1970)

are identical, this should be recorded e g, 144/76/76 Muffling (Phase IV) occurs at pressures 7 to 10 mm Hg higher than direct intra-arterial diastolic pressures Disappearance of sounds (Phase V) occurs close to intra-arterial diastolic pressures in adults at resting heart rate With increase in flow as with exercise, it falls far below true diastolic pressure because the opportunity for intra-arterial turbulence is greater Under such circumstances Phase IV and V may be separated by 40 mm Hg or more, with Phase IV being closest to true diastolic pressure In children, in whom flow velocity is often high, Phase IV has been found the more reliable index of diastolic pressure

Auscultatory Gap. As shown by the sound intensity curve in Figure 3 133, the Korotkoff sounds may temporarily disappear during the latter part and Phase I and Phase II This gap may cover a range of 40 mm Hg and cause marked underestimation of systolic pressure if the cuff pressure is increased only to the level at which the sounds are absent This may be avoided by checking the palpatory systolic pressure first, when the palpatory systolic pressure is highest it should be accepted as the reliable determination Venous congestion associated with slow cuff deflation or rapidly repeated occlusions increases the occurrence of auscultatory gap Thus rapid cuff deflation (2 to 3 mm Hg/sec), allowing 2 to 3 min to elapse between determinations, and raising the arm to promote venous drainage, reduce or eliminate auscultatory gap

Arterial blood pressure cannot be measured with precision by means of sphygmomanometers The method is attended by inaccuracies caused by variations in heart rhythm, the presence of normal respiration, and resistance of the tissues of the part To compensate for tissue resistance, a rule of thumb is that the inflatable arm bag should be approximately 20% wider than the arm diameter, or approximately 12 cm for adults, 8 cm for children less than 8 years, 5 cm for children less than 4 years, 2½ cm for children less than 1 year For the adult thigh the bag width should be approximately 18 cm and such bags are useful also on the upper arm of obese individuals Despite use of such cuffs, a mean error of ±8 mm Hg may be expected in individual readings of systolic and diastolic pressures In general, the auscultatory method tends to underestimate systolic pressure and overestimate diastolic pressure In the arms of people with much fat tissue, the error is further exaggerated, in arrhythmias, deep breathing, or abnormalities of the arterial wall, the errors are still larger Increases in the resistance of the arterial wall, as a result of sclerotic changes or simple hypertonus of the muscular coat, give readings that are too high Repeated compression and decompression just before the actual determination is made may remove any spasm of the arterial wall sufficiently to reduce this source of inaccuracy Though lower readings as a rule are not obtained in a normal individual by repeated readings, in others with apparently normal arteries, the reading obtained after the third or fourth trial may, as a result of the reduction in tone of the vessel wall, be lower than the initial observation by several millimeters

Determination of the blood pressure in the human thigh by the auscultatory method gives incorrectly high values and has led to the misconception that leg blood pressure is higher than arm blood pressure Simultaneous direct intra-arterial measurements in the brachial and femoral arteries have shown the two pressure curves to be similar in all respects (Pascarelli and Bertrand, 1964)

OTHER INDIRECT METHODS

A variety of other methods based on the use of an occluding cuff have been devised in which

various sensors are employed for detecting sound, pulsation, or blood flow below the cuff

Flush Method In this method, cutaneous blood is forced out of the extremity below the cuff, the cuff is inflated above systolic pressure and slowly (6 to 7 mm Hg/sec) deflated Systolic pressure is indicated when the pale, bloodless skin flushes Applied to the adult finger the method gives systolic values below the auscultatory method and is unreliable if digital vasoconstriction is induced by emotional or temperature changes The method has found practical application in newborn infants applied to the hand or foot

Pulse Detectors. Various types of pressure transducers have been applied below the cuff to detect the earliest arrival of pulsation as the indicator for systolic pressure The size of the signal obtained varies as pulsation increases and these characteristic variations have been used to estimate (in general unreliably) mean or diastolic pressure

Microphones. Korotkoff sounds may be amplified by means of piezoelectric microphones mounted within or below the cuff The electrical signal obtained may be amplified to increase audibility or used to actuate a voltmeter or other visual signals such as a flashing light

Ultra-Sound. Ultra-sound may be used to detect arterial wall movements as pressure is decreased in the blood pressure cuff Ultrasound transmitting and receiving crystals are placed over the artery beneath the cuff The doppler signal received identifies the opening and closing of the artery At cuff pressure just below systolic level opening occurs only at the peak of pressure, followed rapidly by closure The time interval between these two signals increases as cuff pressure declines until it is low enough that the vessel remains open during the pulse

INDIRECT MEASUREMENT IN ANIMALS

Indirect blood pressure determinations in animals are made with adaptations of the methods described for man An additional extremity, the tail, is available in many species and exteriorized arterial loops may be employed for application of the occluding cuff The precision and accuracy of these methods decreases with decreasing size of the subject owing to difficulty of pulse and sound detection and vasomotor changes in the muscular distributing arteries to the extremities under various conditions

Equipment and methods for radiotelemetry of blood pressure and flow have been developed and employed in free ranging terrestrial and aquatic animals (Van Citters and Franklin, 1969a, b)

Measurement of Volume Flow of Blood

The most important measurement in the circulation is that of the volume flow of blood through the aorta or through any vital region or organ The blood flow is most sensitive to a change in dilation in a vascular bed If the blood pressure is doubled, the blood flow might also double but doubling the mean bore of a vascular bed might increase the blood flow by 16 times In the past, advancement of flow methodology has been slow and limited in large measure to devices applicable under highly abnormal conditions In use, the animals have been exposed to so much insult by anesthesia, surgery and trauma that the measurements do not necessarily have resemblance to normal values, i e , the relative importance of factors regulating flow can be quite different than in the normal state

VISUALIZATION (HUMAN OR ANIMAL)

Direct microscopic *in vivo* visualization of the components of the microcirculation (terminal arteries, arterioles, capillaries, venules, and very small veins) offers a means for studying qualitatively the peripheral circulation and control of blood flow in various regions When capillaries, arterioles or any of the above vessels are observed to decrease in diameter, they are assumed to have constricted and thus to decrease flow Despite this, such observations have contributed greatly to our knowledge of the circulation Direct microscopic and high speed photography have been used in the frog skin, bat wing, rat mesoappendix, dog omentum, lungs of the open-chest dog, transparent viewing chamber of the rabbit's ear, bulbar conjunctiva and skin of humans, and pial vessels of the brain through a transparent viewing chamber Change in small terminal arteries (and possibly arterioles) has been visualized in the coronary circulation of the heart of the closed-chest dog and in humans with

cinéphotography following injection of contrast medium directly into the coronary arteries

VENOUS DRAINAGE

One of the oldest, simplest and most satisfactory means of determining blood flow is to collect and measure the outflow from a cannulated vein draining a particular organ The rate of flow can be read from a graduate, or from the change in weight of a collecting container on a scale For very low rates of flow, drop recorders are used in which each drop shorts a pair of contacts in an electrical system or interrupts a photocell light beam

PERFUSION SYSTEMS

For many investigations and certain surgical procedures, it is desirable to have controlled perfusion of an organ, body region, or the whole body at constant flow rates and/or at constant perfusion pressures, which are the same or different from the prevailing aortic pressure Pump systems have been used to perfuse isolated organs and to perfuse, in the unanesthetized as well as the anesthetized animal, the vessels of an extremity the brain, liver, kidney, and the coronary vessels of the heart Mechanical pumps serve also at temporary replacement for the left ventricle, right ventricle, and the whole heart, i e , the whole body including the coronary arteries is perfused with a pump Their use for bypass of the right heart, left heart and whole heart is shown in principle in Figure 3 134 *J*, *K*, and *L*

Mechanical Circulatory Assistance (Cardiac Assist Devices). Mechanical assistance to the circulation is the application of any energy-producing device to aid blood flow Methodological complexity extends from simple manual cardiac massage, temporary partial or complete cardiac bypass, through to total cardiac replacement with an implantable artificial heart The chief techniques which have been employed are listed in Table 3 19 and illustrated in Figure 3 134

Cardiac massage, external (Fig 3 134 *A*) or internal (Fig 3 134 *B*), is applicable for assistance for periods up to several hours External manual massage by compressing the heart between the sternum and spine is an effective emergency procedure used to maintain circula-

tion until the cause of cardiac arrest can be corrected or more effective measures applied

The object of *counterpulsation* is to reduce the pressure against which the ventricle must pump during systole (afterload) and to improve coronary flow during diastole Its physiological bases are *1*) that the oxygen requirement of the heart is decreased by reduction of afterload and 2) that coronary volume flow can be greatly increased by a high diastolic perfusion pressure which acts when ventricular wall tension is low and, consequently, coronary vascular compression is minimal *Synchronized arterial assistance* (Fig 3 134 *C*) consists of withdrawal of blood from the aorta just before and during systole, thus reducing the pressure against which the left ventricle ejects blood, and returning the same volume of blood during diastole, to increase diastolic pressure and thereby increase coronary flow

Intra-aortic counterpulsation (Fig 3 134 *D*) is a blood volume displacement method A gas-filled balloon in the aorta is deflated during cardiac systole, thus lowering intra-aortic pressure during left ventricular ejection The balloon is then distended by gas pressure after aortic valve closure, this increases diastolic pressure and coronary flow by volume displacement

Aortic blood volume displacement is also involved in *external limb counterpulsation* (Fig 3 134 *E*) The limbs are incased in a sheath so that when suction is applied during systole, arterial capacity in the limbs is increased, with drawing blood from the aorta Positive pressure during diastole returns blood to the aorta

Right ventricular assist by synchronous respiration (Fig 3 134 *F*) With this method the capacity of the pulmonary vascular bed is increased during cardiac systole so that right ventricular afterload is decreased This is accomplished by pressure variations applied either through an airway or externally to the chest wall by a cuirass The negative pressure is synchronized with systole, increasing pulmonary vascular bed capacity and decreasing right ventricular pressure

Ballistocardiogram-triggered assistance (Fig 3 134 *G*) has been tried with the idea of moving the body appropriately during systole and diastole as a counterpulsation method

An "in series" auxiliary ventricle has been employed to accomplish counterpulsation (Fig 3 134 *H*) A pneumatically activated pumping chamber, which contains no valves, is inserted in series with the aorta During systole the pumping chamber is evacuated to lower aortic pressure (afterload) During diastole, after the aortic valves close, the blood is pumped back into the aorta, increasing flow into the coronary arteries and the rest of the circulation

An *"in-parallel" auxiliary ventricle* (Fig 3 134 *I*) has been developed which takes blood from the left atrium and returns it into the aorta during diastole Thus left ventricular work is decreased and coronary flow increased This is a form of left ventricular bypass Another type of left ventricular bypass via the peripheral circulation similarly accomplishes "parallel pumping" (Fig 3 134 *J*) Blood is withdrawn from the left atrium into a reservoir and pumped back into the arterial system through a femoral artery If the blood is withdrawn rapidly enough, left ventricular filling may be prevented and full bypass of the left ventricle accomplished

Right ventricular bypass (Fig 3 134 *K*) is effected by removal of blood from the right atrium and pumping it back into the pulmonary artery, thus sparing the right ventricle In *complete heart-lung bypass* (Fig 3 134 *L*), the systemic venous return is drained into a reservoir, pumped through an oxygenator and returned to the arterial system under pressure Coronary sinus blood returning to the right

atrium and bronchial flow drainage into the left atrium are removed via catheters

Veno-arterial bypass with oxygenation (Fig 3 134 *M*) is a form of heart lung bypass in which blood is taken from the venous side, oxygenated, and pumped back into the femoral artery, either in an unsynchronized manner or coordinated with the heartbeat (e g , *veno-arterial phased pulsatile partial bypass*, Fig 3 134 *N*)

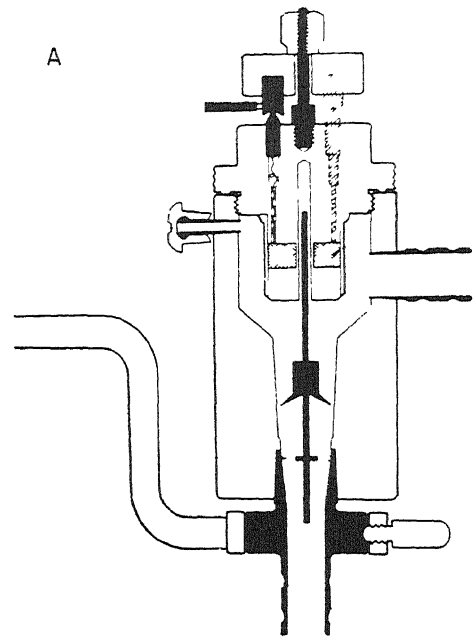
Finally, implantable devices which can supplant the heart mechanically have been devised and tested in animals

Except for short term use, as in cardiopulmonary bypass for heart surgery, these various methods of circulatory assistance are in the experimental stage Some require formidable surgical intervention, many produce serious hemolysis, and lead to thrombosis and embolization through effects on blood clotting factors Although their practical application lies in the future, there can be no doubt of the enormous benefits successful devices will confer in the treatment of cardiac failure and circulatory shock (see Soroff et al , 1969, Proctor, 1969, Kolff et al , 1969, and Burns et al , 1969)

Various expedients have been used to perfuse an organ or region (Fig 3 134, *O*) For example one end of a pump may be connected to a local arterial source and the other end of the same pump to the artery of the organ or region being supplied Either the perfusion pressure or flow rate can be varied separately This approach obviously has the important advantage that it enables the investigator to study separately the peripheral factors in the organ or region that regulate flow

MEAN FLOW RECORDERS

Because of the imposed resistance to flow, most mean flow recorders are not suitable for use in the path of venous flow but are acceptable in the arterial system where a small drop in pressure across the meter is not so important The types that have given much information regarding the operation of the cardiovascular system include the mechanical stromuhr, bubble flow meter, rotameter, and turbinometer How they work is shown in Fig 3 135*A*, *B*, and *C* They have the disadvantages that they require anesthesia, injection of anticoagulant, insertion between the cut ends of the vessel in which flow is being measured, and their response time is slow, the fastest (the rotameter) being of the order of 90% complete in 1 sec Despite these disadvantages and although arterial flow is highly phasic these devices have been most helpful



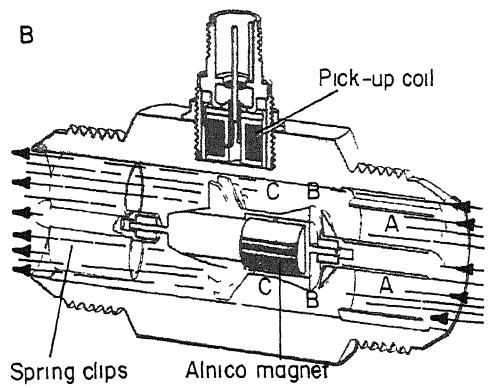


Fig 3 135 *A* sectional view of a rotometer Blood flows through the flow chamber entering the bottom inlet tube and leaving through the outlet tube (*right*) supporting the cylindrical float Float position is detected visually or electrically by an induction coil through which a soft iron upper rod extension of the float projects (Shipley and Wilson 1951)

B sectional view of the Potter turbinometer Flowing blood turns the turbine which contains a magnet The rotating magnet induces an electrical signal in the pick-up coil The amplitude of the induced signal is proportional to the rate of rotation and is calibrated for various flow rates (Sarnoff and Berglund 1953)

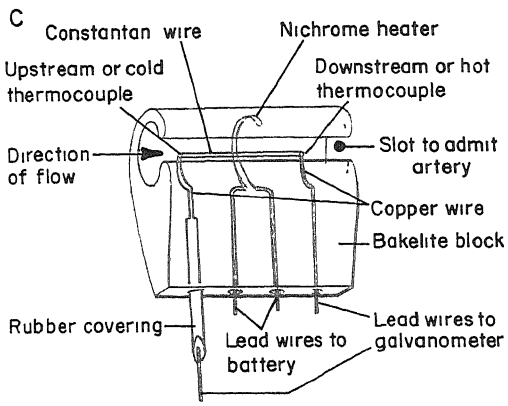

Fig 3 135 *C* diagram of direct current thermostromuhr Blood flowing in a vessel placed in the sleeve reduces the heat created by the electrical heater Temperature changes are detected by the thermocouple unit and reflect rate of blood flow The device is unreliable if external factors alter the relative rate of heat loss (Gregg 1950)

PHASIC FLOW METERS

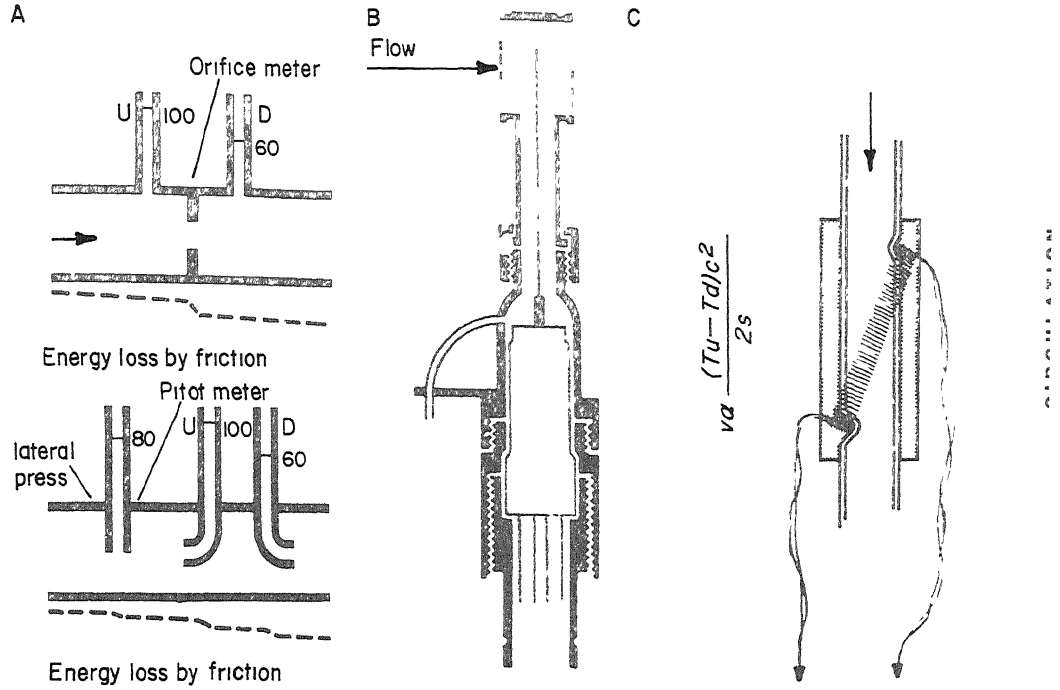
These devices faithfully record the phasic or moment to moment changes in arterial and/or venous flow during a cardiac cycle (Fig 3 136) The differential pressure and pendulum types must be used with heparin and inserted between the cut ends of a vessel, the electromagnetic and sonar flow meters are used to measure blood flow in intact vessels in unanesthetized active animals, the electromagnetic flow meter has been used in anesthetized humans

Differential Pressure Flow Meters By introducing a device between two points in a flowing stream, a pressure difference is created which varies with the velocity of blood flow The ways of creating the pressure differences are illustrated (Fig 3 136*A*)

Pendulum Flow Meters In a principle first described in the 15th century, a small pendulum, paddle, reed, wire, or bristle which is introduced into a blood vessel is deviated from its resting position by the flowing blood, the amount of deviation being proportional to the velocity of flow

Sonar Flow Meter An electrosonic meter has been used to measure flow in the arteries, aorta, and vena cava, and to measure left ventricular diameter of unanesthetized dogs (Fig 3.136 C) In principle, the transit time of sound moving downstream is determined by the velocity of sound in the motionless medium plus the velocity of the medium The transit time of the sound upstream is determined by the velocity of sound in the motionless medium minus the velocity of the medium Thus, the difference in transit time of the ultrasonic waves upstream and downstream is proportional to the velocity of the medium In practice, barium titrate crystals are mounted at diagonally opposed positions near the end of a lucite cylinder divided longitudinally and this is clamped about an artery Bursts of ultrasonic waves (3 megacycles/sec) emitted by one crystal pass through the vessel wall and diagonally through the stream of flowing blood to reach the opposite crystal Bursts are emitted at about 12,000/sec with direction reversal at 800/sec The difference in transit time of the ultrasonic waves is converted into a direct current voltage, amplified and recorded By turning off the ultrasonic pulse generator, the flow beam reaches a position which is the same as that following temporary mechanical occlusion of the vessel This device appears to be usable on both artery and vein

Electromagnetic Flow Meter This type has been used for pulsatile flow recording in the aorta and arteries of the dog and man (Fig 3 136 D and E) A number of different types have been produced, some commercially In the author's laboratory, the Kolin type, somewhat modified, has been used In principle, an electromotive force or voltage is induced in a conductor moving through a magnetic field at right angles to the lines of force In biological use, blood moving within an intact blood vessel serves as the conductor and the induced voltage which is proportional to the blood velocity is picked up by a pair of electrodes positioned against the vessel wall, perpendicular to the magnetic field and to the direction of blood flow The flow meter which is encased in plastic, consists of a miniature electromagnet made up of coils of wire mounted on steel laminations, a slotted plastic tube into which the vessel is inserted, two electrodes, and wires for energizing the electromagnet and for leading off the induced voltage (one-millionth volt) which is amplified and recorded In use, the probe is implanted around an intact blood vessel by temporarily decompressing and forcing the vessel through the longitudinal slit in the probe Its main advantages are its ability to



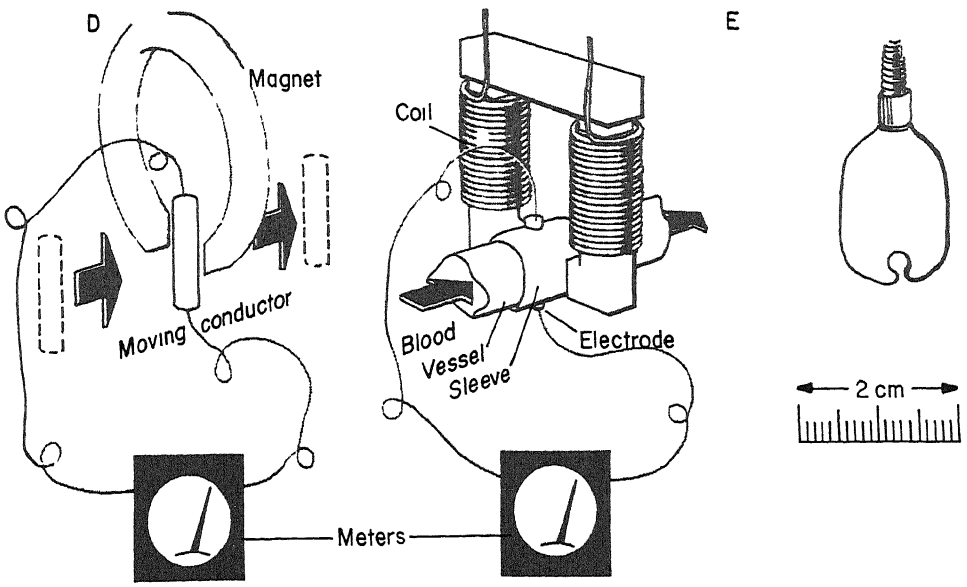


Fig 3 136 ***A B C*** Phasic blood flow meters ***A,*** the orifice meter and the Pitot tube In the orifice flow meter the rate of flow is proportional to the difference in pressure proximal and distal to the region of constriction In the Pitot tube pressure differences are detected between a tube facing upstream and one facing downstream (Brecher 1956) ***B,*** the bristle flow meter Flowing blood deviates a small bristle The degree of deviation is detected electronically and serves as a measure of blood flow (Brecher 1956) ***C*** sonar flow meter Ultrasonic waves are beamed between two crystals Velocity of sound transmission is proportional to the velocity of the blood (Franklin et al 1959) ***D,*** electro magnetic flow meter principle ***E,*** electromagnetic flow meter probe

measure mean and phasic flow in unopened large and small vessels of chronic animals, its linearity of calibration and its high frequency of response The flow beam can be made to approximate the zero flow position by "electronic zeroing" or repeated mechanical flow zeros can be easily obtained even in the exercising dog by temporary (3 to 4 sec) inflation of a rubber pneumatic cuff just distal to the flow meter

FICK PRINCIPLE

Much of our information concerning blood flow, especially the output of the heart is derived from the use of methods based on the Fick principle To employ the Fick principle to determine blood flow through the whole body or an organ, it is necessary to have a substance that is either removed from or added to the blood during its period of flow through the vessels under study The amount which is added or removed from the organ by the blood is equal to the difference between the amount brought into the organ and the amount carried away from the organ The amount of the substance in the blood is expressed as the volume multiplied by the concentration Thus $Q = F_1 \times C_1 - F_0 \times C_0$ in which Q = amount of reference substance picked up or released by the organ, F_1 = blood flow into organ, F_0 = blood flow out of organ, C_1 = concentration of reference substance in the inflowing blood, and C_0 = concentration of reference substance in outflow blood Since the inflowing and outflowing volumes are assumed to be the same, the equation becomes

$$F = Q/(C_0 - C_1) = Q/\Delta C$$

For Cardiac Output with Oxygen and Carbon Dioxide. Measurement of the output of blood by the animal or human heart has been calculated from the difference between the oxygen content of the mixed venous blood and that of the arterial blood and the total oxygen consumption of the body It is evident that if the quantity of oxygen which a unit of blood delivers to the tissues (or takes up from the lungs) is known, together with the total quantity of oxygen consumed over a given period, then the volume of blood which had been engaged in the carriage of this quantity of gas can be calculated For example, the arterial blood contains about 19 volumes of oxygen per 100 ml. It gives up, let us say, 6 volumes to the tissues, i e , the mixed venous blood coming to the lungs contains 13 volumes % The arteriovenous (AV) oxygen difference is, therefore, 6 volumes % If the total quantity of oxygen consumed per minute is found to be 250 ml , then the cardiac output is

$$[250 \text{ ml/min} / (19 - 13 \text{ ml}/100 \text{ ml})] \times 100 = 4\ 2 \text{ liters/min}$$

The oxygen consumption must be measured very accurately for several minutes and the subject must be in a steady state The blood samples for determining arteriovenous oxygen difference should be obtained simultaneously Arterial blood may be obtained from any artery but only *mixed* venous blood can be used since the quantity of oxygen contained in venous blood varies grossly depending upon the vascular bed from which it drains Even the oxygen content of blood in the superior vena cava differs from that in the inferior vena cava by 1 to 2 volumes % Mixing of the blood occurs in the right ventricle and is generally complete by the time the blood reaches the pulmonary artery where sampling must be made for accurate determinations

The cardiac output can be calculated in a similar way from the total carbon dioxide elimination and the arteriovenous carbon dioxide difference (CO_2 in mixed venous blood less CO_2 in arterial blood) However, the vagaries of cardiac output calculation on this basis are such that the measurement is generally ignored The unreliability of the Fick method when carbon dioxide is used is related to the fact that small changes in ventilation strongly influence carbon dioxide storage by the body and a steady state is hard to reach

The direct Fick method was first employed in man by Klein (1930), following Forssman's (1929) demonstration upon himself of the safety of right heart catheterization Cournand and his associates (1941) established the safety of the procedure and stimulated widespread utilization of the method The technique of cardiac catheterization has been described in detail by Cournand and others A sample of mixed venous blood is drawn from the pulmonary artery by means of a catheter passed up an appropriate arm vein The introduction of the catheter is guided by x-ray visualization (fluoroscope) A sample of arterial blood is obtained by arterial puncture The blood samples can be analyzed for their oxygen contents, and after the total oxygen consumption has been deter-

mined in the usual way, calculation of the cardiac output is made from the formula already given The oxygen contents can be measured with the Van Slyke apparatus or, for more rapid determination, a photoelectric method has been developed (Fig 3 137) Blood for analysis is drawn through a cuvette which is transilluminated by a constant intensity light source The light passing through a 628 filter falls upon a photomultiplier tube

The method presupposes that the oxygen consumption and the AV oxygen difference are obtained simultaneously and are constant during the time of measurement Both cardiac and respiratory cyclic changes in the concentration difference of oxygen and the flow rate are capable of introducing large errors in cardiac output calculations These changes do not appear to occur to any significant degree in man when a steady state has been achieved A potentially serious error of the Fick application may occur if gas is stored in, or liberated from, the body, including the lungs This would occur when the relation of aerobic to anaerobic metabolism of the body is altered and, as a consequence, the level of blood oxygen is altered without relation to blood flow Thus, the Fick calculation is dubiously related to cardiac output as the organism goes into or comes out of an anoxic state or in the presence of congenital heart disease with cyanotic episodes In the latter instance, the shunts between the pulmonary and systemic circuits induce large errors in calculation of systemic flow Special formulas have been developed to calculate the volume of blood flow through such shunts

Cardiac output determined by the Fick method probably has an error of $\pm 10\%$ when very carefully done

For Cardiac Output with Foreign Gases. Most of the early figures for cardiac output were based on the Fick principle using a foreign gas For this, the lungs are used as a gas aerotonometer to measure the gas tensions of mixed venous blood and hence, its gas content A subject breathes an inert foreign gas (i e, one which becomes dissolved in plasma but does not combine with hemoglobin, lipoid or other constituents of the blood) If the rate of gas absorption by the blood, its alveolar tension and its stability in blood are known, then the quantity of blood which has passed through the lungs can be calculated

$$\text{Flow} = \frac{\text{rate of gas absorption}}{\text{alveolar gas conc} \times \alpha_B}$$

where α_B is the solubility coefficient of the gas in question in blood

This is the principle on which a foreign gas method is based Nitrous oxide (N_2O), ethyl iodide (C_2H_5I), and especially acetylene (C_2H_2) have been used in the past The main difficulty of the method is that equilibrium between alveolar air and the venous blood must be effected before recirculation Originally, it was felt that the circulation time was 25 to 30 sec, and hence, that a respiratory mixture could be left in the lungs for that length of time without

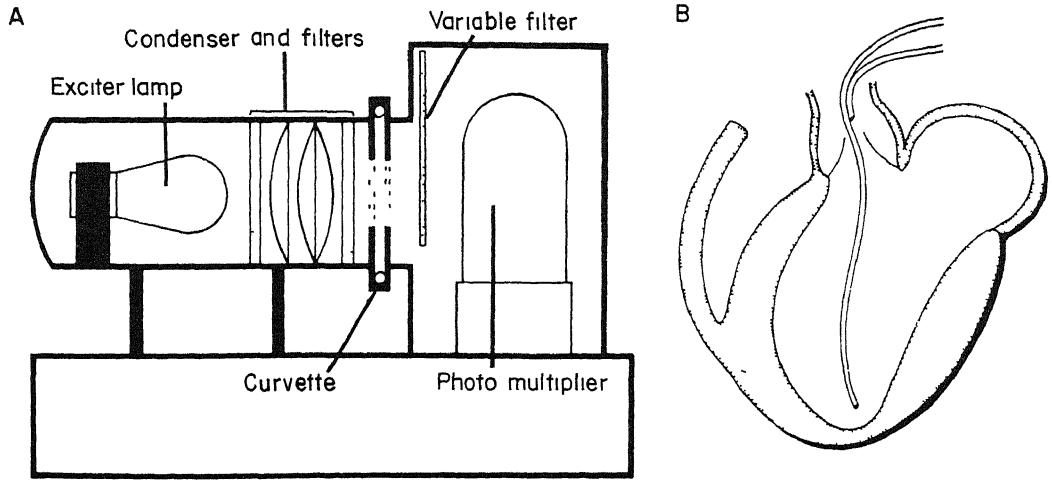

Fig 3 137 *Left* drawing showing principle of the densitometer used to determine instantaneous cardiac output and continuous blood O_2 saturation *Right* principle by which change in blood conductivity in a ventricular cavity is used to determine diastolic ventricular volume and stroke volume

exposure to recirculated blood However, the correct figure for circulation time is much shorter, 10 to 18 sec , which is often an insufficient time for equilibrium to be established, hence, the values for resting cardiac output established by this method are usually lower than normal and, at times, grossly in error Nitrous oxide has been used to estimate not only cardiac output but the instantaneous capillary blood flow since it is so soluble that it is immediately picked up by blood entering the capillary bed of the lung (Fig 3 138) If a subject is in an airtight chamber and takes and holds a single breath of N_2O for 8 to 10 sec , the chamber pressure falls at a rate which indicates the rate of absorption of the gas by the blood and, consequently, the rate of pulmonary capillary blood flow or cardiac output Recirculation is not a problem during this short time The instantaneous rate of blood flow can be calculated since the rate of N_2O absorption, the alveolar gas tension and its blood solubility are known

For Regional Blood Flow. Of the methods considered, except for the electromagnetic flow meter and sonar techniques, measurements of volume of blood flow passing through the splanchnic bed of kidney cannot be made directly even in experimental animals without destructive surgical procedures or unphysiological interference with function The Fick principle has been used to determine mean blood flow in man and animal through the liver, and kidneys, as well as the coronary and cerebral circulation The introduction of venous catheterization has made it possible to obtain blood issuing from the hepatic vein in intact animals and man, thus permitting the development of methods of measuring flow on the basis of the Fick principle Bromsulphalein (BSP) has proved especially useful here because it is taken up by the liver with remarkable efficiency Of the total removed from the blood each minute, when the plasma BSP concentration is maintained by constant intravenous infusion below 2 or 3 mg /100 ml , no more than 5% can be attributed to escape through extrasplanchnic portals For practical purposes, therefore, the hepatic removal of BSP equals the rate of infusion as long as the plasma level is constant The splanchnic blood flow may be calculated by dividing the removal rate by the difference between BSP concentrations in peripheral arterial and hepatic venous blood The flow value is

generally referred to as the estimated hepatic blood flow since sampling is made in only one of several hepatic veins A number of other substances such as Rose Bengal and ^{131}I, have been used in the same way to measure splanchnic blood volume

Similarly, the blood flow through the human kidney can be determined Diodrast, when in low concentration in the plasma, undergoes virtually complete clearance, i e , it is removed from the plasma in a single passage of blood through the kidney This substance is excreted

largely by the tubules, only about 16% is filtered through the glomeruli When the amount excreted in the urine within a time and the plasma concentration are known, the quantity of blood that has passed through active renal tissue can be calculated For example, if 600 mg of Diodrast are excreted in the urine per minute, and each milliliter of plasma contains 1 mg, then to deliver 600 mg of Diodrast, 600 ml of plasma went through the kidney, or with a hematocrit of 40, about 1000 ml of blood flow

Mean blood flow has been successfully determined through the coronary circulation with nitrous oxide inhalation and through the cerebral circulation with nitrous oxide or krypton inhalation It is the only method available for such studies in man (Fig 3 138) In use in the heart or brain, several simultaneous arterial (any artery) and venous (coronary sinus for the heart and the internal jugular vein for the brain) samples are drawn from the beginning of N_2O inhalation (mixture of nitrogen, 64%, N_2O, 15%, O_2, 21%) to the time of its equilibrium in the bloodstream or during denitrogenation after previous inhalation of the nitrogen mixture Continuous simultaneous samples can also be drawn from the artery and vein for analysis The flow per unit of time through these organs is equal to the amount of the substance taken up by that organ in a given time divided by the difference in concentration of the substance in the arterial blood and venous drainage of the organ in the same time period The denominator in the Fick equation is found by computing the integrated difference between the concentrations of N_2O in arterial and venous blood during the period of equilibration with a low concentration of N_2O The concentration of gas in the tissue at the time of equilibration (the numerator in the Fick equation) is unobtainable directly and is assumed to be equal to the product of the venous blood concentration of the gas (after equilibrium is established) and a partition coefficient (1 0 in case of the heart and 1 3 for the brain) When the equation is multiplied by 100, units for blood flow are obtained which are expressed as milliliters of flow per 100 g of heart or myocardium

INDICATOR DILUTION PRINCIPLE

The principle is based on observation of the rate at which a known quantity of material introduced into a vessel or heart cavity is diluted by blood flow through the vessel or cavity In the principle as originally applied by Stewart and modified by Hamilton, it has been shown that the average rate of blood flow can be stated

$$F = E/\int_0^t C\,dt$$

where F = average rate of flow, E = total quantity injected, C = instantaneous concentration of the injected material From this relationship, it is possible to determine the average flow rate in almost any cavity or vessel of reasonable size if the amount of injected material is known and if the concentration-time function can be accurately determined (Fig 3 139)

Blood Velocity

Of the two measurements, volume flow of blood in milliliters per minute and the velocity

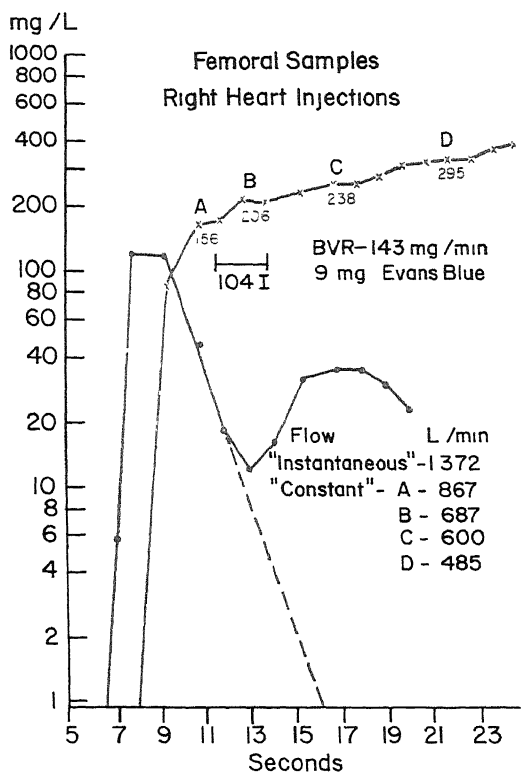

Fig 3 139 Concentration curves resulting from continuous infusions of brilliant vital red (BVR) and rapid injection of T1824 (Evans blue) both started at zero seconds Short horizontal line and figure denote the expected concentration plateau level of the continuous infusion on the basis of instantaneous injection (I) (Howard et al 1953)

of flow in centimeters per second, the former is probably more important The major function of the circulation is to supply the metabolic needs of the tissues and volume flow is closely related to this, whereas measurement of velocity of flow alone does not necessarily tell us anything about the blood supply to the tissues The relation between the observed velocity and volume flow is not consistent For example, in the presence of local constriction in a vessel without constriction in other areas, flow velocity will increase, but flow will decrease In the presence of general as well as local constriction, velocity and volume flow will both decrease Despite this, knowledge of the flow velocity is highly important to an understanding of hemodynamics of the circulation Flow velocity measurements have been made under direct vision, by use of the various flow meters that have been described, by observation of movement of injected substances, and finally, by determination of the differential pressure within an unopened and unrestrained vessel

Visualization. There is a natural tendency to assume that when one actually sees the movement of blood within a vessel, this must supply the most certain evidence of blood velocity However, when this is done, one tends to be impressed by the movement of the red cells and not by that of the blood as a whole

Flow Meters. By insertion into or application onto a blood vessel of almost any of the flow meters described, one automatically measures the velocity of flow since the meter insures a fixed diameter through which the flow occurs

Movement of Injected Materials. Various noteworthy attempts have been made to follow cyclic changes in velocity in the unopened vessel by recording the movements of various injected foreign materials such as air bubbles, dyes, and x-ray opaque fluid The technique is difficult since the moving front of the injected material, i e , the difference of optical density between blood and the contrasting medium, is often difficult to detect This is because the velocity is not the same at different points along the radius of the blood column, the flow being much greater in the axial part of the stream than toward the periphery, and also because the flow is not always unidirectional A mean or average velocity is obtained which is derived from the flow indicated by mean flow meters. It, of course, ignores very large fluctuations in velocity which occur during a cardiac cycle The moment-to-moment or phasic velocity is recorded by those pulsatile flow meters with a frequency of response sufficiently rapid to follow it

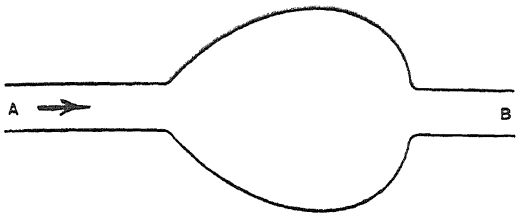
Differential Pressure Velocity The instantaneous blood velocity has been determined in the aorta and arteries from the instantaneous pressure difference between two points located along the axis of flow or along the vessel (Sect 3, chap 1, Fig 3 29) Such pressure gradients have been measured by simultaneous recording of arterial pressure at the two points either with individual pressure manometers or by use of a double lumen catheter attached to a differential pressure strain gauge In the double lumen catheter which has been used in the aorta of humans, the lateral opening of one catheter tip opens at a point about 5 cm from the other From the pressure gradients, velocity curves and flow curves have been calculated which agree well with those directly measured

A rough approximation to mean linear aortic velocity in man can be made using the cardiac output and the cross-sectional area of the aorta (measured in a cadaver of the same size)

The mean velocity ($\bar{v}$), in cm /sec equals cardiac output (V) in ml /sec /cross-sectional area (A) in cm^2

$$\bar{v} = \dot{V}/A$$

For a human aorta of radius 1 0 cm and cardiac output 5 liters/min , the mean velocity would be



$$\bar{v}\,\text{aorta} = 83/3 = 28\ \text{cm /sec}$$

This is *mean* flow Since flow is pulsatile, the velocity at systolic peak is perhaps three times this value and much less at diastolic nadir

CIRCULATION TIME (C T)

Circulation time is defined as the shortest time which a particle of blood takes to go from one point in the circulation to another Circulation time is most often determined for a portion of the circulation, such as from the right to left side of the heart

The circulation time of a particle of a substance can be accurately determined if it is injected instantaneously into a blood vessel, if it moves at the same rate as the blood stream and if its arrival further down the vessel is accurately detected Practically, the situation is much more complicated. When a reasonable amount of a substance is injected, its arrival

$$\text{CIRC TIME IN SEC} = \frac{\text{VOL A TO B}}{\text{FLOW IN ml/SEC}}$$

Fig 3 140 Schematic diagram illustrating the relation between circulation time volume flow and the volume of the vascular bed

time is so spread out at the downstream detection point that detection is difficult If the circulation time is made across an organ or a major portion of the circulatory system, the spreadout is even greater In addition, if all the blood channels between the two points are not approximately uniform in length and diameter, only a part of the blood will pass from point to point at the rate indicated by the measurement Despite these considerations, measurements of circulation time can be semiquantitative

The clinical methods for estimating circulation time use injected substances, such as Decholin and ether, that signal their arrival by effects on special receptors, such as the taste budds in the tongue With Decholin, the normal range of arm to tongue (bitter taste) time is 8 to 17 sec , with ether, the normal arm to lung (patient first smells ether) is from 4 to 8 sec For greater precision in experimental investigations, these classical methods have been superseded by the injection of dyes and radioactive tracers which can be easily and objectively detected by densitometers, conductivity cells and isotope counters The main technical difficulty is the proper calculation of the average transit time In a symmetrical curve, the mean (average of all transit times), the mode (time coordinate of the peak), and the median (time coordinate which halves the area) all coincide But as the curve becomes asymmetrical, and particularly as the terminal portion stretches out more in time than the initial part, the three measures depart more and more from each other The mean circulation time (MCT) it takes all dye to pass is computed as the center of gravity of the curve

The significance of a change in circulation time is debatable The circulation time between two points in the vascular system is equal to the volume of the vessels between the two points divided by the flow (Fig 3 140) The validity of this relationship has been checked in glass models and mathematically It is obvious that a change in circulation time could be due to a change in volume of the vascular bed between the point of injection and sampling, as well as to change in flow Since change in flow follows any vasomotor change, and since the resultant redistribution of pressures causes local volume change, both numerator and denominator of the ratio for circulation time (volume over flow) change simultaneously They generally change in the same direction, and so the circulation time could be a very poor indicator of blood flow, volume of blood, or vasomotor change

3 / CONTROL MECHANISMS OF THE CIRCULATORY SYSTEM

Functional Organization of the Vascular Bed

The sequential segments of the circulatory system are functionally differentiated as illustrated in Figure 3 141 These series-coupled segments make up the vascular beds for the various tissues The circulatory system consists of a set of these circuits coupled in parallel (Fig 3 142)

Vessels may be classified in accordance with their function as follows (Folkow, 1960)

1) Windkessel vessels, which convert pulsatile inflow to a somewhat smoothed outflow
2) Resistance vessels, chiefly the small arteries, the arterioles, and to a lesser extent the capillaries and smallest vessels
   a) Precapillary resistance resides chiefly in the small arteries and arterioles, it is the major site of resistance to flow
   b) Postcapillary resistance is determined by the venules and veins Capillary hydrostatic pressure and, thus, filtration-absorption exchange, is determined by the ratio of precapillary to postcapillary resistance
3) Sphincter vessels, terminal segments of precapillary arterioles which can constrict and restrict or shut off capillary flow They determine the number of open capillaries and hence the area of capillary exchange surface
4) Exchange vessels, the capillaries, which are not contractile, but respond passively to changes in resistance and sphincter vessels
5) Capacitance vessels, chiefly veins which through diameter changes having little influence on resistance can effect marked shifts of blood volume and thus affect cardiac venous return and volume flow dramatically They contain about 80% of regional blood volume
6) Shunt vessels arteriovenous anastomoses found in some tissues, where they allow bypass of exchange vessels

Resistance and capacitance vessels may react differently in accordance with their differing functions Thus, epinephrine dilates some resistance vessels while constricting capacity vessels, norepinephrine constricts both, but affects capacity vessels most

Control of Vascular Smooth Muscle

LOCAL CONTROL

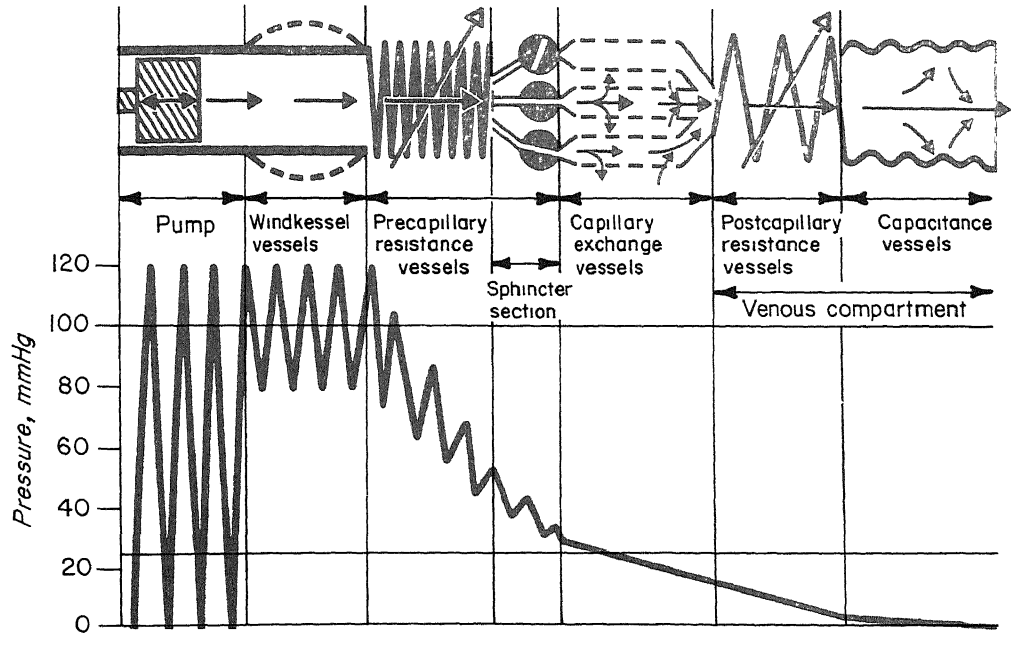
The smallest blood vessels have an inherent, myogenic automaticity or basal degree of contraction of their contained smooth muscle which is independent of blood borne substances or nervous influences, but which can be altered by stimulation of nerve fibers, local electrical stimulation, or by changing the physical and chemical environment The mechanism of this inherent vasomotion is unknown Presumably, it arises from locally produced metabolites which can have complex effects Locally, about the arterioles, precapillaries and capillaries, there are released norepinephrine, acetylcholine, CO_2, lactic acid, products of nuclear metabolism, and presumably many other substances, which can act in many different ways on these vessels

Several potent vasoactive substances such as histamine, prostaglandins, serotonin, and adenosine tri- and diphosphate are found in various tissues, but their importance in local vascular regulation has not been established The extent of such basal vasomotion has been evaluated in sympathectomized, vascular areas where neurohumoral, constrictor influences are eliminated

Although large quantitative differences exist in different parts of the vascular tree, generally speaking there is an inverse relation between the local, inherent activity of smooth muscle cells and the extent of neurohumoral control in any given vascular bed The cutaneous arteriovenous anastomoses, such as in the paw of the

cat, which are strongly controlled from the hypothalamic heat loss center, are maximally dilated when neurohumoral agents are eliminated, while elimination of the vasomotor nerves serving vitally important metabolic areas, such as the brain and myocardium, has scarcely any effect on the local blood flow In areas such as skeletal muscle, neural elimination still leaves a very strong vessel tone in the dog and man, which is increased with time Indeed, some investigators have expressed the belief that in skeletal muscle, blood flow is mainly under local control by metabolites, and not nerves, since subjects with sympathectomized legs do as well running (athletes and normals) before and after sympathectomy Evidence suggests that reactivity to local metabolic effects is stronger in the metarterioles and precapillary sphincters, whereas constrictor fibers predominantly affect the arterioles, indicating that a difference in type of control may exist within the same vascular bed Presumably, in all beds, there is some locally produced vasodilation which counteracts the centrally induced reduction in blood flow by constrictor nerves and protects the tissue against ischemia (see "Autoregulation" p 3-6 et seq)

Myogenic smooth muscle reactions to stretch also operate in local vascular control This has been termed the "*Bayliss mechanism*," since this investigator first proposed that increased stretch might increase vascular tone A variety of experimental observations in vivo and in vitro have confirmed that passive stretch stimulates contractile activity of vascular smooth muscle Two major objections to a regulatory myogenic mechanism have been offered on a priori grounds *1*) Increased vasoconstrictor response to increased wall tension constitutes a positive feedback response leading to instability in the cardiovascular system Thus, increased blood pressure would elevate flow resistance which would further raise the blood pressure, leading to additional vasoconstriction, and so on *2*) Smooth muscle contractile response to vascular distention would tend to abolish the stimulus of stretch The vessel might thus oscillate around a diameter somewhat greater than that at the time of the stretch stimulus These objections are not necessarily valid The possible instability caused by positive feedback could be limited by "metabolic vasodilators" and the maximum range of vasomotor response Considering the structural complexity of passive elastic and viscous elements in vessel walls, the circular, spiral, and longitudinal arrangement of the smooth muscle fibers and the tortuosity of some arteries, it is unlikely that myogenic response to stretch would operate only within rigid diameter limits Thus, both



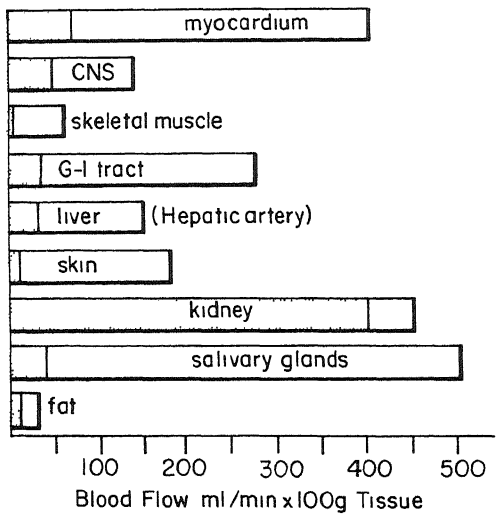


Fig 3 141 Functionally differentiated segments of the vascular bed (Redrawn from Mellander and Johansson 1968)

local metabolic dilator factors and myogenic mechanisms may be envisioned as functioning together to produce autoregulation (Mellander and Johansson, 1968, Mellander, 1970)

SYMPATHETIC VASOCONSTRICTOR FIBERS

Distribution. These were discovered in 1852 by Claude Bernard, who stimulated the cervical sympathetic nerve in the rabbit and observed constriction of the vessels of the ear They belong to the thoracicolumbar (sympathetic) division of the involuntary nervous system The constrictor fibers arise from groups of nerve cells situated in the lateral horns of the spinal gray matter, extending in man from the first thoracic to the second or third lumbar segment, inclusive All the arterioles of the body wher ever situated are supplied with filaments which have their ultimate source in this relatively limited region of the central nervous system They are distributed to the periphery in the manner elsewhere described for the thoracicolumbar outflow in general (see also sect 9, chap 3)

The vascular nerves of the limbs, as shown by Kramer and Todd (1914), are distributed by two distinct modes *1)* A *proximal* innervation arises in the case of the vessels of the upper limb directly from the cervical part of the sympathetic chain—middle and inferior cervical ganglia The fibers pass to the subclavian artery and are conveyed in a plexiform manner along the outer coat of this vessel and its branches, and into the arm along the axillary artery The corresponding supply to the vessels of the lower limb is derived by extension from the aortic plexus in the abdomen The fibers follow the common and external iliac arteries into the thigh The sympathetic fibers derived in the manner just described do not extend beyond the larger vessels of the limbs (proximal portions of the brachial and femoral arteries) *2)* A *distal* innervation is carried to the peripheral vessels via the spinal nerve trunks These nerves reach the arteries at different levels and, penetrating the vascular wall, form a nerve net surrounding the muscular coat, the highest level of this type of innervation probably overlaps the region innervated by the proximal group of fibers mentioned above Adrenergic nerve endings have been identified in all the sequential sections of the vascular beds except the true capillaries Precapillary resistance vessels (small arteries and arterioles) have, in general, a rich innervation In the smallest precapillary vessels the number of fibers is small However, there is experimental evidence for neurogenic constriction of precapillary sphincters The venules have fewer adrenergic fibers than the larger veins, which, themselves, are less richly innervated than the precapillary vessels It is solely through such sympathetic fibers traveling with somatic nerve trunks that constrictor impulses are conveyed to the minute vessels of the limbs Ganglion cells are absent from the vessels of the limbs Section of a peripheral nerve, therefore, causes complete degeneration of vasoconstrictor fibers in the area of its distribution

	Rest blood flow (l/min)	Max blood flow (l/min)	Organ weight (kg)

Fig 3 142 *Upper* bar graph representing approximate blood flows in various organs at maximal vasodilatation (total bar) and at rest (hatched areas) in ml/min × 100 g tissue at perfusion pressure of 100 mm Hg *Lower,* approximate values for regional blood flows in a 70-kg man at rest' and at maximal dilatation, deduced from organ weights The organs included comprise about 70% of total body weight (Redrawn from Mellander and Johansson 1968)

Vasoconstrictor fibers to the head and neck are conveyed from the sympathetic chain through plexuses investing the blood vessels, but also via peripheral nerve trunks (cervical and certain cranial nerves) The vessels of the abdomen and pelvis are supplied with fibers which pass along the vascular walls from plexuses surrounding the aorta and its branches The sympathetic fibers to the heart arise chiefly in five upper dorsal segments of the cord, pass to the stellate ganglia and upper dorsal ganglia as white rami, and proceed to the heart by a complex plexus Although the coronary vasomotor effect of sympathetic stimulation is overshadowed by metabolic, inotropic, and chronotropic effects associated with vasodilatation, stimulation of sympathetic C factors has been shown to cause active vasodilatation directly when other factors are controlled (see p 3-139)

Site and Mode of Action These nerve fibers constitute a group of powerful vasoconstrictor mechanisms The physiological discharge rate of the vasoconstrictor fibers is 1 to 2/sec to maintain normal vessel tone and reaches 10 impulses/sec , with maximal physiological excitation The chemical transmitter released at the smooth muscle cell is norepinephrine, and norepinephrine is released into the blood stream on intense sympathetic stimulation However, such an overflow does not usually occur at physiological discharge rates These constrictor fibers exert control over the resistance vessels (arterioles and adjacent smaller blood vessels) where the main drop in blood pressure from the arterial to the venous system occurs This can be observed by noting the marked increase in blood flow in a vasoconstricted limb immediately following sympathetic blockade The precapillary resistance vessels are controlled by constrictor fibers, but during prolonged constriction accumulation of "vasodilator metabolites" can oppose neurogenic influence, relaxing precapillary sphincters

In addition, these fibers exert strong control over the heart size and the capacity vessels, mainly the veins, and can alter greatly the venous return to the heart and, thus, markedly influence cardiac output To establish this capacitance action, pressure changes occurring in functionally isolated parts of the superficial and deep venous system of dog and man were used to indicate changes in venous constriction, and evidence of a reflex constriction to a variety of stimuli was obtained Isolated venous segments in the intact forearm constrict after reflex sympathetic stimulation by cold, excitement, etc Venoconstriction in the forearm occurs in response to pooling of blood in the leg Similar observations have been made on the capacity vessels of the splanchnic area These effects are abolished by constrictor fiber blockade by hexamethonium Possibly the most clear-cut experiments in dogs on the quantitative importance of the sympathetic system in adjusting total vascular volume, and hence, venous return and cardiac output, are those in which a pump, with output which remained constant under marked variations of peripheral resistance, was substituted for the left ventricle of a dog The pulmonary drainage of blood was carried to a reservoir by means of a plastic tube in the left atrium The blood was pumped from the reservoir through a T tube in the descending thoracic aorta Under equilibrium conditions (reservoir level remaining constant), if norepinephrine (which simulates sympathetic vasoconstriction in physiological dosages) was injected into the dog, there was not only an increase in vascular pressures but also approximately 250 ml (one-fifth of the dog's blood volume) was forced into the pulmonary drainage reservoir feeding the mechanical left ventricle This could come only from the venous system and the right heart When hexamethonium (simulating a functional sympathectomy) was injected instead of norepinephrine, the pressures fell and the dog took up 200 to 300 ml of blood from the reservoir Further work has extended these findings to man In normal man, removal of large amounts of blood in 50-ml increments produces little change in vascular pressure or hemodynamics But, if done following inhibition of sympathetic vasoconstrictor reflexes with hexamethonium, then with each 50 ml of blood withdrawn, there is a perceptible decline in blood pressure After removal of only 350 to 500 ml of blood, the arterial pressure falls, by decrements, to collapse levels During reinfusion, the process is reversed Thus, sympathetic vasoconstrictor inhibition has converted the vasculature into a static system In addition, using the pressure-volume apparatus of Litter and associates (1954), which can be applied to the extremities of man, it is calculated that infused epinephrine and norepinephrine can shift as much as 500 ml of blood from the veins of dependent limbs in a short period of time

These effects of constrictor fibers on venous volume can considerably change venous return by very small changes in vein caliber For example, if the veins contain 60% of blood volume of which 1 to 2% make up the stroke volume of the ventricles, a 1 to 2% shortening of venous vascular smooth muscle would be estimated to double diastolic inflow to the heart, this same amount of constriction of the resistance vessels would only insignificantly increase the peripheral resistance

Excitation of sympathetic vasoconstrictor fibers affects somewhat the aortic smooth muscle cells and possibly other arteries Presumably, the effect is mainly a change in vascular distensibility and only secondarily are mild pressure changes along the arterial tree produced (see also Chap 11) In general, however, the effect is small In vessels from the root of the aorta down to arteries of 1 mm , induced changes in diameter are probably less than 5% of total diameter even with marked vasoconstriction or vasodilation

Functional Significance. Experimental evidence now indicates that these vasoconstrictor fibers are responsible for blood pressure homeostasis (vascular adjustments derived from the baro- and chemoreceptors), and for the regulation of heat loss by the skin blood flow Thus, the most common type of centrally induced vasodilation is caused simply by an inhibition of vascular tone In fulfilling their role as the main neurogenic adjustors of the peripheral circulation, the vasoconstrictor fibers may show a generalized, strictly segmental, or regional function, depending upon the type of stimulus

Central Control. The control of the degree and sites of vasoconstriction depends predominantly on the influence of hormonal action and on the action of the central nervous system

The Spinal Cord The preganglionic sympathetic neurons may, under some circumstances, exhibit spontaneous activity independent of an excitatory drive from afferent fibers or central levels This spontaneous discharge may arise from a changed oxygen and CO_2 tension which is prone to occur in a spinal preparation in which neuronal respiration and blood supply are without doubt considerably altered

Various afferent impulses are able to call forth spinal vasomotor reflexes, the vasoconstrictor neurons form the efferent link Pain or cold stimulation in the skin induces a segmentally arranged constriction of the intestinal vessels in such spinal animals Vasodilation occurs when the skin is moderately heated More intense and widespread effects are seen in humans with chronic transverse lesions of the spinal cord Guttman and Whitteridge (1947) showed the existence of powerful reflexes, in the spinal man, arising from the hollow viscera In patients with high spinal transection, distension of the bladder would raise the blood pressure from normal levels to 300/140 mm Hg This is ascribed to the action of reflexes initiated by the tension in the bladder wall and mediated by the isolated spinal cord and the sympathetic outflow There could also be demonstrated vasoconstriction in the hand and a fall in calf blood flow These phenomena are consistent with a very widespread vasoconstriction as a result of afferent impulses which spread to an unusual extent in the isolated spinal cord

Medulla The constrictor sympathetic vascular effects are controlled primarily by areas in the medulla oblongata situated in the floor of the fourth ventricle Local electrical stimulation has revealed a lateral "pressor area" and a medial "depressor area" causing vasoconstriction and vasodilation, respectively The vasodilation is caused by inhibition of vasoconstrictor tone, specific vasodilator fibers not being involved This area is defined simply as the vasomotor center but does not represent the highest centers of this system The latter are situated in the hypothalamus and in the cerebral cortex In the intact mammal, complicated afferent influences integrated in the cerebral cortex and hypothalamus modify and control the action of the vasomotor center

The state of activity of the medullary vasomotor center depends upon afferent nerve impulses received from various organs and regions of the body, as well as from other nervous centers, respiratory centers, etc , and upon the chemical composition of the blood In turn, the contractility of the heart, the relative peripheral resistance and, hence, the cardiac output, with its distribution to the various organs, are all mainly controlled by the medulla oblongata responding to impulses from all tissues of the body, including the spinal cord and other portions of the brain itself

The vasomotor center exhibits inherent automaticity, since its continuous discharge goes on even after elimination of all incoming nerve influences Section of the brainstem above the

medulla does not affect blood pressure, indicating that upper areas do not dominate vasomotor outflow from the sympathetic nervous system However, such control may be demonstrated by sectioning the cord in the lower cervical region This interrupts the stream of vasoconstrictor impulses passing from the medullary to the spinal centers, the vessels dilate and the blood pressure falls After a time, however, the blood pressure rises again, the spinal centers exhibit their inherent power of autonomous action, and assuming the duties hitherto exercised by the medullary centers, restore the vessels to their previous state of tonic constriction The time required for the vessels to regain their tone after section of the cord varies considerably in different species

The high degree of vasoconstrictor tone which is normally maintained is shown by the fact that section of the splanchnic nerves doubles the flow in vessels of the denervated area (Burton-Opitz, 1903) After the loss of tone resulting from cord section has been restored (see above) it falls again if the splanchnic nerves are sectioned, but after a time a certain degree of tone is regained This resides in the vascular muscle itself—*peripheral tone* Apparently, a long period is required for the development of the intrinsic arteriolar tone

The Hypothalamus In the hypothalamus, electrical stimulation shows the existence of both excitatory and inhibitory neurons which, presumably, have much to do with blood pressure regulation It must be remembered that drastic redistribution of blood flow following extensive changes in the discharge of the constrictor fibers to some areas is often concealed behind slight blood pressure changes and, hence, blood pressure change alone is not a reliable guide Recently, the hypothalamic area has been explored for structures from which a pure inhibition of sympathetic activity could be induced Such a structure, of very restricted dimensions, has been localized in the anterior part of the hypothalamus, only a few millimeters from the relay station of the sympathetic vasodilator fibers (see next section) From this area, topical stimulation induces a generalized, often very marked, inhibition of sympathetic discharge affecting both resistance and capacitance vessels

An immediate and persistent lowering of blood pressure in both normotensive and renal hypertensive dogs occurs following large bilateral coagulations involving the hypothalamic area This lowering of blood pressure is small in magnitude but is as marked as that resulting permanently from bilateral sympathectomy and low cervical cord transection Whether this lowering in blood pressure has a neural or an endocrine basis has not been determined It is not due to the absence of the neurohypophysial antidiuretic principle, because precipitation of a maximal diabetes insipidus (functional neurohypophysectomy) has been accomplished without affecting blood pressure It is believed not to be due to a neighboring adenohypophysial hypofunction, because the lowering of pressure following adenohypophysectomy is delayed rather than immediate as is the case following hypothalamectomy It is perhaps associated with the immediate and marked decrease in basal energy metabolism which supervenes following appropriate hypothalamectomies

In addition, there is a "heat loss center" in the anterior parts of the hypothalamus which controls the discharge to the vasoconstrictor fibers of the cutaneous blood vessels, and, thus, plays an important role in adjusting blood pressure Electrical stimulation or local cooling of this area brings about a rise in blood pressure (vasoconstriction) while direct warming of this region produces a fall in blood pressure (vasodilation) The cutaneous arterioles and precapillary vessels, and, especially, the arteriovenous anastomoses (shunts), are the vessels most sensitively engaged in control of heat loss However, Keller (1960) has marshalled evidence to indicate that vasoconstrictor impulses responsible for the maintained contraction of cutaneous blood vessels *do not take* origin from the hypothalamus as evidenced by the following experiments An asymmetry in the ear vessels and in skin temperature (Horner's syndrome) does not follow unilateral lesions in the hypothalamus or hemisection of the brainstem at a midbrain, pontile, or upper medullary level, nor does a complete transection of the midbrain or pons results in generalized cutaneous vasodilation Ipsilateral vasodilation does occur following hemisection of the lower medulla and this approximates in magnitude and duration that which follows hemisection of the cervical cord

Diencephalic stimulation in the region of the H_2 fields of Forel in the chloralosed dog produces changes in heart rate and blood flow

distribution similar to those which occur in exercise

Cerebral Cortex Quite a number of studies of cortical vasoconstrictor fiber control are available, but relatively little is known about the circulatory adjustments Stimulation of the motor and premotor cerebral cortex results in marked elevation of blood pressure with constriction of the cutaneous, splanchnic, and renal vessels, and, at the same time, a considerable vasodilation in the skeletal muscle It is believed that these higher centers play significant roles in blood pressure response to pain and anxiety

VASODILATOR FIBERS

Dilator impulses emerge from the central nervous system by *1*) the thoracicolumbar outflow, *2*) the cranial outflow of the parasympathetic division reaching the periphery by way of the chorda tympani, glossopharyngeal, and vagus nerves, *3*) the sacral outflow of the pelvic nerve, and *4*) the posterior spinal nerve roots—antidromic impulses

Sympathetic Vasodilator Fibers. The question of dilator fibers in the sympathetic system has been much debated About 15 years ago, it was generally believed that they took an active part in regulation of vascular tone, their activity being governed by the medulla, and that such fibers were distributed to the skeletal muscles, the facial muscles, the buccal mucosa, the coronaries, the intestines, and to certain skin areas, such as the ear These findings were based on direct stimulation of sympathetic fibers and the recording of volume changes by plethysmography Direct measurement of blood flow (volume changes by plethysmography do not always mean change in blood flow), and location of an area of central control has led to considerable clarification The control of the degree of vasodilation of blood vessels is, indeed, supplemented by a system of efferent dilator nerves transmitting from the central nervous system, but this seems to be distributed only to skeletal muscle Electrical stimulation of the sympathetic fibers usually brings about vasoconstriction in the innervated area, since the action of the vasoconstrictor influence usually predominates over that of vasodilation But, if the vasoconstrictor response is first blocked by α-adrenergic blockade or reserpinization, electrical stimulation will produce vasodilation if the sympathetic outflow contains vasodilator fibers The existence of a sympathetic vasodilator innervation to skeletal muscle of the dog and cat has been established by this technique, but appears to be absent in rabbits and certain other mammals The vasodilator nerves may also be activated by topical stimulation in the brain (hypothalamus), with the result that venous outflow from skeletal muscle of the hind leg of the dog may increase 4 to 5 times (as does the local lactic acid production), but the oxygen usage may decrease, suggesting that shunts are being utilized and capillary flow is reduced In addition, such stimulation results in release of epinephrine from the adrenal glands This increased rate of blood flow approximates maximum dilation achieved by other means, such as acetylcholine injection Since blood flow in the human forearm increases during fainting, a potent means of vasodilation must be present in humans Also, since the blood pressure falls, and the blood flow is greater in the normal forearm than in a nerve-blocked forearm during syncope, this might be explained by active vasodilation in the normal forearm excited by sympathetic fibers to the muscles The transmitter is believed to be acetylcholine and the fibers are exclusively cholinergic, i e , they are blocked by small amounts of atropine They take their origin in the motor cortex, synapse in the hypothalamus, pass as a thin bundle through the ventrolateral portion of the medulla oblongata, and down to the lateral horn of the spinal medulla where they are relayed to lower motor neurons This pathway is anatomically and functionally separate from the medullary vasomotor center which mediates vasoconstrictor activity The functional significance of the vasodilator fibers is unknown, but it has been suggested that they are activated in response to cerebral activity, presumably in association with, or in anticipation of skeletal muscle activity The precapillary sphincters and capacitance vessels in muscle seem to lack this cholinergic innervation Conclusive evidences for the existence of these cholinergic vasodilators fibers in man is lacking

Parasympathetic Vasodilator Fibers. The parasympathetic vasodilator fibers run to restricted cranial and sacral areas such as the cerebral vessels, tongue, salivary glands, external genitalia, and to the bladder and rectum These fibers are probably not concerned with baro- and chemoreceptor control of blood vessels, nor are they tonically active It is

generally believed that these fibers are cholinergic, although their vasodilator effect is very resistant to atropine In the salivary glands and skin there is experimental evidence that nerve stimulation causing cholinergic exocrine gland secretion results in the release of an enzyme which acts on plasma protein to produce the vasodilator polypeptide, bradykinin (see p 3–214) While bradykinin has been proposed as the mediator of vasodilation in association with glandular activity, there is evidence that the role of kinins is only of limited or perhaps no importance (Kellermeyer and Graham, 1968) Their distribution to a few areas with highly specialized functions makes it probable that their function is associated with the special tissue in which they are located

Antidromic Vasodilator Impulses. Stricker (1876) years ago reported that stimulation of the peripheral segments of the cut posterior roots of the sacral nerves caused dilation of the vessels of the dog paw This observation was at variance with the Bell-Magendie law which states that the posterior roots convey only centripetal impulses However, in subsequent years, the former view has been fairly well documented Since such fibers do not convey the induced impulses to the central nervous system, but rather the vasodilator impulses are conveyed along the fibers in a direction opposite to that in which ordinary sensory impulses travel, they are called antidromic. It is the consensus that these "*dorsal root vasodilator fibers*" are not activated reflexly from the central nervous system

The effective stimulus leading to vessel dilation may arise in the skin, to be conveyed antidromically to superficial blood vessels. These are called axon reflexes, but they are obviously not true reflexes since no nerve cell is involved The efferent and afferent limbs of the axon reflex are formed by the branching of a single nerve fiber A stimulus applied to one branch sets up an impulse which travels centrally to the point of division where it is reflected down the other branch to an effector organ The most familiar type of axon reflex is that which involves a sensory nerve fiber and through which vasodilation is effected

Dorsal root dilation is of significance only in tissues with a relatively rich distribution of pain fibers, such as the skin and mucous membranes Various substances have been indicated as the transmitter—a histamine-like substance, acetylcholine, and adenosine triphosphate This local axon reflex in the skin is induced by any factor which causes damage to surface tissues—trauma, cooling, heating, frostbite Thus, this local mechanism contributes to local defense and repair in surface tissues by creating an increase of local blood flow in response to the majority of harmful stimuli

ADRENAL MEDULLA VS NEURAL CONTROL OF BLOOD VESSELS

Aside from direct neurogenic connections to the blood vessels, the presence in the blood stream of circulating catecholamines raises the question of their role in controlling the circulation Presumably they appear through some form of hypothalamic stimulation

Vascular Receptors. The concept of α- and β-adrenergic receptors, although an oversimplification, is useful to explain vascular responses to adrenergic agents α-receptors mediate vasoconstriction and β-receptors mediate vasodilatation The β-receptor is believed to be without innervation and limited to blood vessels of skeletal muscle and myocardium Norepinephrine, which has been shown to be the transmitter of sympathetic vasoconstrictor nerves, acts only on the α-receptors Epinephrine has both α and β effects A third receptor for cholinergic effects, the γ-receptor is postulated for sympathetic cholinergic vasodilator action in skeletal muscle

It has been widely assumed, but never proved, that the hormones secreted from the adrenal medulla markedly contribute to the vasomotor control of the blood vessels. Using a method that allowed a direct comparison of the individual actions of the hormone and vasomotor fibers on peripheral resistance in representative vascular beds, it has been found that the blood vessels are completely dominated by their vasoconstrictor fibers The contribution by the adrenal secretion is negligible, except in skeletal muscle, in which small physiological concentrations of epinephrine cause almost maximal vasodilation On the basis of adrenal catecholamine secretion following maximal excitation of the vasomotor center, it is estimated that the maximal secretion is 2 to 3 μg./kg /min Such concentrations of epinephrine and norepinephrine (probably 10 times the normal concentration), when injected intravenously, dilate the vessels of the skeletal muscles and probably those of the liver, but have insig-

nificant vasoconstrictor effects in other regions when compared with the constrictor fibers

The importance of the adrenal catecholamines for the motor control of the blood vessels is next to insignificant as compared with direct vasomotor innervation However, a moderate secretion of epinephrine induces extensive metabolic effects in liver cells (which lack direct sympathetic innervation) In skeletal muscle, physiological amounts of epinephrine produce significant β-receptor dilator response, localized chiefly to the precapillary vessels This reduction in the ratio of precapillary to postcapillary resistance, leads to filtration of fluid from the intravascular to the extravascular space Norepinephrine secretion from the adrenal gland has relatively little influence on the blood vessels, either directly or through metabolic dilation (indirectly)

RENIN-ANGIOTENSIN SYSTEM

Angiotensin is the most potent vasoconstrictor of biogenic origin known Its production following renal renin release is described elsewhere (sect 7, chap 6) The significance of the renin-angiotensin system in normal circulatory control is uncertain, and it would be premature to attribute to it a specific role It may be that angiotensin is of greater importance in the regulation of aldosterone secretion or intrarenal vascular control than as a determinant of peripheral vascular tone

VASOPRESSIN SYSTEM

Normally, plasma concentrations of the hypophysial antidiuretic hormone are too low to produce significant vasoconstrictor effects Thus, its physiological role in cardiovascular control is related primarily to long-term regulation brought about by its influence on water reabsorption in the renal tubules However, vasopressor concentrations can be reached under anesthesia and nonpressor concentrations potentiate pressor responses to catecholamines Thus, vasopressin may play a vasoconstrictor role in emergency situations such as hemorrhage and acute surgical procedures which are known to induce its release

THE ROLE OF VASCULAR TONE IN VASCULAR FUNCTIONS

Vascular tone designates the state of contractile tension in vessel walls *Basal tone* is defined as the degree of contractile tension remaining in vessels after complete elimination of known extrinsic excitatory influences Rhythmic contractions of the small precapillary vessels has been termed *vasomotion* the frequency, duration, and amplitude of these phasic constrictions in numerous arterioles in a vascular bed determine flow resistance in part and their variations represent alterations in tone The underlying smooth muscle contractile activity may be established by different mechanisms Myogenic automaticity and propagation, which may be modulated by vasomotor nerves and vasoactive agents, are characteristic of some vessels Other vessels develop tone from asynchronous spike discharges in smooth muscle cells which are dependent on impulse activity in vasomotor nerves Denervation removes much of such tone Nontetanic-graded contractures of smooth muscle may be another mechanism Possibly, these various types of contractile activity could operate in the same vessel, depending on changes in the local ionic and metabolic environment

The consecutive segments of a given vascular bed have different degrees of basal tone in precapillary resistance vessels tone is high, while it is less in capacitance vessels Flow and pressure in capillaries, which are noncontractile, is governed by contractile activity of the pre- and postcapillary vessels Thus, the number of capillaries carrying blood (i e , the active capillary surface area) is determined by the frequently rhythmic caliber variations of the precapillary sphincters It appears that capillary permeability remains a constant for a given tissue during physiological adjustments of vascular tone Capillary exchange variations primarily depend upon changes in functional capillary surface area and the ratio of precapillary and postcapillary resistance

The degree of basal tone varies in different tissues it is high in resistance vessels of the brain, myocardium, skeletal muscle, and splanchnic organs, but is practically absent in the arteriovenous anastomoses of the skin

Vascular Functions. Variations in vascular tone are determinants of vascular resistance, capillary exchange, arteriovenous shunting, vascular capacitance, and vascular compliance Luminal diameter, in accordance with the Poiseuille relation (p 3-23) is a dominant factor determining vascular resistance to flow and, thereby, tissue blood supply for a given arterial

pressure The ratio of precapillary to postcapillary resistance is a major factor influencing capillary hydrostatic pressure and thus fluid filtration and absorption in accordance with the Starling mechanism (sect 4, chap 12) The adjustment of fluid volume distributions between the intravascular and extravascular compartments depends upon net filtration or absorption which are markedly influenced by the resistance ratio of precapillary and postcapillary vessels Further, the capillary surface area available for exchange, capillary flow volume and capillary flow velocity are dependent on the resistance of precapillary sphincters Shunting of blood around capillary exchange networks is important, for example, in the skin circulation Here arteriovenous anastomoses can dilate, accommodating large volume flow for thermoregulatory purposes, without disturbing capillary flow Increased tone in capacitance vessels, venules and veins, permits mobilization of blood and decreases compliance to prevent blood pooling, factors which promote venous return to the heart Finally, alterations in arterial wall compliance influence pulsatile pressure and volume transmission through arterial circuits

VASCULAR CIRCULATORY DIMENSIONS AND VESSEL TONE

As shown in Figure 3 142, the parallel coupled vascular circuits to individual organs differ markedly in the ratio of resting to maximal flow rates Three relations are distinguishable

1) Vascular beds in which dimensions are sufficient so that with maximal dilatation blood flow and capillary surface area will meet maximal metabolic needs, e g , myocardium and central nervous system

2) Vascular beds too small to provide for maximal metabolic activity, e g , skeletal muscle, which during strenuous exercise must go into "oxygen debt "

3) Vascular beds in which maximal vascular dimensions exceed maximal metabolic needs, e g , kidney, skin, glands, and adipose tissue Here regional circulation has functions in addition to supply of nutriments and removal of wastes, e g , excretory function of the kidney, thermoregulatory function of the skin, glandular synthesis of secretory materials, and mobilization of energy stores from adipose tissue

If all circulatory beds dilated maximally at once, cardiac output could not equal the total flow rate required and pressure would fall Thus, total vascular resistance must be maintained at some minimal level by appropriate reciprocal adjustments when maximal flows prevail in some organs

SUMMARY OF REMOTE AND LOCAL CONTROL SYSTEMS

Remote control systems (e g , nervous system, adrenomedullary system, etc) function to regulate arterial blood pressure and blood volume They bring about regional and general circulatory adjustments as required to subserve such needs as thermoregulation, fluid balance, exercise, defense-alarm reactions, sexual responses, diving reflexes, etc

In muscle, vasconstrictor nerve stimulation with constant arterial and venous pressures can increase the resting 4 1 pre- to postcapillary resistance ratio two or more times The resultant lowering of capillary hydrostatic pressure, causes fluid absorption into the plasma compartment Such resistance adjustments form the basis of reflex vasomotor regulation of plasma volume called forth by arterial baro- and chemoreceptors and cardiac stretch receptors Sympathetic nerve stimulation also affects *capacitance vessels*, leading to expulsion of up to 30% of regional venous blood volume Additionally, arteriolar resistance is increased by sympathetic vasoconstrictor activity Thus, the muscle vascular bed functions importantly in reflex vasomotor adjustments of blood pressure (arteriolar resistance), plasma volume (transcapillary exchange), and venous return (capacitance vessels)

Reflex activation or direct stimulation of sympathetic adrenergic vasoconstrictors to the skin produce contraction of resistance, capacitance, and arteriovenous shunt vessels A dominant effect is constriction of resistance and arteriovenous shunt vessels, thus increasing total resistance and decreasing cutaneous flow Reflexly induced changes in cutaneous flow are important in thermoregulation, as can be demonstrated by large increases or decreases in skin flow in response to heating or cooling of diencephalic heat regulation centers or of the entire body. Reflex venoconstriction is for the most part transitory in the skin, indicating little sustained change in capacitance function Thus, skin circulatory changes are more concerned with temperature regulation, rather

than with circulatory homeostasis as in the case of skeletal muscle

In the intestine, sympathetic adrenergic activation induces initial elevation of arteriolar resistance, that is later overcome by an autoregulatory escape from the vasoconstrictor influence Changes in pre- to postcapillary resistance ratio are likewise transient, so that capillary hydrostatic pressure returns to control levels The decrease in vascular capacitance produced is sustained and can mobilize substantial volumes of blood from the splanchnic region Thus, the intestinal vascular response to increased sympathetic nerve activity is characterized by moderate alterations in arteriolar resistance and sustained decreases in blood volume with little change in capillary fluid absorption In contrast to muscle, the intestine participates little in neurogenic plasma volume control It does contribute effectively to blood pressure homeostasis through reflex arteriolar resistance and capacitance alterations

The sympathetic cholinergic vasodilator system, confined to skeletal muscle in those species in which it has been demonstrated, has its predominant effect on arteriolar vessels, while precapillary sphincters and capacitance vessels have little or no cholinergic innervation Stimulation of these fibers decreases the pre- to postcapillary resistance ratio, thus increasing net transcapillary fluid filtration The sympathetic cholinergic dilator system does not appear to be activated by homeostatic chemo- or baroreceptor reflexes Stimulation of the hypothalamic vasodilator area produces the behavioral pattern of alerting, flight, or attack in conscious animals This suggests a role for these cholinergic vasodilators in alerting and fright-flight reactions

The *parasympathetic cholinergic vasodilator fibers* function in vasodilatation associated with specific organ activity such as salivary secretion and penile erection *Dorsal root vasodilator fibers* are not activated reflexly from the central nervous system and appear to be involved only in local vascular effects of the "axon reflex" type In general, reflex vasodilatation such as that induced by baroreceptor stimulation, results from diminished sympathetic vasoconstrictor discharge rather than parasympathetic cholinergic vasodilator effects

The adrenomedullary hormones produce α-adrenergic vasoconstrictor action similar to that of sympathetic vasoconstrictor fibers The latter dominate during reflex pressor responses The β-adrenergic vasodilator effect is of unique significance since these receptors are not innervated For example, skeletal muscle β-receptor dilator response to epinephrine is significant and cannot be elicited by nerve action The metabolic actions of epinephrine, already mentioned, are also of importance in influencing local factors which govern blood flow

Local mechanisms of vascular control effect so-called autoregulation and have as their chief targets precapillary resistance vessels and sphincters Changes in the ionic and chemical metabolic milieu and vascular smooth muscle response to stretch cause vasomotor reactions appropriate to tissue metabolic needs which can oppose or override the remote effects This permits a degree of local autonomy important as a regional safeguard against the more generalized responses to homeostatic circulatory reflexes and adrenomedullary hormones Thus "metabolic vasodilators" protect against excessive vasoconstriction and myogenic control of precapillary resistance vessels and sphincters protects against capillary hydrostatic overload

The vasomotor system of nerves discussed above is the main adjustor of the peripheral circulation, whereby the blood pumped by the heart is distributed throughout the body according to the needs of each individual tissue and of the organism as a whole This vital role is accomplished by constant, moment-to-moment adjustments of the resistance in the local vascular beds, and it is mediated and regulated by the central nervous system through various reflex mechanisms (Fig 3 143)

Our knowledge and understanding of these reflex mechanisms is far from complete, the function of some of them is fairly well established, the existence of others is known without any certainty regarding their function, and it is safe to assume that there exist still others, totally unknown to us at the present time Inevitably, in the ensuing parts, the lengthiest considerations will be given to the most completely studied mechanisms, but it should be clear that this is not necessarily proportional to their respective physiological importance

Vasomotor reflexes can be elicited by the stimulation of practically any afferent nerve—somatic or visceral

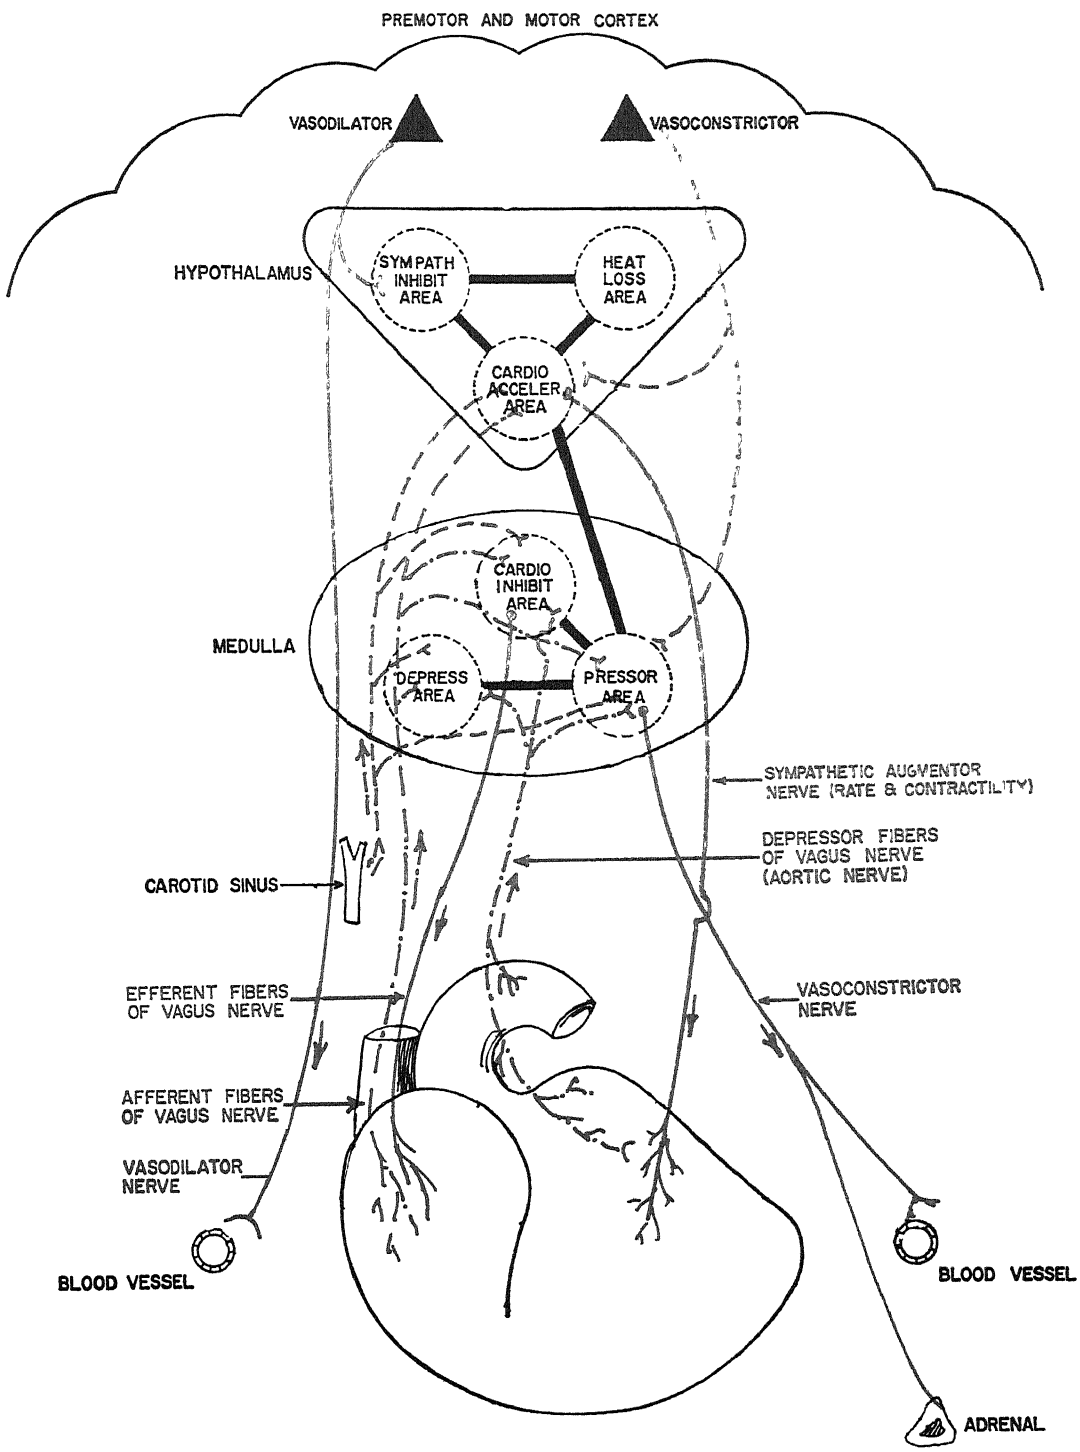

Fig 3 143 Diagrammatic representation of cardiovascular reflex mechanisms

Reflex Control Mechanisms

VASCULAR REFLEXES RESULTING FROM THE STIMULATION OF SOMATIC NERVES

Historically, these are among the earliest vascular reflex mechanisms known, although their importance in overall circulatory regulation is relatively minor

Stimulation of the central end of a nerve, such as the sciatic, the median or a sensory cranial nerve, may result in either a rise or a fall in the arterial blood pressure according to the strength and type of the stimulus employed The components of the reflex arc upon which the responses depend are *1*) afferent fibers in the peripheral nerve, *2*) the vasomotor centers, and *3*) the efferent vascular nerves, i e , the vasoconstrictors or vasodilators To elicit a pressor reflex, a stimulus much stronger than that necessary to provoke a depressor response must, as a rule, be applied, that is, one which would elicit pain in a conscious animal In the elicitation of either reflex, the magnitude of the response is apparently dependent upon the number of afferent fibers involved For example, stimulation of various nerves of the brachial or lumbar plexus causes practically equivalent depressions or elevations in the blood pressure when the number of afferent fibers in the respective nerves is taken into account

It must be re-emphasized that not all the pressor or depressor impulses ascend to the medulla, but that reflex arcs exist which have their centers within the cord, both vasoconstrictor and vasodilator reflexes can be elicited in an animal whose cord has been divided in the lower cervical region a short time previously

From the results of experiments upon animals, it is to be expected that in the human subject a painful stimulus applied to a somatic nerve will be followed by a pressor response The excitation of psychic centers and, also, the liberation of epinephrine are additional factors which play an important part in the pressor response resulting from painful stimuli On the other hand, there are numerous afferent fibers in the hollow viscera which respond to stretch and result in a decreased blood pressure Stimulation of the mesentery, peritoneum, and abdominal viscera or of certain regions such as the anus, vagina, and spermatic cord may be followed by a fall in blood pressure Finally, there may be obvious reflex effects which may or may not be associated with blood pressure changes For example, in normal persons with bladder distention, there may be facial flushing, but with evidence of widespread venous constriction Following inflation of balloons placed in the esophagus, rectum, or in an ileostomy, regional venoconstriction also can be demonstrated

ARTERIAL STRETCH RECEPTORS

Experiments have shown that the fundamental regulation of systemic blood pressure is reflexly controlled by the action of the arterial pressure itself on stretch sensitive receptors (also termed *baroreceptors* or *pressoreceptors*) located in the vascular walls, especially of the aortic arch and carotid sinus areas

Aortic or Cardiac Depressor Nerve The branch of the vagus which is known as the *aortic* or *cardiac depressor* nerve is purely afferent and depressor in function, when it is sectioned, and its central (cerebral) end stimulated, a pronounced fall in pressure occurs (Fig 3 144), excitation of the cardiac end, on the other hand, causes no effect Two factors are involved in the depressor response following stimulation of the fibers

Slowing of the Heart Rate The efferent fibers of the vagus of the same and of the opposite side constitute the efferent limb of the reflex arc through which this response is chiefly brought about, for its full elicitation at least one vagus must, therefore, remain intact

Vasodilation The vasomotor pathways constitute the efferent limb of this reflex Vasoconstriction is inhibited and vasodilation results

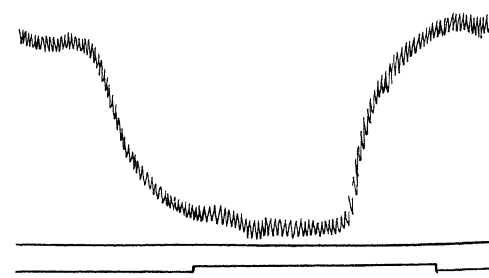

Fig 3 144 Fall in arterial blood pressure resulting from stimulation of the central end of the cardiac depressor (aortic) nerve The drum was stopped in the middle of the curve and the excitation maintained for 17 min The line of zero pressure should be 30 mm lower than here shown (From Bayliss 1893)

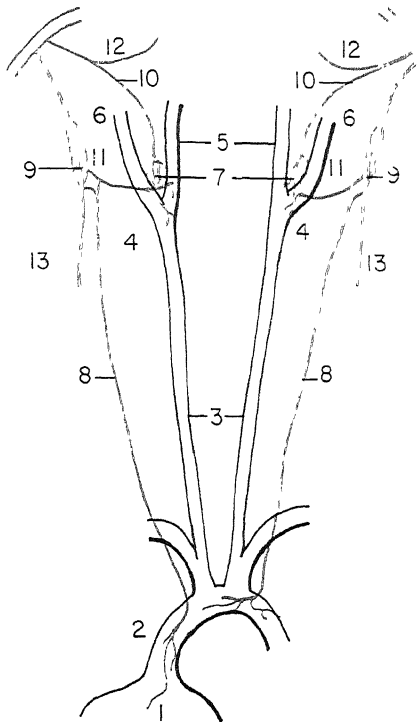

Fig 3 145 Innervation of the carotid sinus and arch of aorta *1* heart *2* arch of aorta *3* common carotid *4* carotid sinus *5* external carotid *6* internal carotid *7* carotid bodies *8* cardiac depressor nerve *9* ganglion of vagus *10* sinus nerve branch of the glossopharyngeal nerve *11* nerve branch connecting the carotid sinus with the vagus ganglion *12* glossopharyngeal nerve and *13* vagus nerve (After Heymans et al 1933)

The reflex effect upon the vessels cannot, therefore, be elicited after section of the spinal cord in the lower cervical region

The receptors of the reflex (the terminals of the aortic nerve) are situated in the aortic arch and upper part of the thoracic aorta, in the ventricles and possibly also, according to Daly and Verney (1926), in the coronary and pulmonary vessels (see Fig 3 145)

The fall in pressure is due mainly to dilation of the splanchnic vessels The dilation is not, however, confined to these vessels but includes those of the skin and muscles Cardiac slowing plays a role in the production of the fall in blood pressure, although almost as great an effect can be obtained after both vagi have been cut The depressor reflex can be elicited by mechanical or electrical stimulation of the aortic wall itself, wherein the special proprioceptors are located, stretching is an especially effective type of stimulus It was shown that action currents ascend the nerve synchronously with the heart beats (Fig 3 146) The normal stimulus is evidently the pulsatile expansion of the aortic wall, a rise in general blood pressure increasing the intensity of the stimulus a fall in pressure causing the reverse effect The primary reflex response of the pulmonary vascular bed to carotid sinus and aortic arch pressoreceptor stimulation is vasodilatation, a response which may be masked by bronchial artery dilatation and redistribution of blood from bronchial to pulmonary circuits (Daly and Hebb, 1966)

Carotid Sinus Mechanism. The carotid sinus is the term applied to the slight enlargement of the common carotid artery where it bifurcates into the internal and external carotids (Fig 3 145) The carotid sinus was shown by Hering in 1923 to play an important role in the regulation of the cardiac rate and arterial blood pressure Compression of the carotid at its bifurcation (so as to raise the pressure within the sinus) causes a marked slowing of the heart rate, vasodilation (see p 3-179), and

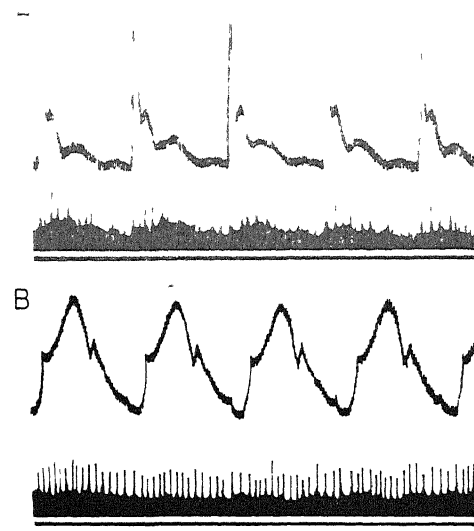

Fig 3 146 The upper curve in each record represents the arterial blood pressure registered by a membrane manometer the lower curve of each record shows the electrical discharge from a single fiber of the carotid sinus nerve of the rabbit In the upper record (*A*) the mean arterial pressure was 55 mm Hg even at this low level a discharge of 4 impulses accompanied each ventricular systole In the lower record (*B*) the mean arterial pressure was 135 mm Hg in this instance there was a more rapid and more continuous discharge from the end-organ (Bronk and Stella 1932)

a fall in blood pressure, these effects result even though mechanical stimulation of the vagus is carefully avoided Electrical stimulation of the sinus wall produces similar effects Pressure upon the common carotid some distance below the sinus (so as to reduce the blood pressure within the sinus itself) causes cardiac acceleration, vasoconstriction, and a rise in arterial pressure together with, as shown by Heymans, the liberation of epinephrine The carotid sinus therefore constitutes a mechanism whereby both pressor and depressor effects are mediated The effects are brought about through the following neural mechanism

The Sinus Reflex Arc. The afferent fibers of the reflex arc are contained in the *sinus nerve*, a branch of the glossopharyngeal This delicate filament descends between the internal and external carotids to the sinus where its fibers terminate in sensory organs (proprioceptors) situated between the connective tissue fibers in the adventitia of the sinus wall Centrally the fibers of the sinus nerve make connections with the cardioinhibitory and vasomotor centers The efferent limb of the cardiac part of the reflex is the vagus The efferent limbs of the vasodilator and vasoconstrictor reflexes are apparently sympathetic fibers, for these reflexes are abolished by complete removal of the sympathetic chains

Study of the action currents passing along the sinus nerve shows that impulses stimulated by the arterial pressure pulse are discharged throughout the cardiac cycle, their frequency increasing during systole and decreasing during diastole A rise in general blood pressure increases the rate of impulse discharge as well as the number of sense organs excited The latter show slow adaptation so that though the stimulus (distension of the arterial wall) persists the impulse discharge shows little reduction in frequency, and when the pressure is very high, they extend with little reduction in rate throughout diastole At low pressures, impulses are discharged only during systole

The sinus reflexes have been studied exhaustively by Heymans and his associates (1958) They carried out cross-circulation experiments which speak conclusively for the physiological importance of these reflexes in cardiovascular regulation (see Fig 3 147) The sinus of one dog (B) was isolated from the general circulation and perfused with the blood of another animal (A) in the manner shown in the figure

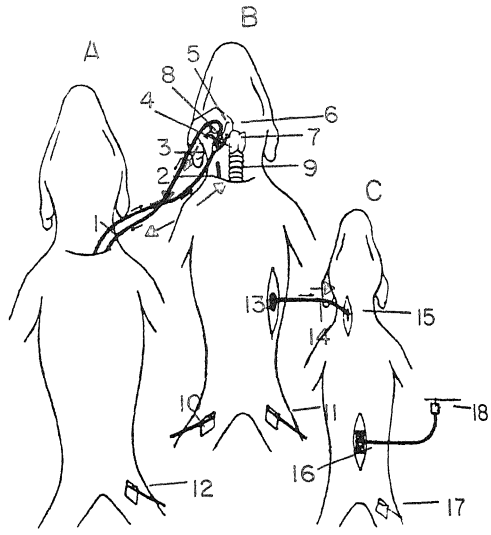

Fig 3 147 Scheme of perfusion of the isolated carotid sinus of dog *B* by dog *A* and an anastomosis between the suprarenal vein of *B* and the jugular vein of dog *C* *1* left carotid artery of dog *A* *2* right carotid artery of *B* anastomosed with carotid of *A* *3* left external jugular vein of *A* *4* isolated right carotid sinus of *B* *5* lingual artery of *B* anastomosed with jugular vein of dog *A*, *6* nerve supply to carotid sinus of *B* The blood from dog *A* flows through the carotid sinus of dog *B* and back to *A* via the lingual artery of *B* and the external jugular of *A* *7* internal carotid *8* facial and maxillary arteries *9* common carotid *10* *11* *12* and *17* femoral arteries to manometers *13* adrenal gland *14* and *15* suprarenal-jugular anastomosis *16* decapsulated spleen in plethysmograph *18* piston recorder for plethysmograph (After Heymans et al., 1933)

The nerve supply to the sinus was left intact When the arterial pressure of dog A was raised, that of dog B, recorded in the femoral artery, fell Conversely, a reduction in blood pressure of dog A caused a rise in the blood pressure of dog B In the latter instance, epinephrine liberation also occurred which was a contributory factor in the blood pressure elevation as indicated by its pressor effect upon the circulation of dog C, connected to the suprarenal vein of B These effects could not be obtained after denervation of the sinus

The sinus and aortic nerves, or so-called "buffer" nerves, constitute a mechanism of the utmost importance in controlling the arterial blood pressure and in maintaining the circulation to the brain The rise in diastolic pressure and the increase in heart rate which occur when the body changes from the recumbent to the sitting position, or from the sitting to the standing position are apparently brought about

through these nerves, they therefore play an essential part in compensating for the effect of gravity upon the circulation

An underfilled state of the vessels, as may result from hemorrhage or shock, or any other condition which tends to cause a fall in blood pressure, will call these mechanisms into play A generalized vasoconstriction results to adjust the vascular capacity to the reduced blood volume and thus maintain the blood pressure Excessive elevation of the blood pressure, on the other hand, is countered by a depressor reflex (see diagram Fig 3 143) The great importance of these reflex mechanisms in hemorrhage is shown by the fact that in an animal in which all four buffer nerves have been sectioned the rapid loss of only about one-tenth of the blood volume proves fatal, whereas usually a reduction in blood volume of from 35 to 45% is required to cause death Mayerson (1942) found that tilting anesthetized dogs from the horizontal to the upright position caused a sharp drop in blood pressure, followed within 10 sec by a compensatory rise After section of both sets of buffer nerves the compensatory rise did not, as a rule, occur

Moderate arterial hypertension can be produced in dogs by denervation of the sinoaortic baroreceptors (Heymans and Neil, 1958) It is characterized by increased lability of arterial pressure with marked hypertensive response to various external stimuli and, in one series (Ferrario et al, 1969), a paradoxical increase in blood pressure during sleep

A rise of pressure within the carotid sinus produces the behavioral signs of sleep (Koch, 1932), can diminish or abolish drug induced convulsions, and induce cortical electroencephalographic synchronization The physiological significance of this effect in the regulation of sleep-wake patterns is somewhat uncertain Studies in cats suggest that synchronous inflow from baroreceptors is in part responsible for synchronous sleep (Baust and Heinemann, 1967)

Mechanism of Action. The mechanism of action of the blood pressure on the baroreceptors is complex and only partially understood They are essentially stretch receptors and if deformation of the baroreceptive arterial walls from a raised arterial pressure is prevented, the baroreceptors no longer respond to the pressure change Reflex blood pressure depression from carotid sinus stimulation is greater with pulsatile than with steady pressure stimulation At moderate sinusoidal stimulating pressures within the carotid sinus the blood pressure depression increases with both frequency and amplitude of the stimulating pressure This frequency effect disappears at higher intrasinal pressures and if stimulation pressure exceeds a range of 160 to 180 mm Hg (in dogs) the blood pressure reaction is inverted (Stegemann and Tibes, 1969)

Local application of drugs, such as epinephrine or norepinephrine, increases the smooth muscle tension in the arterial wall of the isolated carotid sinus preparation which, in turn, is associated with a large increase in impulse traffic along the baroreceptor fibers throughout the cardiac cycle and a resetting of the baroreceptive mechanisms at a higher level, with resultant blood pressure adjustment Sodium nitrite, which relaxes smooth muscle, reduces the intramural tension in these sensitive regions decreases the impulse traffic, and resets the blood pressure regulation at a lower level

In experimental and clinical hypertension the pressure sensitivity of the carotid sinus receptor response is reduced, thus baroreceptor response can be "reset" in its range of function to maintain blood pressure at a higher level When hypertension is relieved the range of function can be "reset" downward (McCubbin et al, 1968) These observations indicate that under normal conditions, the response of the baroreceptor area and the level of blood pressure maintained depend not only on the level of arterial pressure, but, possibly, even more so on the resistance of the baroreceptive arterial walls to deformation by the intravascular pressure

Other Arterial Baroreceptors. Possible additional arterial baroreceptor types have been studied in the common carotid artery, the thoracic, and mesenteric arteries Experiments in which a sudden rise in intracranial pressure causes systemic hypertension, and sudden reduction in intracranial pressure leads to systemic hypotension, suggest, but do not prove, that pressure sensitive receptors are present in the cranial cavity. However, the systemic hypertensive effect of increased intracranial pressure (*Cushing effect*) is largely, or entirely, secondary to asphyxia of medullary centers (see pp 3-208 and 3-211) Cushing (1902) first demonstrated in animals that an acute rise in intracranial pressure induces an increase in systemic arterial pressure which just exceeds

that within the cranial cavity Impulse output in the mesenteric baroreceptors exists throughout the cardiac cycle, and, if pressure is changed in the mesenteric artery or the artery is clamped, vasomotor reflexes are induced These reflexes do affect the systemic blood pressure even when the sinoaortic nerves are cut It is a segmental, reflex adaptation of the circulation and vasomotor state related to pressure changes in a given area It apparently exists in the cat but not in the dog Reflex responses can also be obtained in the innervated perfused hind leg of the open-chest dog, when the descending aorta between the left subclavian artery and the diaphragm is isolated and perfused at varying pulsatile pressures, or when epinephrine is added

The importance of these afferent mechanisms in control of the circulation is not known

BALANCED AND RECIPROCAL VASCULAR REACTIONS

In the intact animal the height of the blood pressure at any moment, insofar as the nervous control of the peripheral vessels is concerned, is apparently the algebraic sum of the effects of afferent impulses impinging upon the vasomotor centers Under ordinary circumstances, impulses arising from the carotid sinus and aortic arch play the most prominent roles, but impulses from skin, muscles, and viscera and from higher nervous centers also exert an important influence That pronounced effects upon peripheral vessels can be produced by radiation of impulses from higher centers is evidenced by such phenomena as blushing, pallor, penile erection, and certain types of syncope (fainting) When a dog is excited, similar vascular changes can be observed in the mucosa of the exteriorized colon and in splenic volume Even very mild excitation of psychic centers exerts an influence upon the vascular mechanisms The psychogalvanic reflex (due to changes in the electrical resistance of the skin) has a vascular basis A reciprocal relationship also exists between splanchnic and cutaneous vascular areas on the one hand and the vessels of the muscles on the other Epinephrine, for example, causes dilation of the latter vessels accompanied by vasoconstriction in the skin and abdominal viscera Stimulation of the wall of a large vein or distension of the duodenum causes reflex constriction of the cutaneous vessels, and stimulation of the skin results in an increased amount of blood in the liver and in the renal cortex Furthermore, the muscular and cutaneous tissues may show opposite vascular reactions Thus, in the dog, cooling of the body causes constriction of the skin vessels and vasodilation in the muscles

A mechanism also exists in the experimental animal, whereby afferent impulses arising within an organ, although leading to generalized vasoconstriction, result locally in dilation and increased blood flow This is sometimes called the *Loven reflex* after the investigator who first described it in 1866

An interesting example of the complex nature of the reflex vascular adjustments has been described An electrical record obtained from a nerve twig coming from a Pacinian corpuscle in the mesentery during perfusion of the mesenteric vessels showed an increase in the frequency of the afferent impulses when the perfusion pressure was raised The impulse frequency was reduced by bleeding the animal and increased again when the blood was reintroduced into the body It is suggested that the Pacinian corpuscles, which lie in close relation to the vessels, are stimulated when the latter dilate Messages pass to the vasomotor center which then discharges vasoconstrictor impulses to the vessels of the area from which the afferent impulses arose Thus, undue distention of the vessels and pooling of blood in the splanchnic region is prevented It has also been shown that stimulation of the peripheral end of the splanchnic nerve causes a much greater rise in blood pressure than usual if the carotid sinuses have been excluded from the circulation (by clamping the carotids) This observation indicates that ordinarily the pressor effect of splanchnic stimulation is largely counteracted by a depressor reflex initiated from the sinus

EXTRARESISTANCE (CARDIAC) EFFECTS OF BARORECEPTOR REFLEXES

Most important changes during reflex, systemic hypertension of sinoaortic origin are *venoconstriction* (effects on the capacity vessels) and direct sympathetic stimulation of the heart Occlusion of the common carotid arteries causes systemic hypertension with resultant decrease in the plethysmographic volume of spleen, limb, kidney, and other parts of the circulation If the systemic hypertension is ascribed to widespread arteriolar vasocon-

striction, cardiac output would be expected to fall or, at least, not to increase However, total pulmonary, muscle and kidney blood flow have been shown to increase during carotid occlusion There is always some increase in peripheral resistance but it is of less quantitative significance, since the cardiac output increases Experiments, utilizing an extracorporeal circulation with exclusion of the heart and lungs to allow continuous measurement of alterations of intravascular blood volume and of venous return, have also demonstrated venoconstriction (decreased vascular volume) and an increased venous return to the heart when hypotension was induced in the isolated canine carotid sinus The opposite effects occurred with carotid sinus hypertension Venoconstriction has also been shown in the forelimb vascular bed of the dog during carotid baroreceptor stimulation Some studies have failed to confirm these convincing data

Reflex sympathetic and parasympathetic effects can significantly alter the atrial and ventricular contractility The circulatory response to carotid sinus hypotension can be, dominantly, an increased cardiac action and, secondarily, an increase in peripheral resistance

In unanesthetized dogs electrical stimulation of the carotid sinus nerves produced vagal cardiac slowing, arterial hypotension, and decreased mesenteric, renal, and hind limb vascular resistance (Vatner et al , 1970) The most profound decrease in resistance and increase in flow occurred in the hind limb The increase in hind limb flow took place also in exercising animals when the muscular bed was already dilated on a metabolic basis Observations in man are instructive (Fig 3 148) Pressures within the carotid sinus regions were directly measured with indwelling catheters in conscious, supine man while the internal pressure was lowered by central, bilateral, carotid artery compression As the carotid sinus pressure dropped from a mean of 100 to 40 mm Hg, the arterial blood pressure and heart rate increased only mildly There is no evidence that the pressor response is secondary to reduction in caliber of the limb and skeletal muscle vessels The resistance to flow which they offer is actually slightly less than in the control state as the result of a mild increase in systemic blood pressure and in blood flow through the limbs Simultaneous measurement of cardiac output

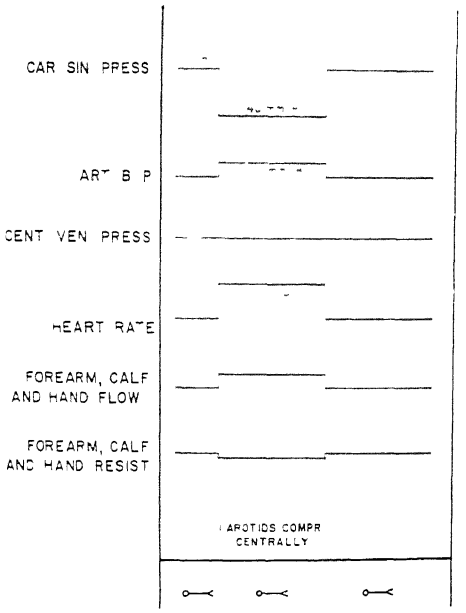

Fig 3 148 Bilateral carotid artery compression in supine man producing carotid sinus hypotension reflexly causes a rise in systemic pressure a tachycardia and an increase in peripheral flow with concomitant decrease in peripheral resistance

would have been helpful here, since the increase in arterial blood pressure could arise from the increased cardiac output or from increased vessel resistance in another area

CARDIOVASCULAR REFLEXES OF CHEMORECEPTOR ORIGIN

The carotid and aortic bodies adjacent to the carotid sinus and root of the aorta contain epitheloid cells and nerve endings sensitive to the chemical composition of the arterial blood The fibers of the aortic body run in the vagus, while the fibers of the carotid body are branches of the glossopharyngeal nerves The aortic body is connected with a branch of a fine artery arising from the aorta beyond its arch The carotid body (glomus caroticum) is a small structure situated upon a branch of the occipital artery, or upon a small vessel arising directly from the external carotid just above the bifurcation of the common carotid It is composed of rounded clumps of polyhedral cells, and possesses a rich network of capillaries of sinusoidal character Both the carotid and aortic chemoreceptors sample the blood for its Po_2, Pco_2, pH, and possibly for other qualities Blood flow through the carotid body appears to be by far the

largest for any body tissue Calculations based on direct flow measurements indicate a flow of 2000 ml /100 g /min (left ventricle = 80 to 100 ml /100 g /min) while the oxygen usage of 9 ml /100 g /min , compares with that of the left ventricle This flow can be cut to one-third by stimulation of the cervical sympathetic nerves Reflex vasomotor effects evoked by chemoreceptor stimulation have been extensively studied In general, the chemoreceptors are stimulated by anoxia, hypercapnia, and acidosis The mechanism by which changes in blood chemical composition effect a response in these two structures is not clearly understood nor has the chemoreceptor intermediate that stimulates the nerve endings been identified, but it has been shown that electroneurographic evidence of chemoreceptor activity exists at CO_2 tensions above 30 mm Hg and at O_2 tensions of approximately 90 mm Hg or less With increasing Pco_2 and decreasing Po_2, discharge of the chemoreceptors is diffuse, but the discharge with increasing CO_2 tension is rarely as great as that resulting from anoxia Acute hypoxia (inhalation of low oxygen mixtures or of nitrogen) causes systemic hypertension and vasoconstriction (decreased blood flow) in the limbs and intestine, responses are abolished if the chemoreceptor areas are blocked It is unlikely that chemoreflexes cause systemic hypertension only by inducing an increase in arteriolar resistance, but there are no studies of the reflex effects of such stimulation on cardiac output or on the capacitance vessels It is certain, however, that they contribute to the maintenance of the circulation following depletion of the blood volume The latter can be shown in an animal in which, following massive hemorrhage, the blood pressure decreased to 70 mm Hg There was intense firing of the chemoreceptors which could be stopped by raising the oxygen tension while resection of the sinus nerves caused a further fall of blood pressure The latter can only be due to withdrawal of chemoreceptor reflex vasoconstriction, since the baroreceptors are not operative at this blood pressure level Presumably the capacitance vessels (veins) are involved here as well as the resistance vessels

VASCULAR EFFECTS OF NORMAL VARIATIONS IN BLOOD OXYGEN, CARBON DIOXIDE AND pH

Cardiac response to chemoreceptor stimulation is complex In experimental preparations arranged so as to prevent secondary influence of respiratory stimulation on cardiac activity, stimulation of the carotid bodies produces reflex bradycardia while stimulation of the aortic bodies produces reflex tachycardia Where respiratory effects are allowed, cardiac response to carotid body stimulation is related to the intensity of the ventilatory augmentation With mild ventilatory stimulation the heart rate is usually decreased, with marked increase in ventilation, cardiac acceleration occurs (Berne and Levy, 1967)

The primary effect of chemoreceptor stimulation on the pulmonary circulation is vasoconstriction, which may be masked, however, by the vasomotor changes in the bronchial (systemic) circulation (Daly and Hebb, 1966)

It is generally stated that both carbon dioxide and oxygen have dual effects Although CO_2 may have a minor reflex effect through the aortic and carotid body chemoreceptors, it may also have a large direct central effect on the medullary centers which leads to peripheral vasoconstriction with rising blood CO_2 concentrations, while with decreasing blood CO_2, the center will ultimately cease giving out its normal tonic influence It also may have a large direct peripheral vessel effect, an increasing blood CO_2 causing peripheral dilation and a decreasing blood CO_2 leading to vasoconstriction Similarly, the central effects of oxygen lack are supposedly largely mediated through the sinus and aortic bodies, a decrease in oxygen leading to reflex peripheral vasoconstriction, while in the periphery, local hypoxia has the effect of vasodilation While these statements based on experimental data have been perpetuated, it is very difficult to make such a functional separation and yet retain some reasonable degree of normalcy in the experimental approach to the problem Aside from the effects mediated through the chemoreceptors, it is doubtful that the relative effects of physiological variations in blood gases and pH on the vasomotor centers and the general peripheral circulation are known However, for some individual organs or regions, one can distinguish between the local vascular effects of chemical changes in the blood and their central neural effects For example, the main body of evidence indicates that small increases in carbon dioxide have a direct vasodilating action on cerebral and skin vessels in animals and in humans

The complexity of the problem, even in indi-

vidual regions, is indicated when one compares the effect of carbon dioxide on the vasomotor state in the extremities The hind limb of an animal perfused with blood from a heart-lung preparation shows vasodilation (greater blood flow at the same perfusion pressure) when the lungs are ventilated by air containing a small amount of carbon dioxide or by air with some reduction in its oxygen content The vasodilation must result from local chemical reactions However, in human subjects with hypercapnia alone, induced from breathing a small concentration of carbon dioxide in the inspired air, the forearm's vascular resistance (mainly muscle) is greatly increased, for systemic blood pressure is increased with little or no change in local blood flow In the same subjects in whom hypoxia was produced by breathing 5 to 10% oxygen in nitrogen, forearm blood flow increases 100% in the presence of a constant systemic arterial and venous pressure so that vascular resistance in the forearm is considerably reduced Since the same results are observed in the nerve-blocked arm, the local change in vasomotor state is due to a humoral mechanism and not to a nervous mechanism When the increased elimination of CO_2 during hypoxia is prevented by adding enough CO_2 to the oxygen-poor gas mixture to maintain the alveolar P_{CO_2} constant, vascular resistance in the forearm is not significantly changed This indicates that marked hypoxia does not affect local overall vessel resistance Thus, in man, a humoral vasoconstriction occurs with hypercapnia, a humoral vasodilation occurs with hypoxia in the muscles of the forearm which is due to the hypocapnia resulting from the hypoxia rather than directly to the lack of oxygen The exact mechanism is not clear The CO_2 or altered pH could have had a local effect, but it is just as probable that a rapid change in arterial P_{CO_2} evoked biochemical changes in the blood which caused local vasoconstriction or dilation Of several possible humoral vasodilators which are known, epinephrine, which causes vasodilation in skeletal muscle, might have been released by the lowered P_{CO_2}

In the past, it has been debatable whether the circulatory effects observed with respiratory or metabolic acidosis come from the elevated P_{CO_2}, the fall in pH, or a combination of both, because there has not been any good way of separating these effects However, with the use of the organic buffer Tris (hydroxymethyl) amino methane, reasonable experimental separation has been performed with the finding that the cardiovascular effects arise from the decrease in pH and not from the associated change in blood Pa_{CO_2} (Fig 3 149) To make this study, the effects of metabolic acidosis were observed in dogs under apneic oxygenation with and without Tris injection Apneic oxygenation is a condition of ventilatory arrest during which oxygenation of the blood is maintained while acute hypercapnia develops This condition is produced by ventilating the dog with 100% oxygen in an open circuit for 1 hr During this time, oxygen replaces nitrogen throughout the body After this period of denitrogenation, apnea is induced by succinylcholine, and the lungs are left connected to a reservoir of oxygen Thus, the blood is maintained

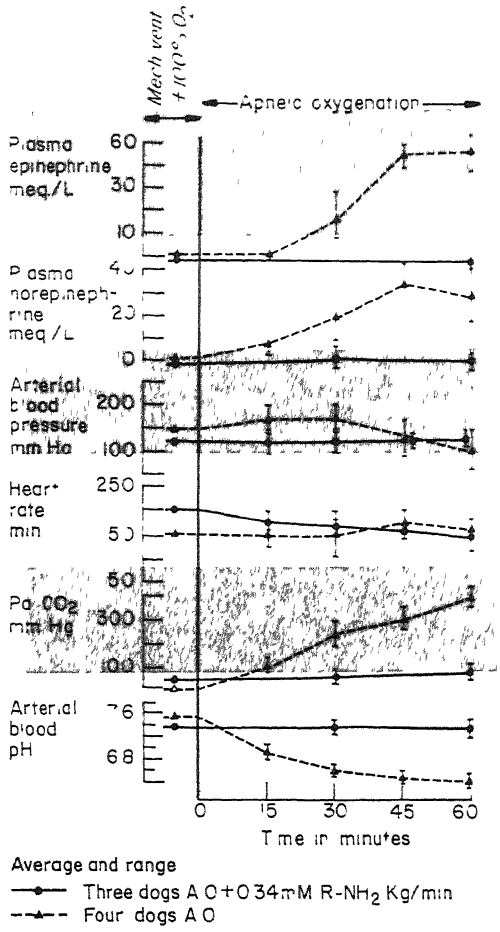

Fig 3 149 Comparative changes in pH P_{CO_2} blood pressure and catecholamine levels during apneic oxygenation with and without tris administration (Nahas et al 1959)

in full oxygen saturation, but blood CO_2 accumulates slowly Without the presence of Tris in such dogs, there is a rise in CO_2, arterial, pulmonary artery and central venous blood pressures, Pa_{CO_2}, and plasma norepinephrine and epinephrine, the blood pH drops precipitously, the heart rate mildly In similar dogs treated with intravenous drip of Tris, all these physiological variables remain close to their control values except Pa_{CO_2} which rises from 38 to 82 mm Hg Since such a P_{CO_2} increase in the intact animal does produce the above circulatory changes when it is accompanied by a parallel fall in pH, the H^+ concentration increase during hypercapnia seems to be a determinant factor in the stimulation of the cardiovascular system This type of experiment, however, still does not clearly separate the effects of CO_2 and pH, for the latter does change (7 45 to 7 31), and the vascular system may be very sensitive to it

REFLEXES FROM THE HEART AND LUNGS

From various intrathoracic vessels (including the chambers of the heart) arise other reflexes affecting vasomotor tone Although their importance in the regulation of the circulation may possibly be comparable to that of the previously mentioned reflexes, much less is known about their function, since it is much more difficult to investigate cardiopulmonary reflexes than those related to the baroreceptors in the systemic circuit

Right Heart Reflexes. Observations have shown conclusively that in the walls of the atria and great veins, there are receptors which have fairly large afferent nerve fibers and which respond to change of pressure in the atria by firing during atrial contraction (type A), or during the passive distention of atrial diastole (type B) These afferent fibers are in the vagi

In 1914, Bainbridge showed that the intravenous injection of saline or blood produced tachycardia in the anesthetized dog and that this was abolished only by bilateral vagotomy The location and nature of receptors responsible for this reflex have not been identified and fluid infusions frequently fail to elicit tachycardia It has been shown in anesthetized dogs that intravenous infusions increase the heart rate when the initial rate is below 140/min, but actually decrease the heart rate at more rapid initial rates Thus both the mechanism and physiological role of this reflex remain controversial.

In anesthetized dogs, partial occlusion of the pulmonary artery leads to an increase in pulmonary blood flow It has been shown that this reflex is dependent on an intact sympathetic innervation of the heart, the vagi and medullary centers are not involved Presumably the increase in pulmonary blood flow is due to a reflex myocardial stimulation initiated by a rise in right ventricular systolic pressure and is mediated by the cardiac sympathetic nerves

Pulmonary Vessel Reflexes Most investigators now admit that the pulmonary blood vessels have tone and, therefore, the possibility that this tone can be altered Daly has found evidence in the anesthetized dog that the pulmonary vascular resistance can be altered by extrinsic vasomotor nerves Both vasoconstrictor and vasodilator responses have been demonstrated The primary effect of chemoreceptor (carotid body) stimulation is pulmonary vasoconstriction, although the reflex vasoconstrictor effect on the bronchial circulation, which occurs simultaneously, may actually produce a decrease in pulmonary vascular resistance (Daly and Hebb, 1966)

Pulmonary Artery Reflexes Elevation of pressure in the main pulmonary artery and its bifurcation within physiological limits reflexly induces systemic hypotension and inconstant bradycardia Vagotomy abolishes the response Elevating the pressure above physiological limits (e g, 80 to 120 mm Hg) causes, paradoxically, a rise in systemic arterial pressure

Reflexes from the Smaller Pulmonary Vessels Despite a tremendous amount of investigation, it is problematic whether reflexes are initiated from the smaller vessels of the pulmonary circuit—arterioles, capillaries, and venules Embolization by clots, starch grain, glass, and plastic beads had not determined conclusively whether the results have a mechanical or a reflex explanation From the work of Daly (see Daly and Hebb, 1966), it is known that the sympathetic innervation of the vessels is largely vasoconstrictor and that stimulation of the stellates may, at times, reduce lung blood flow by as much as 30% A variety of experiments have demonstrated pulmonary vasoconstriction resulting from such stimuli as pulmonary embolization and venous congestion There are indications that some of these responses may be mediated by local pulmonary axon reflexes

An "alveolar-vascular reflex of the lung" has been demonstrated If water is introduced into the airways of sheep, a reflex response occurs

via the parasympathetic nervous system (blocked by atropine) producing pulmonary vasoconstriction The vagus is not involved for vagotomy does not abolish the response, the reflex is therefore considered to be local in nature This reflex would lead to a homeostatic redistribution of blood flow away from nonventilated lung areas (see also p 3-210)

Left Heart Reflexes. *Left Ventricle* Daly and Verney (1926) were first to show that pressor receptors existed in the left heart In an innervated heart-lung preparation in which the aortic pressure was kept constant, an increased pressure in the left side of the heart caused cardiac slowing More recently, it has been shown that when the pressure is elevated in a vascularly isolated left heart, reflex bradycardia, systemic hypotension, and vasodilation of the leg vessels result Since left atrial pressure elevation alone was ineffective, it is concluded the receptors were in the left ventricle Upon vagal blockage the effect disappeared These effects may also arise from pressoreceptors of the aortic arch which are known to extend into the left side of the heart

Ross and co-workers (1961a, b) studied this reflex by perfusing the systemic vascular bed, using an extracorporeal circulation, pressures could be varied independently in the innervated but isolated heart Significant decreases in systemic vascular resistance occurred when left ventricular systolic pressure was elevated, or when left ventricular diastolic and mean left atrial pressure were *also* elevated Only minimal alterations in vascular resistance were observed to accompany right ventricular pressure elevations alone Most important, the elevations in left intracardiac pressure produced a large increase in systemic vascular volume and a diminished venous return This suggests that left ventricular baroreceptor stimulation reflexly inhibits venous tone Informative experiments are those of Doutheil and Kramer (1959), who varied the left ventricular stretch and pressure by an adjustable clamp on the aorta, while the systemic flow was metered, and its perfusion pressure maintained constant during aortic constriction by a very large pressure buffering chamber attached to the aorta It was observed (Fig 3 150) that within 4 sec after elevation of left ventricular pressure by mechanical constriction, the aortic flow starts to rise and is almost doubled, indicating massive peripheral dilation arising reflexly from the beginning of the aorta or in the left heart The

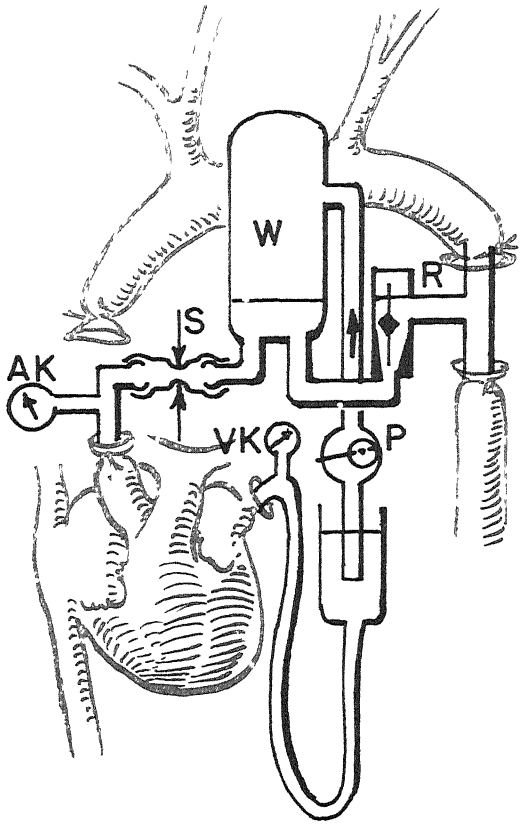

Fig 3 150 Experimental device to show presence of left ventricular pressure (stretch) receptors by aortic compression *S* clamp *AK* and *VK* aortic and left atrial pressure manometers respectively *W* constant pressure buffering chamber *R* systemic flow meter *P* pump (Doutheil and Kramer 1959)

afferent pathway for this reflex was demonstrated to be the vagus nerve, for following its cervical section, the effect disappeared To what extent this reflex is invoked under normal conditions is problematic, since a rather large increase in ventricular pressure (and presumably, therefore, stretch) is necessary to elicit a systemic flow response

Coronary Chemoreflex (Bezold-Jarisch Reflex) Intravenous injection of veratridine and certain other agents (e g , nicotine, some antihistaminics, etc) produces reflex cardiac slowing, hypotension, and apnea (the *Bezold-Jarisch* reflex) The reflex apnea is caused by excitation of the receptors for the Hering-Breuer (lung inflation) reflex The receptors responsible for the bradycardia and hypotension can be reached through injections into the coronary arteries or the pericardial sac In the cat, injections into the right or left coronary

arteries elicit the response while in the dog only injections into the left coronary arteries or pericardial sac are effective (Comroe, 1965, Aviado, 1965) The hypotension is independent of the bradycardia, being caused by reflex vasodilation

Left Atrial Receptors Receptors in the left atrium (and probably pulmonary veins) which respond to stretch have been implicated in the regulation of blood volume (Herd, 1970, Gauer et al , 1970) Acute distention of the left atrium, as with a balloon, increases heart rate, in general decreases arterial pressure (although the reverse may occur), and causes diuresis Procedures which produce a shift of blood into the intrathoracic circulation, thus elevating central blood volume and atrial pressure, produce diuresis and lead to reduction of plasma volume This redistribution of blood volume can be produced, for example, by continuous *negative pressure breathing*, head-out *body immersion* in a thermoindifferent bath, and human centrifuge simulated *gravitational effects* (so-called transverse G) The reduction in plasma volume observed in *bed rest* and *weightlessness* of space pilots, is presumed to have a similar basis Procedures which decrease central blood volume, e g , *hemorrhage*, *positive pressure breathing*, have the opposite effect The effects on fluid volume are mediated by reflex effects on antidiuretic hormone and aldosterone release and on renal blood flow Right atrial receptors and arterial baroreceptors participate in these responses as well The importance of vagal receptors for these actions is clear since vagal cooling or vagotomy blocks many of them Thus, intrathoracic vascular receptors importantly represented in the left atrium, respond appropriately to central blood volume and pressure fluctuations, so as to regulate blood volume Figure 3 151 illustrates several of these effects in response to graded hemorrhage (see also p 3-235)

Other experiments in man have functionally implicated pressoreceptors in the thoracic portion of the central blood pool in adjustments of the circulation (Fig 3 152) When the legs of a recumbent man are passively raised, the blood flow through the skeletal muscles of the forearm is increased greatly as is the central pool of blood Since at this time, the arterial blood pressure remains the same or even decreases, this dilation in the forearm is evidently not a consequence of arterial baroreceptor stimulation Inflation of leg cuffs before trunk and leg elevation, or the use of sympathetic blockade to the forearm, eliminates the flow response While the precise nature of the stimulus and accurate location of the receptors concerned in the reflex have not been determined, it seems

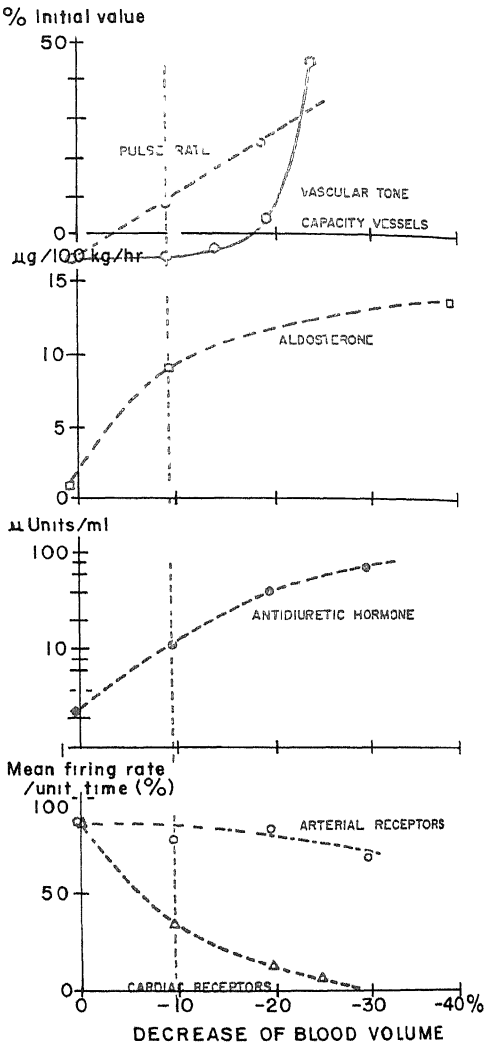

Fig 3 151 Responses to a graded hemorrhage With loss of the first 10% of blood volume the firing rate of atrial (cardiac) receptors falls to one-half As the loss exceeds 20% there is a fall in firing rate of aortic (arterial) baroreceptors The plasma aldosterone (μg released into the plasma) and antidiuretic hormone (μ units/ml) concentrations rise causing sodium and water retention The pulse rate increases steadily as blood volume falls There is little change in tone of capacity vessels until collapse threatens when it increases effectively to move blood to central regions (Redrawn from Gauer et al 1970)

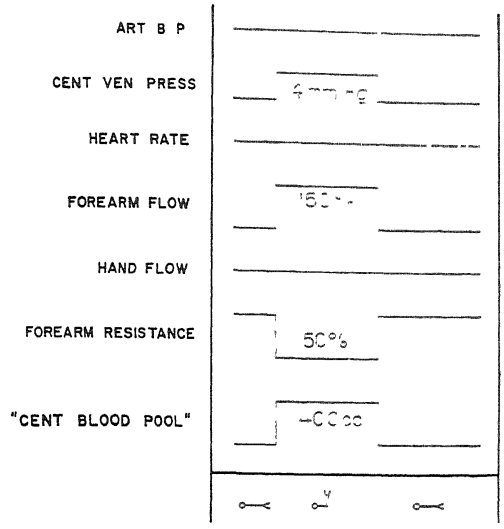

Fig 3 152 Passive elevation of the legs in recumbent man produces elevations in the central blood pool and central venous pressure with increased peripheral flow while heart rate and systemic arterial pressure are unchanged The decreased peripheral resistance is felt to be secondary to reflex dilation

likely that forearm dilation is due to stimulation of receptors in the low pressure area of the thoracic vascular bed Rapid positive and negative pressure breathing causes a similar augmentation of blood flow in forearm and calf without changes in arterial blood pressure and heart rate Presumably, this response is also to be explained through stimulation of pressoreceptors in the chest

Respiratory Reflexes. *Vasoconstriction in the Finger* Vasoconstriction occurs in a finger after voluntary deep inspiration or passive deep inflation of the chest with air under positive pressure The vasoconstriction was determined by a finger plethysmograph in which a blood flow decrease was noted with inspiration which bore no relation to the respiratory fluctuations of systemic blood pressure The receptors and afferent pathways of this reflex are unknown except that without doubt, they arise within the lungs

Respiratory sinus arrhythmia (increase in heart rate during inspiration, decrease during expiration) has been variously attributed to the influence on medullary cardioregulatory centers of impulses from· *1*) medullary respiratory centers, *2*) stretch receptors in the lung, or *3*) right heart volume receptors Experimentally, paralysis of respiratory movements and β-adrenergic blockade does not abolish the arrhythmia, while bilateral vagotomy does (Hamlin et al , 1966) Thus, sinus arrhythmia can result only from waxing and waning of vagal efferent activity in phase with periodic respiratory center discharge There is evidence that fluctuations in efferent sympathetic activity also play a role Periodic Hering-Breuer (q v) reflexes and right atrial distention during inspiration have not been ruled out as playing a contributory role In addition to the effect on heart rate, a positive inotropic action on left ventricular contraction during the acceleratory phase has been demonstrated

PERIPHERAL VASCULATURE REFLEXES

Although little is known concerning reflexes originating in the peripheral blood vessels, interest has been aroused in sensory mechanisms that may lie in the peripheral vasculature Haddy and Gilbert (1956), using anesthetized dogs in which pressures were measured in the brachial artery, cephalic vein, and a small artery and a small vein of the paw (with maintenance of a constant brachial artery flow by a pump), found that elevation of cephalic vein pressure produced dilation of the arteries and veins which was completely compensated for by constriction in the small vessel segment After procaine nerve block, the vessels respond like a passive elastic system Therefore, the observed small vessel constriction must have been of venous origin However, this local venovasomotor reflex has not been confirmed by Greenfield and Patterson (1956) using the plethysmograph

Summary

Change in activation of the vasoconstrictor fibers is responsible for blood pressure homeostasis and heat loss regulation of the skin blood flow Centrally induced vasodilation is caused almost entirely by inhibition of constrictor tone There may be a generalized or a strictly segmental or regional engagement, depending upon the type of stimulus Together with the sympathetic vasodilator fibers to skeletal muscles, vasoconstrictor fibers may affect specific vascular areas in a discharge pattern causing marked redistribution of blood flow The vasoconstrictor fibers are looked upon as the main neurogenic adjustors of the peripheral circula-

tion showing prompt and rational adjustments of their impulse discharge to any change in environment, especially those changes that affect the hypothalamus and the vasoconstrictor center in the medulla.

In the nerves from the pressure or stretch sensitive vascular walls of the aorta and carotid sinus, an increased number of impulses is discharged with each rise of blood pressure; the impulse frequency, systemic blood pressure, and heart rate can be varied at will when these areas are artificially perfused at different pressures and pulse pressures; section of the nerves results in a persistent hypertension. These presso- or baroreceptors are joined by the aortic and carotid sinus nerves with the nerve centers in the medulla oblongata, which maintain systemic blood pressure at normal levels. Any arterial blood pressure deviation causes compensatory reflexes, through the baroreceptors, to re-establish a normal blood pressure. The efferent pathways to the heart for these baroreceptor vasomotor reflexes are the vagus and the sympathetic; in addition, the sympathetic vasoconstrictor fibers adjust the size of the "resistance" and "capacity" vessels in control of peripheral resistance to blood flow and the return of blood to the heart. The sympathetic fibers which control secretion of epinephrine and norepinephrine by the adrenal glands also stimulate these secretions and add a blood-borne hormone to the nervous influence, but as already indicated, this humoral influence is almost insignificant compared to that of the direct nerve effect.

The baroreceptors also react to nonspecific pharmacological agents. Baroreceptors exist in several other tissues—common carotid artery, thoracic and mesenteric arteries; these are probably not related to blood pressure homeostasis, but may be engaged in local reflex adjustments of peripheral resistance and blood flow. Baroreceptor nerve endings are in the walls of the caval veins, heart (mainly the atria), and in the pulmonary circulation. Presumably, these receptors are primarily engaged in the reflex adjustment of venous return, heart rate, blood volume, and cardiac output. In the presence of marked hypotension from hemorrhage, chemoreceptors in the carotid and aortic bodies are excited to induce vasoconstriction in the resistance and capacitance vessels through the sympathetic constrictor fibers. Chemoreceptors are also present in the pulmonary and coronary circulations, but the physiological stimuli adequate for their activation are not known.

9 / REGULATION OF SYSTEMIC AND PULMONARY CIRCULATION

SYSTEMIC CIRCULATION

Arterial Blood Pressure

The first determination of arterial blood pressure was in 1733 when the Reverend Stephen Hales inserted a brass cannula into the central end of the femoral artery of a horse, connected it to a long vertical glass tube, and observed that a column of blood filled the tube to a height of 8 ft , 3 in (185 mm Hg)

ARTERIAL BLOOD PRESSURE IN MAN

Normal Values. The average systolic pressure of young male adults at mental and physical rest in the sitting position (as usually measured in a routine medical examination) is usually given as 120 mm Hg, the diastolic as 80, the mean pressure as 100, and the pulse pressure as 40 However, the range of normal blood pressures may be from 90 to 120 mm Hg systolic, and 60 to 80 mm Hg diastolic Slight diurnal variations in blood pressure of from 5 to 10 mm Hg systolic occur, the peak being in the afternoon and the lowest level in the early hours of the morning

Age, Sex, and Build. Age exerts a definite influence upon the blood pressure levels At birth, the systolic pressure measures from 20 to 60 mm with an average of 40 mm It rises rapidly, however, and has an average value of about 70 mm at the end of a fortnight and 80 mm at the end of a month A slow steady rise takes place from this time until about the 12th year when it averages 105 mm With the onset of puberty, a more sudden rise occurs, which in boys reaches 120 mm at about the age of 17 A steady though not great rise in blood pressure, from adolescence to old age, is the rule in health, the averages for the age of 60 being given as about 140 systolic pressure and 87 diastolic In women up to the time of the menopause, the systolic pressure is from 4 to 5 mm lower than for men of the same age At the menopause however there is a somewhat abrupt rise and the pressure remains a little above the male average from then on (Table 3 20)

Comparing groups of markedly obese and normal persons, the former have a rather pronounced increase of systolic pressure The incidence of abnormally high blood pressure (hypertension) is also definitely greater in overweight persons

The Effects of Digestion, Emotion, Exercise, and Posture The systolic pressure is influenced to a small but definite extent by meals A rise of from 6 to 8 mm is the usual effect, and this lasts for an hour or so There is little change in the diastolic pressure, if anything, it is reduced, presumably as a result of vasodilation in the digestive organs and skin

Quiet, restful sleep may be accompanied by a fall of from 15 to 30 mm in the systolic pressure The fall is most marked during the first hours, rising gradually again after this until the time of waking If the sleep is disturbed and accompanied by imaginary motor activities, there may be no depression of the pressure, but rather an elevation, in some instances to as high as 200 mm systolic and 105 mm diastolic Excitement, fear, worry, etc , markedly affect the arterial blood pressure, especially the systolic The effects are brought about through increased cardiac action and changes in the state of the vessels through impulses playing upon the cardiac and vasomotor centers in the medulla The liberation of adrenaline into the blood stream may also be a factor

Of all physiological conditions, exercise, if of a strenous nature, has the most powerful effect upon the arterial blood pressure During the muscular effort or even immediately before, i e , at the instant that the exertion is contemplated, the systolic pressure commences to rise and may reach a height of 180 or 200 mm Hg Except in well-trained persons or athletes, this

Table 3 20

The average variations of blood pressure (after Hunter's compilation of observations on a quarter million healthy Americans)

Age	Systolic Pressure	Diastolic Pressure	Pulse Pressure
10	103	70	33
15	113	75	38
20	120	80	40
25	122	81	41
30	123	82	41
35	124	83	41
40	126	84	42
45	128	85	43
50	130	86	44
55	132	87	45
60	135	89	46

After Gager, 1930

is invariably associated with a large increase in heart rate to 150 or 180/min In the trained individual, the blood pressure rise may be quite mild The diastolic pressure shows a less pronounced rise (100 to 110) so that the pulse pressure is increased In light exercise the diastolic pressure may remain at the normal level while the systolic rises several millimeters Immediately after the exercise the pressure drops momentarily to normal or even slightly below It then mounts rapidly to its previous high level, from which it gradually declines again, and in a healthy person reaches the normal within from 1 to 4½ min The evanescent drop in pressure is explained as being due to the sudden relaxation of the abdominal muscles The blood is drained into the venous reservoirs These when deprived of their support (abdominal muscles) have their capacity increased and the blood flow into the right heart is temporarily curtailed It is not until an appreciable time has elapsed to enable the increased venous capacity to become filled again by blood pouring in from the recently active muscles, that an adequate flow into the right heart is restored

The diastolic pressure is somewhat higher in the standing than in the sitting position and lowest in recumbency This change is found to occur whether the postural change is brought about actively or passively and is evidently an overcompensation for the gravity effect The systolic pressure usually rises but to a less extent than the diastolic, so the pulse pressure is reduced Pressures, however, taken at as short an interval as 10 sec after the erect position has been assumed, show that the initial effect is a fall of from 6 to 22 mm Hg in the systolic pressure This is sufficient to stimulate the carotid sinus and aortic mechanisms and cause increased vascular tone with a consequent compensatory rise in pressure Compensation is usually complete within 30 sec Reverting from the standing to the sitting or recumbent position has the reverse effect, fall in diastolic pressure and rise in pulse pressure In persons with an abnormally and habitually low blood pressure, the systolic pressure may actually rise in the lying-down position and fall when the subject stands The diastolic, on the other hand, is always lowered in recumbency and raised in the erect posture

The Systolic, Diastolic, Mean, and Pulse Pressures. Hales, in describing his experiment, speaks of the blood column after it had ceased to rise further in the tube, oscillating above and below a mean level To quote his own words, "When it (the blood) was at its full height, it would rise and fall at, and after, each pulse, 2, 3 or 4 inches" By recording with an adequate pressure manometric system, these fluctuations are seen as waves synchronous with the heart beats (see Fig 3 153) The crest of the wave represents the maximal pressure, corresponding to the contraction or systole of the ventricle, and is called the systolic pressure The trough of the wave, i e, the point of minimal pressure, coincides with the end of the

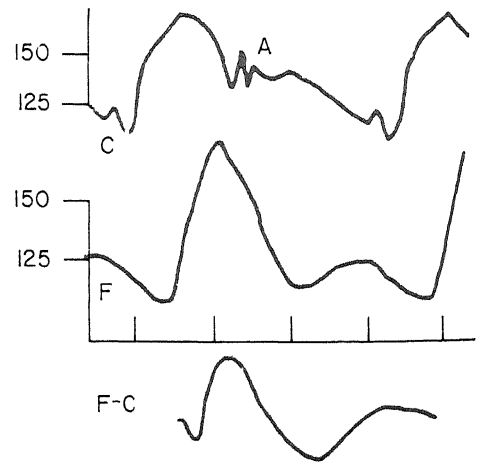

Fig 3 153 Arterial pressure pulses recorded from the central aorta *C* and the femoral artery *F* in the anesthetized dog Curve *F-C* beneath pulse tracings obtained by coordirectographic subtraction of the aortic pulse from the femoral pulse This represents the reflected or standing wave in the distal portion of the arterial tree Time 0 1 sec ordinate pressures in millimeters of mercury (After Alexander 1949)

resting phase or diastole of the cardiac cycle, and is called the diastolic pressure The mean pressure is usually given as half the sum of the values for the systolic and diastolic pressures This would be strictly accurate only if the pulse wave inscribed a perfect triangle which, however, is not the case The average pressure throughout the cardiac cycle, i e , the true or geometric mean, is generally somewhat lower than this, lying nearer the diastolic than the systolic pressure This can be obtained by integration of the curve

The difference between the diastolic and systolic pressures is the pulse pressure This is caused by the ejection of blood into the aorta during systole Its magnitude, other things being equal, will vary with the quantity of blood ejected by the heart at each beat

The systolic pressure reflects mainly the distensibility characteristics of the arterial system as it receives blood from the left ventricle It would be expected to undergo wider variations under the stresses of every day life than the diastolic pressure The latter represents the constant load which the arterial walls are called upon to bear and the resistance which the ventricular contraction must overcome to throw open the aortic valves Details of arterial pulse pressure changes are given on p 3-195 In the distributing arteries there is some amplification of the pulse pressure toward the periphery, but the two pressures tend to become more nearly equal in the terminal arteries, the pulse pressure there being reduced Since the pulse pressure is the difference between the systolic and diastolic pressures, it may be reduced by an alteration in one or other of these A rise in the systolic or a fall in the diastolic, will cause the pulse pressure to increase, while a fall in the systolic or a rise in the diastolic will lower the pulse pressure If both systolic and diastolic pressures rise or fall to an equal extent, the pulse pressure remains unchanged The mean pressure will rise as a result of a rise in either the diastolic or systolic pressure, or of both together, and will fall when a reduction of either or of both of these pressures occurs

DETERMINANTS OF NORMAL ARTERIAL BLOOD PRESSURE

Several factors combine to maintain normal arterial blood pressure They are, *1*) the pumping action of the heart, *2*) the peripheral resistance, *3*) the quantity of blood in the arterial system, *4*) the viscosity of the blood, and *5*) the elasticity of the arterial walls

Pumping Action of the Heart. The means by which the cardiac contraction exerts its effect upon the arterial blood pressure is, obviously through the *quantity* of blood which it is capable of discharging into the aorta in a unit period of time, i e , upon the output of the heart per minute or stroke volume times heart rate When more blood is forced into the already filled arterial system, it cannot escape at once from the system in the same amount as it is thrown into the aorta so the arterial walls become stretched The pressure rises until the velocity of flow through the arterioles is great enough to balance again the outflow from the system with the inflow Hales grasped this fundamental fact when he wrote, "the real force (pressure) of the blood in the arteries depends on the proportion which the quantity of blood thrown out of the left ventricle in a given time bears to the quantity which can pass through the capillary arteries (arterioles) into the veins at that time "
